Leydig's and Sertoli's cells and spermatogonia and spermatozoa are more resistant to degeneration than cells of the intermediate stages of spermatogenesis; therefore semen analysis varies depending on the extent of damage.[113] In most cases, gonadal atrophy does not affect libido.

Although not easy to do, one can diagnose the condition by evaluating circulating levels of LH, FSH, testosterone, and total estrogens and inhibin. Elevated serum concentrations of FSH often indicate seminiferous epithelial damage,[114] whereas low levels of LH could indicate a pituitary problem. Evaluation of efficiency of sperm production also can aid in the diagnosis of gonadal degeneration.

A degenerative process in the testicle often is reversible, provided one removes the causal factor. The condition of hypogonadotropic hypogonadism in men is treated routinely with Gn-RH administered in a pulsatile manner. Anecdotal evidence suggests that similar conditions in stallions respond to Gn-RH therapy administered as subcutaneous osmotic minipumps. To date, no study indicates the benefit of Gn-RH therapy in stallions with poor semen quality.[114]

16.10.4.3.5

Testicular Hypertrophy/Hyperplasia

Hypertrophy refers to a condition in which the individual cells of the testes increase in size. The most common cause of testicular hypertrophy is removal of one testis, triggering a compensatory growth of the contralateral gonad.

Hyperplasia refers to an increase in the number of cells and can be focal or generalized. Testicular hyperplasiais rare in stallions.

16.10.4.3.6

Testicular Neoplasia

Among domestic species the stallion has a low incidence (4%) of testicular neoplasia.[115,116] Of 30 equine testicular neoplasias, McEntee reported that *teratomas* were the most common (37%), followed by interstitial cell tumors (30%), seminomas (23%), lipomata (7%), and mast cell tumors (3%).[115]

The cause of testicular tumors is not clear. Environmental and genetic factors may be important. Becauseof the alteration in temperature and hormone supply, cryptorchid stallions appear to have a higher incidence of germ cell tumors, particularly Leydig's cell tumors or seminomas, of the retained testis.[117] In general, equine testicular tumors have a low degree of metastatic activity; however, because of the potential of spreading to somatic organs, they are considered malignant. The incidence of regional lymph node involvement appears to be low compared with other domestic species.[118]

Diagnosis of testicular neoplasia if both testiclesare in the scrotum is based on a careful examination of the suspect and the contralateral testis. One should palpate the scrotal contents and note soft spots, nodules, or asymmetry. Ultrasonographic examination is crucial for the identification of fluid-filled or solid nonpalpable lesions embedded deep in the testicular stroma. Spermiogram can be useful if the semen collected has a high incidence of abnormal spermatozoa combined with round spermatids and other testicular cells. One commonly finds low sperm numbers but otherwise normal seminal parameters in horses with testicular neoplasia.[119] 1161

1162

One can diagnose a testicular tumor in an abdominal testicle by rectal palpation and ultrasonography, combined with endocrinologic tests. Depending on the size and location of the testicle, an inguinal, flank, or ventral midline incision is recommended. Often abdominal tumors are only an incidental finding during routine postmortem examinations.

Gross appearance of some tumors can help the clinician make a presumptive diagnosis. Leydig's (interstitial) cell tumors are usually soft, orange, and nodular withno clear demarcation with the adjacent testicular tissue. Seminomas can vary in color from white to dark gray with a glistening appearance; the neoplastic area frequently bulges above the adjacent testicular tissue. Fluid-filled cysts are often present. Sertoli's cell tumors are usually firm and nodular and pale gray. Teratomas are easily identifiable by the presence of tissue of different origins (bone, hair, etc.). Ultimately, one confirms diagnosis by histopathologic examination. One can obtain samples for histopathologic examination by fine needle aspiration or by testicular biopsy. Unilateral or bilateral orchiectomy is the treatment of choice regardless of the type of tumor. Ligation and removal of as much of the cord as possible is strongly recommended. If one suspects metastasis, excision of the adjacent lymph nodes is recommended.

16.10.4.3.7

Orchitis

An inflammatory process of the testicles is referred to as *orchitis*. The cause of orchitis in stallions may be bacterial, viral, parasitic, or aseptic following trauma. Orchitis can be primary or secondary as a postoperative complication of abdominal surgery. One must differentiate the condition from the more common periorchitis or scrotal edema, although the conditions may be present simultaneously. Bacterial orchitis in horses may be caused by *Brucella abortus, Actinobacillus equuli, Pseudomonas pseudomallei, Streptococcus zooepidemicus* and *S. equisimilis, Salmonella* spp., *Escherichia coli, and Staphylococcus* spp.[115]

Parasitic orchitis is usually a sequela of migratory larvae of the parasite *Strongylus* spp.[120] The condition can affect descended or undescended testicles and the tunics and spermatic cords. A possible secondary lesion associated with the larvae is the condition known as *focal lymphocytic orchitis*, which occurs around the seminiferous tubules.[121] Focal lymphocytic orchitis is different from the condition of autoimmune orchitis reported for the mouse in which foci of lymphocytes are localized exclusively at the rete testis and efferent ductules. Initial diagnosis of the granulomatous-type lesions in the testicle caused by strongylosis sometimes can be done by ultrasonography; however, histopathologic identification is necessary for a definitive diagnosis. Regular deworming programs with ivermectin can help control this condition.

Equine viral arteritis and equine infectious anemia are the primary viral diseases that potentially may affect the testis. The viral agents of equine infectious anemia and EVA are shed in the semen of affected stallions. Onemay observe focal lymphocytic infiltrations in affected stallions.

As soon as spermatogonia enter leptotene stage during the meiotic phase, they become isolated from the general immune system by tight junctions between adjacent Sertoli's cells. These gap junctions are known as the blood-testis barrier. A fine balance is maintained so that maturing spermatids can migrate toward the adluminal compartment without eliciting an immunologic response. In addition to the blood-testis barrier, local immunosuppresors are present in the testicular interstitium. Factors that disrupt the blood-testis barrier with the consequent formation of antisperm antibodies include tumors, trauma, biopsies, and testicular torsions of more than 360 degrees. The association between antisperm antibodies and infertility, although reported for the stallion, warrants further investigation.[122]

16.10.4.4

DISEASES OF THE EPIDIDYMIS

Problems that affect the epididymis can be grouped into congenital abnormalities and into infectious or physical causes. In the stallion a condition known as blind-ending ductules has been observed. If sufficient numbers of tubules are blocked, the condition may lead to spermiostasis with development of cystic dilations, formation of sperm granulomas, and reduction of fertility. One may diagnose these cystic dilations by palpation and ultrasonography.

Because the epididymis in the stallion is not fused completely with the testicle as in other species, a diagnosis of epididymal aplasia or agenesis is not uncommon. In some cases an abdominal testicle may have a caput attached with the corpus and cauda epididymis present in the scrotum. The inexperienced clinician sometimes mistakenly removes an epididymis and leaves the testicle in the inguinal canal or in the abdomen when performing a castration. Epididymal aplasia is rare in the stallion and if present is related to other

anomalies of the wolffian duct system. One commonly detects spermatoceles and cystic dilations by palpation or ultrasonography. Other less common conditions include adenomyosis and tumors.[123]

Bacteria or trauma to the scrotal area may cause inflammation of the epididymis, or epididymitis. Infectious epididymitis as a primary disease is rare in stallions and is considered a sequela to orchitis or to deep lacerations of the scrotal area. However, some authors report the presense of *Streptococcus zooepidemicus* in association with epididymal infection. Migration of *Strongylus edentatus* larvae also may cause epididymitis, with the consequent formation of granulomas.[124] 1162

1163 One confirms a diagnosis of epididymitis by palpation, ultrasonography, the presence of inflammatory cells in the ejaculate, or bacterial growth on culture.[125]

Other causes of epididymal dysfunction can be attributed to abnormal accumulation of sperm in the cauda epididymides or generalized dysfunction of the epididymal epithelium associated with deficiencies in electrolyte, protein, or steroid secretion or resorption. Such dysfunction would cause changes in pH and osmolarity that might affect adversely the ability of sperm cells to fertilize. One should diagnose this condition by frequent semen collections (twice daily for 7 to 10 days) and evaluation of sperm morphology and motility.

16.10.4.5 DISEASES OF THE SPERMATIC CORD

Problems associated with the spermatic cord are limited to infections or vascular problems. Infectious processes of the cord result from larvae migration or secondary contamination with *Streptococcus* spp. after castration. Failure of the castration site to heal and continuous draining of purulent material with intermittent febrile periods often indicates an infection of the spermatic cord known also as scirrous cord or *champignon*. Therapy includes opening the area and aggressive therapy with penicillin.

Vascular problems associated with the cord include torsion, varicoceles, and thrombosis.[126,127] Torsion of the cord is significant when the cord has rotated more than 180 degrees. Torsions of less than 180 degrees are an incidental finding and can be permanent or transient and are of little clinical significance. Torsions greater than 270 degrees are associated with scrotal swelling, severe pain, abnormal gaits, and colic symptoms and are considered an emergency. Diagnosis is by palpation and history, and one must differentiate torsion from scrotal herniae. If the tail of the epididymis is palpable, in torsions of 360 degrees the tail will be located in a dorsal position with respect to the normal stallion. The treatment of choice is hemiorchiectomy because the affected testicle will be nonfunctional. In addition, one should consider the possibility of developing immune-mediated infertility because of antisperm antibody production.[121]

Varicoceles and thrombosis of the spermatic cord are rare in stallions; however, they might interfere with testicular thermoregulation.[126] The presence of varicoceles is of questionable significance in the stallion and is diagnosed easily by ultrasonography. One must ensure that no adhesions of the spermatic cord occur because adhesions may result in fluid accumulation betweenthe testicular tunics.[128] Thrombosis of the cord is a more serious condition. The clinical signs resemble thoseof higher-degree torsions, and unilateral castration is recommended.

16.10.4.6

SEMEN

Problems associated with semen may be divided into two distinct groups: (1) volume, color, and pH/osmolarity of seminal fluids and (2) spermatozoa. Abnormal volumes may be too small or too large. Extremely low volumes are associated with incomplete ejaculation or nonejaculation. Large volumes may be associated with extraneous fluids such as water, urine (urospermia), blood (hemospermia), or pus (pyospermia).[128]

16.10.4.6.1

Urospermia

Urine-contaminated semen is readily detectable. Color, odor, and increase in volume are obvious on gross examination. One may evaluate small amounts of urine for urea nitrogen and creatinine concentration. The effect of urine on the sperm cells is unknown. However, the reduction in motility and perhaps infertility is significant because of the effects of hyperosmotic medium and water removal from the sperm cells. Neurologic or behavioral dysfunctionshave been associated with urospermia.[129] The author has observed several cases associated with self-mutilating stallions. Pharmacologic therapy of the problem is purely empirical and limited to drugs that act to close the neck of the bladder such as α-blockers. A more common approach is to use managerial procedures such as collection of the semen directly into extender and immediate centrifuging. The ideal procedure is to be able to fractionate the ejaculate during collection with an open-ended AV. For breeds for which artificial insemination is not allowed, one may infuse extender into the uterus and flush it out a few hours later.

16.10.4.6.2

Hemospermia

Lacerations of the penis and urethra can result in the presence of blood cells in the semen. Diagnosis is often obvious because of the pinkish or red color of the ejaculate. The presence of blood is believed to interfere with fertility, but no study has proved this. Stallions infected with *Pseudomonas aeuroginosa* may be at a higher risk for hemospermia.[130] Diagnosis is based on identification of the site of bleeding. If one suspects urethral bleeding, one may use a pediatric endoscope to examine the penile and pelvic urethra. If one cannot find the bleeding site externally, a common bleeding site is where the urethra folds over the ischium. A common approach to therapy is to rest the stallion so that cauterization takes place. A complete urethrostomy of the area is indicated sometimes until the urethra heals. One also may consider some of the management procedures described for urospermia.

16.10.4.6.3

Bacteriospermia/Pyospermia

Every ejaculate contains a small amount of mixed bacteria, with no signs of inflammation. These bacteria 1163
are of little significance and should be interpreted in light of the fertility of the stallion. The presence of 1164
large numbers of white blood cells in the ejaculate usually indicates accessory sex gland infection. One should culture quantitative pre- and postejaculatory swabs and semen samples in an attempt to isolate the causative bacteria. Giemsa, Wright's, or Dif-quick stains of the semen aid in identifying the type of white blood cell present.

16.10.4.6.4

Spermatozoal Problems

Spermatozoal defects may be in number, motility, and morphology. Reduction in number, also known as oligospermia, can have several levels of severity culminating in azoospermia, or the lack of sperm in the ejaculate. Poor motility is referred as asthenospermia, whereas poor morphology is known as teratospermia. If the defectsare in number, motility, and morphology simultaneously, the condition is described as oligoteratoasthnospermia. Testicular problems such as degeneration or hypoplasia; sperm stasis in the efferent ducts, epididymis, vas deferens, or ampulla; inadequate collection procedures or ejaculation failure; and increased frequency of ejaculation have a dramatic effect on the total number of sperm present in the ejaculate. Accurate assessment of the sperm production of the stallion and a good history are essential for diagnosis and prognosis of the condition.

Abnormal spermatozoal motility and morphology can result during the process of sperm formation, during posttesticular sperm transport, and epididymal storage and during collection and handling. Improper handling procedures also may adversely affect the quality of a semen sample.

Stallion spermatozoa do not always display the same type of forward progressive motility as observed in human or ruminant sperm. Equine sperm normally may tendto swim in a wide circular pattern.[130] Backward motility, tight circular movement, or static motion (not boundto the glass) is considered abnormal. Midpiece and tail abnormalities—whether induced by cold shock, by other mechanical means, or as a direct result of spermatogenesis, spermiogenesis, and epididymal transport—are the most common causes of motility abnormalities.[128]

Every ejaculate contains some degree of sperm abnormalities, but in general normal stallions are expected to have at least 60% morphologically normal sperm. One can evaluate spermatozoal morphology by diluting raw semen in buffered formal saline under phase-contrast microscopy or under light microscopy using eosin-nigrosin or eosin–aniline blue stains (see the previous section).

16.10.4.7

DISEASES OF THE PREPUCE AND PENIS

16.10.4.7.1

Prepuce

Preputial inflammation or posthitis may be traumatic or infectious. Regardless of the origin, inflammation of the prepuce invariably results in phimosis or paraphimosis, which is the ability to exteriorize or retract the penis, respectively. One should differentiate inflammation caused by trauma, infection, or parasitic diseases from edema following priapism or penile paralysis. Traumatic injuries to the prepuce most commonly are associated with breeding accidents that can be avoided with proper breeding management practices.

Infectious, parasitic, and neoplastic preputial problems are similar to those affecting the scrotum and were described previously. Infections caused by equine herpesvirus 3 or coital exanthema are a common occurrence, as is colonization of the penis by gram-negative bacteria. Congenital problems affecting the prepuce, penis, and scrotum often are linked to developmental abnormalities and are diagnosed easily.

16.10.4.7.2

Penis

16.10.4.7.2.1

Penile Tumors

The most common neoplasia affecting the penis is squamous cell carcinoma. Smegma accumulation on the penis may be a predisposing factor for this type of neoplasia. The tumors start as small keratinized plaques that slowly progress into necrotic foci with foul-smelling material caused by secondary bacterial contamination. Conclusive diagnosis is based on histopathologic examination. Treatment of the condition is with cryosurgery, reefing, or phallectomy.

Penile warts or squamous papillomas, sarcoids, melanomas, fibromas, and lipomas may occur on the penis. Cryotherapy or autogenous vaccines have been used with varying degrees of success to treat these conditions.

16.10.4.7.2.2

Penile Paralysis/Priapism

Malnourished or exhausted horses, animals with neurologic disease, or treatment with phenothiazine derivatives sometimes may induce loss of tone of the retractor penis muscle in horses that culminates in relaxation of the penis, extensive penile edema, and secondary trauma.[131,132] Because venous return is impaired, the condition progresses to the development of ulcers, secondary bacterial contamination, and necrosis. Treatment of the condition aims to restore the venous blood flow. Hydrotherapy, mechanical support of the penis, and application of topical emollients, antiinflammatory drugs, and diuretics are recommended. In some instances, flushing of the corpus cavernosum penis with heparinized saline or intracavernous injection of phenylephrine may aid in blood drainage and penile retraction. Traumatic accidents involving the penis are not uncommon. Cuts with mare tail hair, poorly constructed breeding phantoms, or AVs may result in laceration or abrasion of the penis varying from simple skin cuts to severe hematomas. One treats these wounds with supportive therapy or surgical intervention. Prevention of secondary contamination and adhesion formation is important. 1164

1165

Other mechanical problems observed in the penis and prepuce of stallions include fibrosis, strictures, or lacerations caused by the misuse of penile rings or brushes to dissuade the stallion from masturbation. The use of such instruments is inhumane and should be discouraged.

17 # CHAPTER 17 DISORDERS OF THE URINARY SYSTEM

17.1 ## 17.1—Anatomy and Development

Harold C. Schott, II

17.1.1 ### Anatomy

The urinary system of the horse, like that of most mammals, consists of paired kidneys and ureters, the bladder, and the urethra. With the exception of the abdominal portion of the urinary bladder, the entire urinary tract is located in the retroperitoneal space. In a newborn foal, each kidney weighs about 175 g. In an adult horse the left kidney weighs 600 to 700 g, and the right kidney is usually 25 to 50 g heavier, although this is not a consistent finding, and one may observe the reverse relation.[1,2] Thus the kidneys account for approximately 0.65% to 0.75% and 0.27% to 0.37% of the total body mass of the foal and adult horse, respectively.[1,3] The right kidney is located immediately below the dorsal extent of the last two or three ribs and the first lumbar transverse process, is shaped like a horseshoe, and measures about 15 cm long, 15 cm wide, and 5 to 6 cm high (dorsal to ventral). Craniolaterally, the right kidney is embedded into the liver, and its more craniad position compared with the left kidney prevents it from being accessible on rectal palpation. Although not the classically bean-shaped organ found in human beings and small animals, the left kidney is more elongated than the right kidney, with the cranial pole at the level of the hilus of the right kidney and is about 18 cm long, 10 to 12 cm wide, and 5 to 6 cm high. Because of its more caudal location, one routinely can palpate the caudoventral aspect of the left kidney during rectal examination. The blood supply to the kidneys comes from one or more renal arteries branching from the aorta. Accessory renal arteries (which generally enter caudally) may arise from the caudal mesenteric, testicular or ovarian, or deep circumflex iliac arteries.[1,2]

The ureters are 6 to 8 mm in diameter and travel about 70 cm to their insertions in the dorsal bladder neck or trigone, close to the urethra. The distal 5 to7 cm of each ureter courses within the bladder wall. This intramural segment of the ureter functions as aone-way valve to prevent vesicoureteral reflux with progressive bladder distention. The urinary bladder lies on the pelvic floor when empty but can increase in size and drop forward over the pelvic brim when filled with urine. The bladder can accommodate up to 3 to 4 L of urine before stimulation of micturition. In the foal the bladder is attached to the ventral abdominal wall by the urachus and remnants of the umbilical arteries. Consequently, when empty, the bladder is commonly a band-shaped structure in a neonatal foal. During the first few months of life, this ventral attachment loosens as the urachal remnant becomes the middle ligament and the umbilical arterial remnants become the round ligaments of the free border of the paired lateral ligaments of the bladder.[1]

The urethra is about 2 to 3 cm long in a mare and75 to 90 cm long in a male. In the intact male the pelvic urethra, which is 10 to 12 cm long, widens in an elliptic pattern to a diameter of 5 cm across and 2 to 3 cm from dorsal to ventral. A rounded dorsal prominence, the colliculus seminalis, is located immediately caudal tothe urethral orifice and is the site of the common openings of the ductus deferens and ducts of the seminal vesicles. The openings of the prostatic ducts are on two groups of small papillae lateral to the colliculus seminalis. 1169
Between 2 and 3 cm farther caudad, the ducts of the bulbourethral glands open in paired dorsal lines. The 1170
smaller openings of the ducts of the lateral urethral glands open at the same level on the lateral aspect of the urethra.[1]

The surface of each kidney is covered by a fibrous capsule that peels easily from the normal kidney. The equine kidney consists of an outer cortex slightly wider than the inner medulla. The cortex is dotted with dark spots—renal corpuscles or glomeruli within Bowman's capsules. In horses, the corticomedullary junction is less distinct than in other species and is typically a deep red that contrasts well against the paler medulla and red-brown cortex. This region undulates along renal pyramids (cortex) and renal columns (medulla). The pyramidsare subdivisions of the renal parenchyma, which are separated by arcuate arteries at the level of the corticomedullary junction. The equine kidney contains a total of 40 to 60 pyramids arranged in four parallel rows. The renal pelvis is the dilated proximal portion of the ureter. Microscopic examination reveals numerous small openings of the collecting ducts (ducts of Bellini). Additionally, the renal pelvis and proximal ureter are lined with compound tubular mucous glands and goblet cells that secrete thick, viscid mucus usually found in the renal pelvis and urine of normal horses.[1,4]

The functional unit of the kidney is the nephron. Each nephron is composed of a renal corpuscle (glomerulus within Bowman's capsule), a proximal tubule (convoluted and straight components), an intermediate tubule (loop of Henle), a distal convoluted tubule, a connecting tubule, and cortical, outer medullary, and inner medullary collecting ducts (Figure 17.1-1). The two populations of nephrons are (1) the superficial (or cortical) nephrons possessing short loops of Henle and (2) the juxtamedullary nephrons with long loops of Henle. Gradations exist between these two general categories of nephrons, as well as species variationin the ratio of short-looped nephrons to long ones. For example, human beings have 7 times more short- than long-looped nephrons, whereas essentially 100% of nephrons in dogs and cats have long loops.[5] An early anatomic study found approximately 4 million glomeruli (nephrons) in the adult bovine kidney[6]; however, a recent study of kidney organogenesis using unbiased stereologic techniques to examine 45 equine left kidneys indicated that the left kidney of the horse may contain closer to 10 million glomeruli (for a total of 20 million in both kidneys).[7] The latter study also confirmedthat the total number of glomeruli does not increase after birth despite continued growth of the kidney until about 1 year of age. At present, little information is available on the ratio of short- to long-looped nephrons in horses. Histologically, equine nephrons are similarto those of other 1170
mammalian species; however, the diameter and epithelial height of the tubule and collecting duct segments are 1171
comparatively larger. In addition, the equine macula densa (segment of the ascending loop of Henle that lies in close association with the juxtaglomerular apparatus of the afferent arteriole) appears more prominent than that of other mammals.[8] Whether these subtle histologic differences are accompanied by functional differences has not been investigated.

Relative to its size, the mammalian kidney has aricher innervation than almost any other organ.[9] Although the neuroanatomy of the equine kidney has not been well studied, autonomic nerves course from the aorticorenal and renal ganglia along the major renal vessels into the kidneys.[1] These nerves are predominantly sympathetic, for the kidneys appear to be poorly supplied by cholinergic nerves. Although the best-recognized effect of renal nerves is control of renal vascular resistance (for regulation of renal blood flow over a wide range of perfusion pressures), the nerves also act directly on renal tubules and juxtaglomerular cells. For example, low-frequency stimulation of renal nerves (below the threshold for vasoconstriction) increases proximal tubular sodium reabsorption and renin release by activation of α_1-adrenoceptors.[10] In addition to α- and β-adrenoceptors, renal vasculature is rich in dopaminergic adrenoceptors, and activation of the latter, specifically dopamine type 1 receptors, leads to increased perfusion of the outer renal medulla. Presence of these receptors is the basis for use of dopamine, and more recently the DA-1 receptor agonist fenoldopam, in an attempt to improve renal blood flow in acute renal failure or to decrease the risk of radiocontrast nephropathy.[11–13] The administration of drugs also can activate renal adrenoceptors unintentionally. A common clinical example is the diuresis induced by administration of the α_2-agonists xylazine and detomidine. Although the diuresis has been attributed to a transient hyperglycemia and glucosuria, the latter is often absent.[14,15] An alternative explanation may be drug binding to α_2-adrenoceptors located on collecting duct epithelium. Activation of these receptors can lead to antagonizm of the effects of antidiuretic hormone on cortical collecting ducts, which results in diuresis.[16] More recently, renal afferent nerves have been identified, and these nerves appear to play a role in the pathogenesis of hypertension in species affected by this disorder.[9]

Autonomic innervation of the ureters, bladder, and urethra is important to ureteral peristalsis and micturition. The equine ureteral smooth muscle contains α_1- and β_2-adrenoceptors, which induce contraction and relaxation, respectively, when activated by norepinephrine.[17] Recent studies of the innervation of the equine ureter demonstrated greater densities of adrenergic neurons in the proximal (renal pelvis) and intravesicular (bladder wall) portions of the ureter.[18] Increased densities in these regions are consistent with the suspected pacemaker activity of the renal pelvis, which initiates ureteral peristalsis and the sphincterlike function of the distal segment of the ureter. The sympathetic nerve supply to the urinary bladder is provided via the hypogastric nerve, with preganglionic fibers arriving from spinal segments L1 to L4 to synapse in the caudal mesenteric ganglion. Postganglionic fibers supply the bladder (β_2-adrenergic receptors) and proximal urethra (primarily α_1- and some α_2-adrenergic receptors).[19,20] In addition to adrenergic innervation, the equine bladder also is innervated by cholinergic and peptidergic nerve fibers.[21] Parasympathetic innervation originates in the sacral segments of the spinal cord with neurons joining to form the pelvic nerve.[19,20] Many complex interneuronal connections exist between sympathetic and parasympathetic nerves in the wall of the bladder, along with small adrenergic cells that facilitate interaction between sympathetic and parasympathetic pathways.[22] As a result, complete denervation of the bladder is virtually impossible. Somatic innervation of the lower urinary tract is primarily to the striated muscle of the external urethral sphincter via a branch of the pudendal nerve, which originates from the sacral cord segments (S1 to S2).[1]

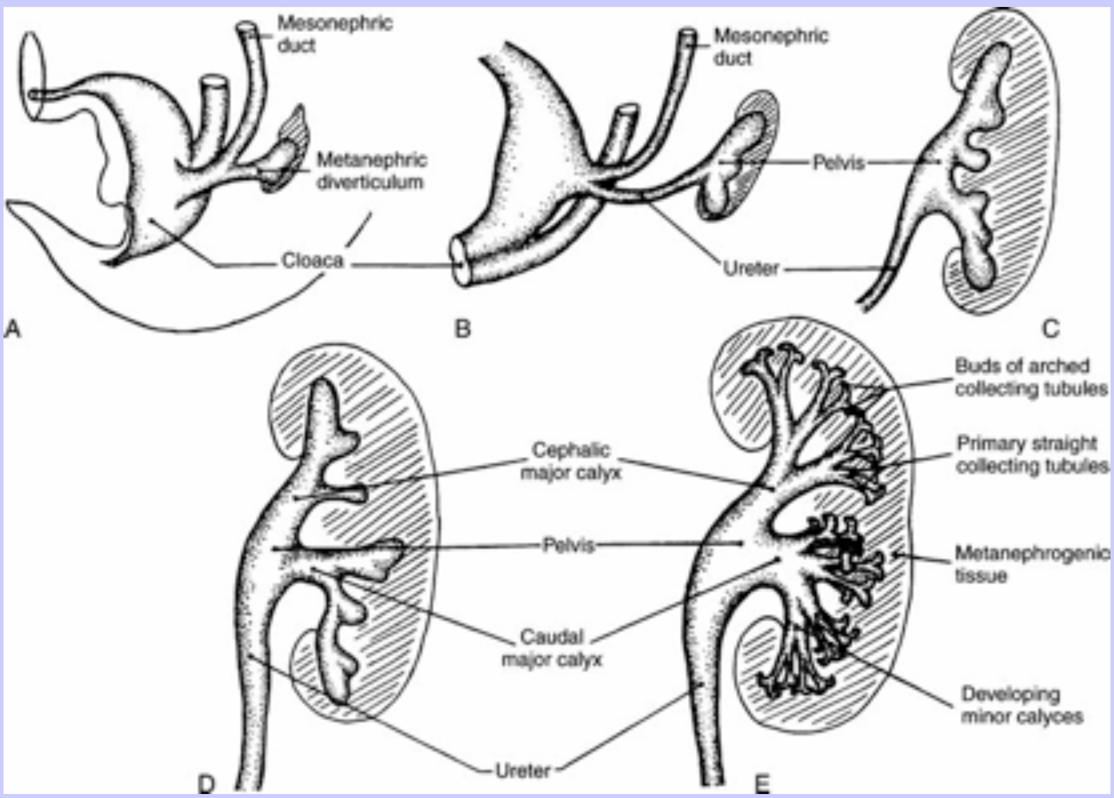
17.1.2 Development

The embryonic upper urinary tract arises from bilateral primordial mesonephric ducts and intermediate mesoderm. The metanephric diverticulum originates from the caudal end of each mesonephric duct and develops craniad to become the ureter and renal pelvis. The advancing metanephric diverticuli collect about

their ends intermediate mesoderm (metanephrogenic tissue), which becomes the collecting system and parenchyma of the mature kidney (Figure 17.1-2). The vascular supply is derived from a branch of the aorta (renal artery) that invades the metanephrogenic tissue. The urinary bladder develops as a dilated proximal portion of the allantois. The bladder is separated from the hindgut by the craniocaudad growth of the urorectal fold, which divides the rectum from the urogenital sinus. The latter structure gives rise to the urethra (Figure 17.1-3). The mesonephric and metanephric ducts initially open into the urogenital sinus, but as development continues, the distal segments of the mesonephric ducts are absorbed into the bladder wall and the openings of the metanephric ducts are pulled craniad to their final site in the dorsal bladder neck.[23]

The fate of the mesonephric tubules (mesonephros) and mesonephric ducts varies with gender. Paired paramesonephric ducts (müllerian ducts) arise parallel to the mesonephric ducts in both sexes. In the female, the 1171
ducts fuse distally to become the vagina and uterine body, whereas proximally they remain separate to give rise 1172
to uterine horns and oviducts. The mesonephric ducts regress into vestigial remnants termed the *epoöphoron* proximally (near the ovaries) and *Gartner's canals* distally (near the vagina and uterus) (Figure 17.1-4). In the male, sexual differentiation of the gonads and production of androgenic steroid hormones leadto regression of the müllerian ducts. The duct system of the male reproductive tract is appropriated from the mesonephros and mesonephric ducts (also termed *wolffian ducts*). Androgenic steroid hormones also stimulate these structures to develop into the seminiferous tubules, epididymis, and ductus deferens. The distal portion of the mesonephric duct becomes the ejaculatory duct, the terminal portion of the ductus deferens.[23]

Figure 17.1-2 Progression of the differentiation and development of the metanephric diverticulum into the collecting system of the mature kidney. **A**, Metanephric diverticulum originates from the caudal end of the mesonephric duct. **B**, Metanephric diverticulum develops craniad, and intermediate mesoderm (metanephrogenic tissue, hatched lines) collects about its cranial end. **C** to **E**, The metanephric diverticulum becomes the ureter and renal pelvis, and the metanephrogenic tissue becomes the collecting system and parenchyma of the mature kidney. (From Patten BM, Carlson BM: *Foundations of embryology*, ed 3, New York, 1974, McGraw-Hill.)



17.1.3 Developmental Malformationsof the Urinary Tract

Anomalies of the urinary tract are uncommon in horses. A survey by Höflinger revealed a similar frequency of unilateral renal agenesis (0.07%) in horses[24] and human beings (0.10%).[5] In contrast, horseshoe kidneys

(attached at the cranial or caudal poles) are the most common anomaly in human beings (0.25%) but rarely have been described in horses.[5,25]

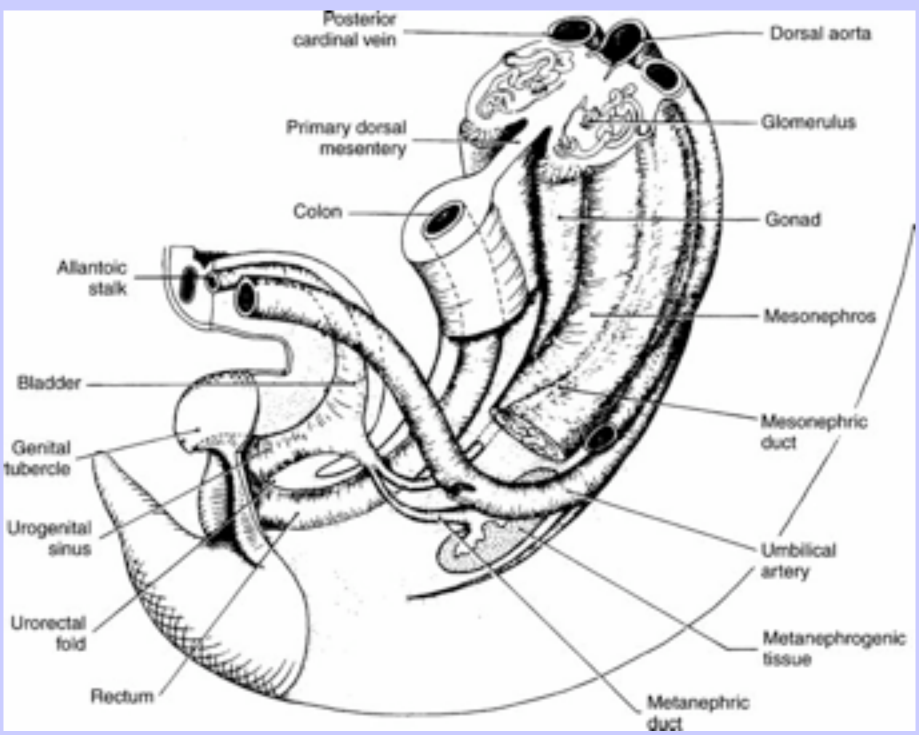
17.1.3.1 RENAL AGENESIS, HYPOPLASIA, AND DYSPLASIA

Renal agenesis, which may be unilateral or bilateral, results from failure of the metanephric duct to fuse with the metanephrogenic mesodermal tissue. Although unilateral anomalies have been described more frequently, this simply may reflect the incompatibility of bilateral agenesis with postnatal life.[24,26–28] Brown, Parks, Mullaney, et al. described a foal with bilateral renal agenesis in which severe azotemia was detected shortly after birth. Bilateral ureteral dysgenesis and cryptorchidism, agenesis of the right adrenal gland, and atresia ani accompanied the renal agenesis in this foal.[28] Unilateral defects may be incidental findings in otherwise healthy horses[29] or may be detectable during examination ofthe reproductive tract, because many horses have associated anomalies of that system. Occasionally, unilateral agenesis may result in clinical renal disease if a problem arises in the contralateral kidney. Johnson, Klingborg, Heitman, et al. described a 4-year-old Quarter Horse with unilateral renal agenesis and a ureterolith causing contralateral hydronephrosis. The gelding was presented for weight loss, pollakiuria, and stranguria. In addition to the renal anomaly, unilateral agenesis of the ipsilateral testicle also was found on necropsy.[27] Renal agenesis may be a familial disorder in several species.[25,30] Although no information is available to suggest a hereditary basis in horses, one probably should discourage repeat matings after detecting such an anomaly.

1172

1173

Figure 17.1-3 Developing urogenital tract of the young mammalian embryo. (From Patten PM, Carlson BM: *Foundations of embryology*, ed 3, New York, 1974, McGraw-Hill.)



One diagnoses renal hypoplasia when one kidneyis at least 50% smaller than normal or when the totalrenal mass is decreased by more than one third.[25] Renal hypoplasia is a quantitative defect caused by a reduced mass of metanephrogenic tissue or by incomplete induction of nephron formation by the metanephric duct. The condition may be confused with renal dysplasia. Unilateral renal hypoplasia usually is associated with contralateral hypertrophy and normal renal function, whereas bilateral hypoplasia generally leads to chronic renal failure.[25,30] Andrews, Rosol, Kohn, et al.[31] described bilateral renal hypoplasia in a foal presented after death and in three young horses with chronicrenal failure that had poor growth from birth. Anomalies in these four horses were limited to the upper urinary tract.

Renal dysplasia is disorganized development of renal tissue caused by anomalous differentiation, intrauterine ureteral obstruction, fetal viral infection, or teratogens.[25,32] Bilateral dysplasia usually leads to renal failure. In general, dysplastic kidneys are normal in size unless concurrent hypoplasia exists or the animal lives for 1173
months to years before developing renal failure. Roberts and Kelly reported a case of bilateral renal dysplasia 1174
in a 19-month-old pony gelding.[33] The pony was presented for weight loss over a 3-month period, and clinicopathologic assessment revealed chronic renal failure. A small, firm, and nodular left kidney was palpable per rectum. At necropsy, the kidneys weighed 280 g each (33% smaller than normal for body weight) and were nodular. Renal dysplasia was suspected because glomeruli in the collapsed areas of the kidneys were small, tubules were immature, and inflammatory cells were scant. Six similar cases of bilateral renal dysplasia resulted in chronic renal failure in horses from 2 months to 7 years of age.[34–38] Small kidneys with increased echogenicity and an indistinct corticomedullary junction were typical ultrasonographic findings,[36–38] and these findings were corroborated by computed tomography in one Miniature horse foal.[38] At necropsy, kidneys were typically small and irregular, the cortex and medulla were not well-delineated, and immature glomeruli and primitive tubules were found on histologic examination (Figure 17.1-5). Renal dysplasia also may cause renal failure in neonates. For example, Zicker, Marty, Carlson, et al. reported a case 1174
of renal dysplasia in a 2-day-old Quarter Horse foal presented for diarrhea and depression.[39] 1175
Clinicopathologic assessment revealed azotemia, hyponatremia, hypochloremia, and urinary sodium wastage. At necropsy, the kidneys were normal in size (380 g), but histologic examination revealed immature glomeruli, hypoplastic tubules and vasa recta, and extensive myxomatous connective tissue occupying 90% of the total medullary volume. Finally, renal dysplasia also may be a unilateral problem that does not result in renal failure. Jones, Langer, Sterner-Koch, et al. found ureteropelvic polyps to be the cause of unilateral hydronephrosis and renal dysplasia in a Trakehner colt.[40] Poor growth and hematuria of several weeks' duration were the presenting complaints. Renal function remained normal for 8 months following nephrectomy until the colt developed a severe bout of colic, prompting euthanasia. Ureteral obstruction by the polyps was the suggested cause of renal dysplasia, because urinary tract obstruction has been found in a large percentage of cases of human renal dysplasia.[32]

Figure 17.1-4 Development of the mesonephric tubules (mesonephros) and mesonephric ducts into the female reproductive tract. **A** and **B**, Paired paramesonephric ducts (müllerian ducts) arise parallel to the mesonephric ducts in both sexes. **C** to **E**, In females, the paramesonephric ducts fuse distally to become the vagina and uterine body but remain separate proximally to give rise to uterine horns. **D** and **E**, The mesonephric ducts regress into vestigial remnants termed *Gartner's canals*. (From Patten BM, Carlson BM: *Foundations of embryology*, ed 3, New York, 1974, McGraw-Hill.)

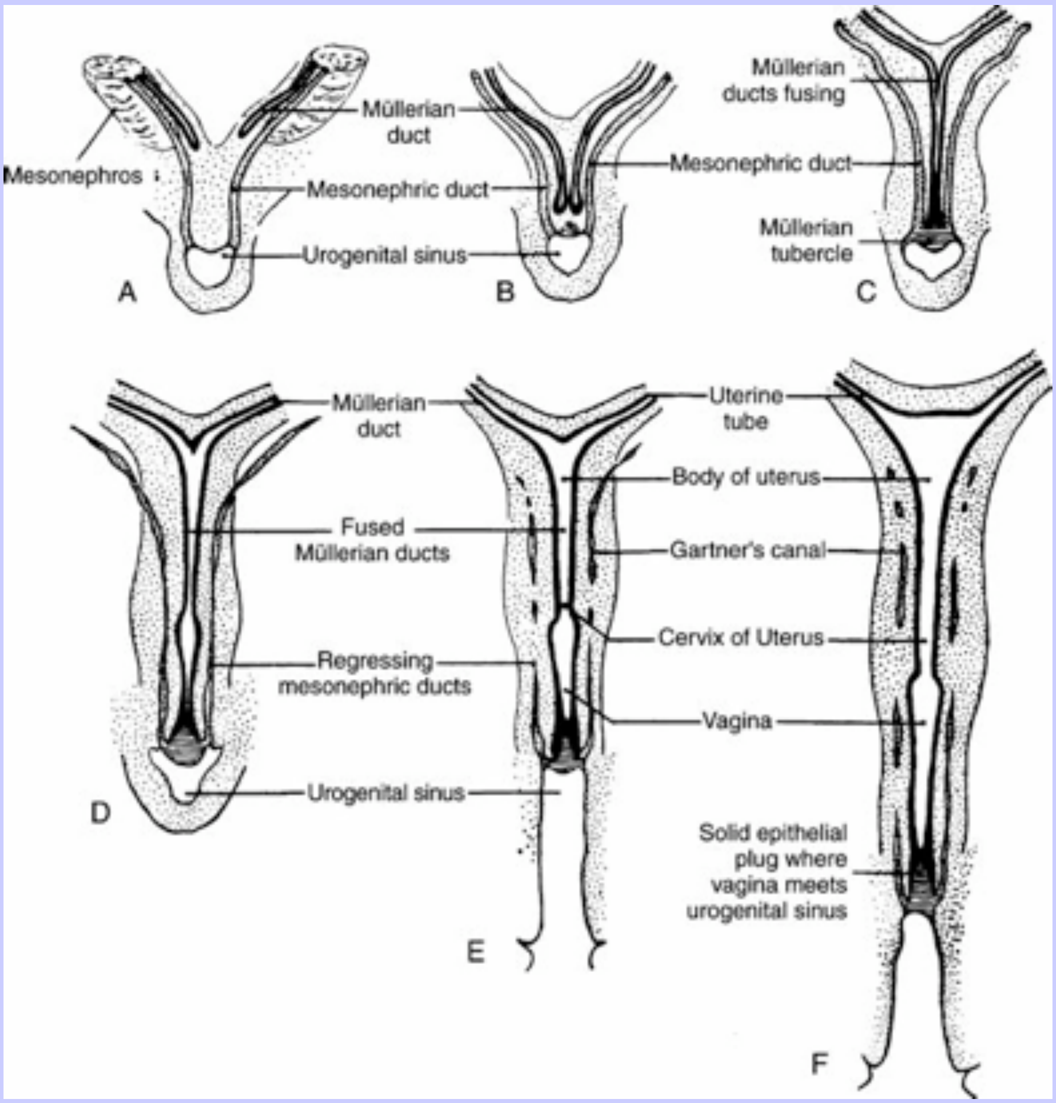


Figure 17.1-5 A, Longitudinal section of the right kidney from a 7-year-old Arabian gelding with renal dysplasia shows focal, irregular thinning of the cortex *(arrowheads)* resulting in a nodular surface and poor delineation of the corticomedullary junction. **B**, Histologic section of same kidney (Masson trichrome stain; original magnification ×35) reveals an immature glomerulus *(large arrowhead)* and primitive tubules *(arrows)* surrounded by persistent mesenchyme. 17.1.3.2

RENAL CYSTS

One or more renal cysts occasionally are discovered as incidental findings on necropsy examination. The cysts may arise from any portion of the nephron but more often occur in the cortex than in the medulla. The pathogenesis is not known, but a defect in the basement membrane that allows tubular dilation is suspected. Renal cysts vary in size from microscopic to as large as the organ itself and routinely have a clear to slightly opaque wall and contain a thin, clear fluid. Congenital cysts are differentiated easily from acquired cysts (following obstruction) by the extensive scarring that accompanies the latter. Renal cysts also may develop as a consequence of drug therapy (i.e., long-acting corticosteroids) or exposure to certain chemicals.[25,30]

17.1.3.3

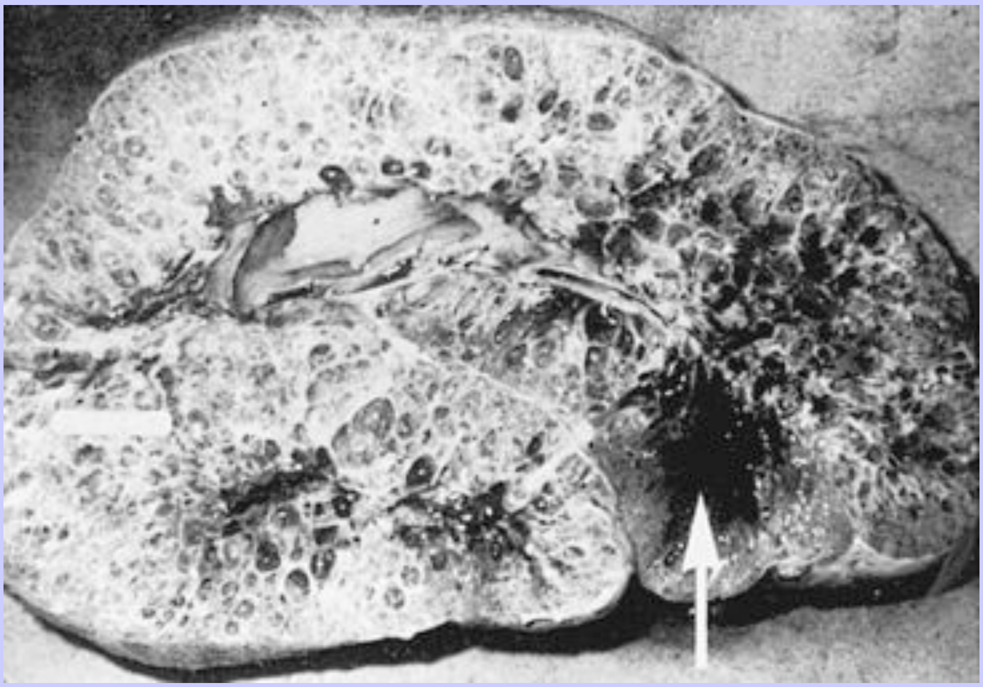
POLYCYSTIC KIDNEY DISEASE, GLOMERULOCYSTIC DISEASE, AND OTHER HEREDITARY NEPHROPATHIES

Polycystic kidney disease (PKD) is a disorder in which numerous, variably sized cysts are found throughout the cortex and medulla. With glomerulocystic disease, cysts are microscopic and limited to Bowman's spaces. Cysts of the bile duct and pancreas also may occur with PKD, and both conditions have been described in stillbirths in many species, including foals.[25] The two major types of human PKD are (1) a rare

congenital or infantile form inherited as an autosomal recessive trait (which may be found in stillbirths) and (2) a more common adult form inherited as an autosomal dominant trait that leads to renal insufficiency in later life in association with dramatically enlarged, cystic kidneys.[41,42] The latter form of PKD develops because of mutations in genes encoding for polycystins, integral membrane proteins responsible for cell-to-cell interaction.[43] Autosomal dominant PKD also has been documented in Persian cats and related breeds and 1175
in bull terriers.[44-46] The genetic defect in Persian cats is thought to be similar to the most common defect in 1176
human beings (*PKD1* gene) and leads to end-stage renal disease by 3 to 10 years of age.[45] As in human beings, the disorder is detectable by renal ultrasonographic screening of juvenile cats and preventable by avoiding subsequent mating of affected animals. Nevertheless, because of heavy inbreeding the prevalence of PKD in Persian cats and related breeds is between40% and 50%.[44,45]

Ramsay, Rothwell, Gibson, et al. described polycystic kidneys in a 9-year-old Thoroughbred mare that exhibited anorexia and weight loss. Clinicopathologic assessment revealed chronic renal failure, and euthanasia was performed. At necropsy, the kidneys were grossly enlarged and each weighed 12 kg (Figure 17.1-6).[47] A similar case of bilateral PKD was described in a 15-year-old pony with a 4-week history of hematuria and moderate weight loss. Evaluation revealed azotemia and presence of large masses in the area of both kidneys on rectal examination, and dramatically enlarged polycystic kidneys weighing 11.4 and 9.1 kg, respectively, were found at necropsy.[48] Bertone, Traub-Dargatz, Fettman, et al. reported a third case of adult PKD in a 10-year-old Paint gelding with weight loss.[49] The horse was mildly azotemic, and several 2- to 15-cm diameter cysts were imaged in both kidneys during ultrasonographic examination. In human beings, polycystic kidneys are believed to result in renal failure as cysts expand (sometimes under pressure) and compress adjacent normal renal tissue. Altered compliance of tubular basement membranes and proliferation of renal tubular epithelium result in outflow obstruction and proximal ballooning, leading to renal cyst formation.[42] In some human cases, pressure within cysts may be 5 to 10 times higher than surrounding interstitial tissue pressures. Bertone, Traub-Dargatz, Fettman, et al. found no increase in pressure in several cysts catheterized percutaneously in a gelding with polycystic kidney disease, but differences in sodium concentrations suggested that the sampled cysts had arisen from different segments of the renal tubule.[49] Euthanasia was performed after a prolonged hospital course(235 days), and the kidneys were not grossly enlarged except where distorted by large cysts. Although not well documented, PKD has been described anecdotally in two additional Paint horses, suggesting that an inherited form of PKD may occur in that breed. A recent report also documented PKD in an 11-year-old Andalusian gelding.[50]

Figure 17.1-6 Longitudinal section of the left kidney (35 cm long, 25 cm wide, 20 cm deep, and weighing 12 kg) from a9-year-old Thoroughbred mare with polycystic kidneys. A calculus is located in the renal pelvis, and the arrow demonstrates the only grossly normal-looking renal parenchyma. (From Ramsey G, Rothwell TLW, Gibson KT et al: Polycystic kidneys in an adult horse, *Equine Vet J* 19:243, 1987.)



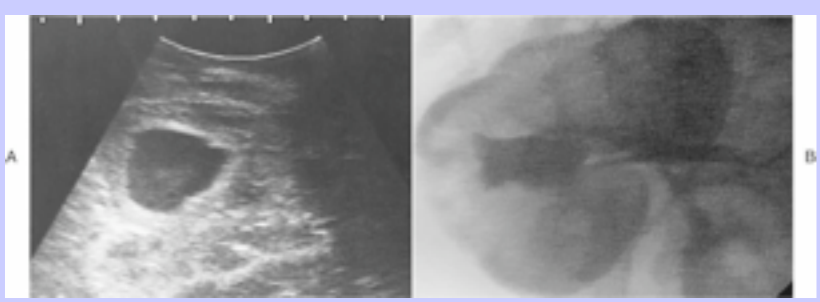
In addition to PKD, a variety of other hereditary nephropathies have been described in human beings.[48] Similar disorders are starting to be recognized in domestic animals, including hereditary nephritis in bull terriers, Samoyeds, and English cocker spaniels. Analogous to Alport's syndrome in human beings, a defective molecular structure of type IV collagen, an important component of the glomerular basement membrane, appears to be the cause of hereditary nephritis in these dog breeds.[46] Similarly, a syndrome of renal tubular dysplasia with autosomal recessive pattern of inheritance recently has been described in a population of highly inbred Japanese black cattle,[51–53] as has a syndromeof suspected hereditary renal oxalosis in Beefmaster calves.[54] Similar hereditary nephropathies are likelyto occur in horses but to date the only one documented is a syndrome of nephrogenic diabetes insipidus in Thoroughbreds.[55]

17.1.3.4

VASCULAR ANOMALIES

Anomalies of the vascular supply to the equine urinary tract are rare but may result in hematuria, hemoglobinuria, partial ureteral obstruction, or hydronephrosis.[30,56] Latimer, Magnus, and Duncan described a distal aortic aneurysm and associated extrarenal arterioureteral fistula in a 5-month-old colt presented for intermittent hematuria, colic, and lameness. Partial ureteral obstruction and hydronephrosis were observed on the affected side.[57] Intrarenal vascular anomalies, termed *renal arteriovenous malformations*, are similarly rare (reported frequency of 0.04% in human beings).[58] Interestingly, these vascular malformations may be silent until later in life, when varying degrees of hematuria and flank pain may ensue. The anomalous vessels are often tortuous and may be enlarged focally and devoid of elastic tissue. Hematuria and hemoglobinuria 1176
are thought to arise from areas where the anomalous vessels lie close tothe collecting system.[58,59] With 1177
vascular anomalies, one should attempt to determine the extent of the defect (unilateral or bilateral) via ultrasonographic examination, contrast radiographic studies, or cystoscopy (visualization that hematuria is coming from only one ureteral orifice). When a unilateral defect is documented in the absence of azotemia, unilateral nephrectomy or selective renal embolization has been recommended to prevent possible fatal exsanguination through the urinary tract[56,57]; however, one may consider conservative treatment if the urinary tract bleeding is minor and has not resulted in anemia.

Figure 17.1-7 Ultrasonographic image of the right kidney of a 9-day-old Quarter Horse colt shows a 2 × 3 cm hypoechoic cavity on a dorsal oblique view. **A**, A swirling pattern, similar in appearance to blood in the ventricles of the heart, was consistent with an arteriovenous malformation. **B**, In a selective nephrogram of the right kidney of the same colt at 20 daysof age, immediately after injection of contrast a dilated vascular space was demonstrated (contrast appears dark because of reverse gray scale), and the renal cortical tissue abaxial to this structure appeared to have reduced capillary phase contrast. (From Schott HC, Barbee DD, Hines MT et al: Renal arteriovenous malformation in a Quarter horse foal, *J Vet Intern Med* 10:204, 1996.)



A large vascular anomaly resulting in transient hemoglobinuria has been reported in a Quarter Horse colt.[60] Over several weeks the large anomalous vascular structure (Figure 17.1-7) spontaneously filled with a thrombus so that specific treatment (a nephrectomy) was not pursued. Severe adult-onset, idiopathic renal hemorrhage also has been described in horses.[61] Whether this latter syndrome may have been a consequence of congenital renal vascular malformations has not been determined (see Section 17.8). Occasionally gross hematuria with passage of blood clots can accompany omphalitis or bladder rupture.[62] One usually can detect these problems during ultrasonographic examination of the umbilical structures, and sometimes can image tissue echogenicity within the bladder that is attributable to a blood clot.

17.1.3.5 PENDULANT KIDNEY

A pendulant kidney is a rare anomaly in the horse.[63] Rectal examination reveals an extremely mobile kidney attached to the dorsal body wall by a thin band of tissue. Although a pendulous kidney could result from extreme weight loss, hydronephrosis, or perirenal trauma, the condition usually is thought to be congenital. The abnormality is an incidental finding unless displacement or rotation leads to partial or complete ureteral obstruction. As an example, the author has palpated the entire right kidney of one mare immediately craniad of the pelvic canal, and ultrasonographic imaging revealed normal size and structure of the anomalously located kidney.

17.1.3.6 ECTOPIC URETER

Although ureteral ectopia occurs rarely in the horse,[64] the condition is the most commonly reported developmental anomaly of the equine urinary tract.[64–82] Ectopic ureters may develop when (1) the ureteric bud (metanephric duct) fails to be incorporated into the urogenital sinus or fails to migrate craniad to the bladder neck, or (2) the mesonephric duct fails to regress. In the former case, the ectopic ureter opens near the urethral papilla in females or into the pelvic urethra near the colliculus seminalis in males, whereas in the latter, the ureter may open anywhere along the vagina, cervix, or uterus (but only in females because this 1177
portion of the mesonephric duct becomes the wolffian duct system in males). In 118 reported cases of ectopic 1178
ureter in horses, 105 (89%) were females[65–68,72–77,79–82]; however, this sex distribution may reflect easier recognition in females of the presenting complaint of urinary incontinence rather than a true sex predilection. Incontinence is recognized more often in females because urine entering the pelvic urethra in males may pass retrograde into the bladder. Although a genetic predisposition for ectopic ureter exists for several dog breeds,[83] no breed predilectionhas been established in horses. However, Quarter Horses may be at greater risk because the condition has been reported in five Quarter Horses, three Standardbreds, two Thoroughbreds, two Appaloosas, an Arabian, a Clydesdale, a Shire, a Fresian, a Foxtrotter, and a Warmblood. The author also has seen the condition in two Quarter Horse fillies (one unilateral and one bilateral), yielding a total of 20 cases.

In horses with ureteral ectopia, urinary incontinence is generally apparent from birth, and affected animals are presented for extensive scalding of the hindlimbs. With unilateral ectopia, horses also void normally, because the other ureter enters the bladder in the appropriate location. Renal function is usually normal, but the affected ureter may be greatly dilated. Urine pooling in the vagina and uterus was a complicating factor in one case.[73] To determine the site of the ectopic ureteral orifice(s), one initially visually examines the vestibule and vagina (using a blade speculum) to look for intermittent urine flow from the area of the urethral papilla. Ectopic ureteral openings usually are not apparent unless urine flow is visible. Endoscopy may be

helpful in females (while inflating the vestibule and vagina with air and using a hand to form a seal at the vulva) and is required in males to visualize the ectopic ureteral opening. Intravesical placement of methylene blue dye was performed in one filly to provide evidence for ureteral ectopia. Continued dribbling of clear urine (from the ectopic ureter) followed by passage of blue, discolored urine indicated that only one ureter emptied into the bladder but provided no information on the location of the opening of the ectopic ureter.[66] Intravenous administration of dyes—including sodium fluorescein (10 mg/kg intravenously; yellow-green), indigotindisulfonate (indigo carmine, 0.25 mg/kg intravenously; blue-purple), azosulfamide (2.0 mg/kg intravenously; red), or phenolsulfonphthalein (1.0 mg/kg intravenously; red)—to discolor the urine may help locate ectopic ureteral openings.[84] Contrast radiography (excretory urography or retrograde contrast studies via catheterization of the bladder and ureters) has been used to detail renal architecture and the course of the ureters in some affected animals; however, results of intravenous urograms are frequently inconclusive in foals weighing more than50 kg (contrast agent is poorly imaged). In a recent report, ultrasound-guided pyelography, in which contrast agent was injected directly into the renal pelvis using a spinal needle, proved to be a more effective technique than imaging after intravenous administration of contrast agent to detail the course of an ectopicureter, and one should consider this technique in future cases.[82]

Treatment has included ureterocystostomy (surgical reimplantation of the ectopic ureter or ureters into the bladder) or unilateral nephrectomy. Before surgery, one must determine whether the condition is unilateral or bilateral, which side is affected if unilateral, and whether urinary tract infection is present. Further, one should attempt to rule out other anomalies, especially of the reproductive tract. If the problem is bilateral (8 of 20 cases), one should establish the presence of a normal micturition response by measuring the intravesicular pressure response to progressive distention until the fluid infused is voided spontaneously. This procedure provides an estimate of bladder volume and ensures competency of the urethral sphincter before reimplantation. Among 14 cases in which surgical correction was pursued, ureterocystostomy was successful in establishing a functional urinary system in nine published cases[67,68,75,76,81,82] and one foal seen by the author, but four died of postoperative complications.[68,75,82] In contrast, all four cases treated by unilateral nephrectomy had a favorable outcome.[72,73,79] Because affected ureters often are dilated and tortuous, surgical reimplantation can be difficult and may not result in a functional ureteral orifice. Consequently, when the problem is unilateral, nephrectomy of the affected side may be the preferred treatment option.[85,86]

17.1.3.7 URETERAL DEFECTS OR TEARS(URETERORRHEXIS)

Retroperitoneal accumulation of urine and uroperitoneum has been described in seven foals with unilateral or bilateral ureteral defects[87–93] and has been observedin three additional foals by the author. These included seven male and three female foals of several breeds(five Standardbreds, two Thoroughbreds, one Belgian, one Oldenburg, and one Appaloosa). Clinical signs (decreased nursing, depression, abdominal distention, diarrhea, and muscle twitching or other signs of neuromuscular irritability) and clinicopathologic abnormalities (hyponatremia, hyperkalemia, hypochloremia, and azotemia) are similar to those in horses with bladder rupture but may have a slightly later onset (4 to 16 days of age). Mild protrusion of the vagina may occur in fillies in which the peritoneum has remained intact.[94] In affected foals, ultrasonographic 1178
examination may reveal dilation of the renal pelvis and affected ureter and fluid accumulation around the 1179
kidneys or farther caudad within the retroperitoneal space. As with ectopic ureters, excretory urography generally has been an unrewarding diagnostic procedure, but contrast pyelography was used successfully to image leakage of contrast agent from a proximal ureteral defect in a recent report.[93] Contrast radiography has not been pursued routinely because exploratory celiotomy generally was performed shortly after a diagnosis of uroperitoneum. Catheterization of the ureters via a cystotomy and retrograde injection of methylene blue

allowed localization of the defect(s), and surgical correction was performed successfully in four cases by suturing the defect around an indwelling catheter.[89,90,93] Although ascending urinary tract infection should be an expected complication with a stent, repair of a defect in one foal without use of an indwelling catheter resulted in further urine leakage from the ureter, prompting a nephrectomy 4 days after the initial surgery.[91] Of the remaining five foals, one died after three unsuccessful attempts at surgical repair,[88] and euthanasia was performed in four cases without attempting repair.[87,92]

At surgery or necropsy a single defect was found in six foals, whereas bilateral defects were found in four foals and multiple defects were apparent in one ureter. In most cases the defects have been located in the proximal third of the ureter near the kidney. Interestingly, distended, tortuous ureters, occasionally accompanied by hydronephrosis, also were described in three affected foals,[88,91,93] and distal obstruction of the ureters at the bladder was suspected in two of these cases, prompting ureteroneocystostomy. Although several reports suggest that these ureteral defects may be anomalies of development, the actual cause of these ureteral defects is not known. Traumatic disruption was suggested in the initial report in which histologic examination of the marginsof the defect revealed hemorrhage and proliferation of immature connective tissue.[87] A traumatic cause was further supported by a subsequent report in which histologic examination of the defects revealed absence of transitional epithelium and inflammation in a foal that had been attacked by dogs.[92] Inflammation and granulation tissue also were visible in the apparently obstructed distal ureter in one of the foals with ureteral distention, again suggesting an acquired lesion. Blunt abdominal trauma, often sustained during automobile accidents, can cause retroperitoneal accumulation of urine and uroperitoneum in human beings.[95] Disruption of the ureter is usually near the kidney, and this complicationof trauma may not be recognized for several days following injury. In one foal evaluated by the author, multiple rib fractures found at necropsy suggested that these ureteral tears actually could be a complication of foaling trauma.

17.1.3.8 RECTOURETHRAL AND RECTOVAGINAL FISTULAE

If the urorectal fold fails to separate completely the primitive hindgut from the urogenital sinus, a rectourethral fistula may be found in a colt or a rectovaginal fistula or a persistent cloaca may be found in a filly.[96] These anomalies are rare in horses and when present usually are associated with atresia ani and other anomalies, including agenesis of the coccygeal vertebrae and tail, scoliosis, adherence of the tail to the anal sphincter area, angular limb deformities, and microphthalmia.[70,71,97–102] Affected foals usually are presented for atresia ani, although one also may observe signs of colic and straining. Evidence for a fistula is passage of fecal material from the vulva or urethra. In fillies one may detect rectovaginal fistulae by digital palpation of the dorsal vestibule and vagina, but in colts a definitive diagnosis usually requires contrast radiographic procedures such as a barium enema or a retrograde urethrogram (Figure 17.1-8). Surgical correction of atresia ani and fistulae has been performed successfully in several foals, but multiple surgical procedures may be required. Because ascending urinary tract infection may be a complication, one should submit a sample of urine collected via bladder catheterization (preferably during surgery) for bacterial culture.[96] In human beings the evidence suggests that these anomalies are hereditary, and in one report several foals born with atresia ani were sired by the same stallion.[97] Consequently, affected horses should not be used for breeding after surgical correction of the anomalies.

Figure 17.1-8 A positive contrast urethrogram in a 3-day-old burro that had atresia ani and intermittent passage of fecal material from the urethra. A catheter passed via the urethra and contrast agent injected into the catheter resulted in accumulation of a large amount of contrast agent in the rectum and a lesser amount in the intrapelvic portion of the urethra. A small amount of contrast agent is visible in the urethrorectal fistula *(arrow)*.

1179

A urethrorectal fistula resulting in passage of urine from the anus also has been described in a 3-year-old Thoroughbred gelding.[103] The fistula in this gelding was thought to be acquired following trauma or straining because no other developmental problems were detected and the edges of the defect were irregular and inflamed when examined with a speculum inserted into the rectum. 1180

17.1.3.9 BLADDER DEFECTS

Uroperitoneum may result from bladder rupture during parturition in foals (most commonly males)[104] or as a consequence of urachal leakage following infection ofthe umbilical structures.[105,106] In addition, Wellington described uroperitoneum in two foals that were full brothers.[107] Urine entered the abdomen from a dorsal

defect in both colts, and smooth margins to the defects combined with a lack of appreciable inflammation provided evidence in favor of anomalous development rather than trauma. Other authors have suggestedthat some cases of uroperitoneum likely are associated with anomalous bladder defects because of the size, location, or lack of apparent inflammation of the margins of the defects.[70,108–111] For example, Bain[108] described uroperitoneum in a foal in which the ventral portion of the bladder was absent between the lateral ligaments (umbilical artery remnants) from the umbilicus to the urethra.

Anomalous fusion of the bladder to the inner umbilical ring (absence of the urachus) has been describedin one foal.[112] The malformation precluded normal contraction and evacuation of the bladder, and a megavesica —a greatly enlarged bladder—developed. The clinical appearance was similar to that of uroperitoneum, and surgical separation of the bladder from the umbilical ring restored normal anatomic and functional integrity of the bladder. A similar case with a greatly distended bladder was reported in a foal evaluated for abdominal distention[70] that was attributed to an adhesion of the bladder to the urachus or umbilical remnant. An enlarged, flaccid bladder also was described in a foal undergoing exploratory celiotomy for suspected urinary tract disruption.[105] Adhesions to the abdominal wall were not reported, and the foal survived following the surgery during which 50% of the distended bladder was resected. In addition to bladder distention, persistent attachment of the bladder to the area of the umbilicus via a urachal remnant was reported to cause pollakiuria and dysuria in a 15-month-old Thoroughbred filly.[113] The author also has seen postpartum bladder rupturein a mare in which a persistent urachal attachment was suspected to be a contributing factor.

Excessive bladder distention or megavesica has been described further in four stillborn foals[114] and one neonatal foal.[115] In the latter foal and in another report,[116] chronic bladder distention appeared to lead to loss of smooth muscle in the dorsal bladder wall and replacement with collagen. The result was bladder rupture during parturition. Although these reports are similar to an early report by Rooney describing the dorsal bladder wall as the anatomic weak link and likely area for rupture,[104] they differ in that chronic distention of the bladder in utero with smooth muscle loss is not recognized in more typical bladder ruptures in neonatal foals. Why bladder distention should occur in utero without obstruction of the lower tract (not found in these cases) is not clear. Although an excessively long umbilical cord (longer than 85 cm) may lead to urachal obstruction,[114,117] urine produced in utero alternatively could drain into the amniotic cavity via the urethra. Thus this form of megavesica remains poorly characterized and poorly understood.

Bladder distention also is recognized in some foals with hypoxic-ischemic encephalopathy. Affected foals may posture to urinate frequently, and ultrasonographic examination may reveal an enlarged bladder or incomplete bladder emptying. In recumbent foals, one may note abdominal distention, and temporary use of an indwelling bladder catheter to keep the bladder empty is helpful, but ascending urinary tract infection may be a complication. Cystometrography would be useful to assess detrusor function in affected foals, but no reports describe use of this diagnostic test in equine neonates. Although administration of cholinergic drugs (e.g., bethanechol) to improve detrusor function or α-adrenergic blockers (e.g., phenoxybenzamine or acepromazine) to decrease urethral sphincter tone has been described anecdotally to be of benefit, no reports describe the efficacy of these medications in foals with this problem.

17.1.3.10 PATENT URACHUS

The urachus is the conduit through which fetal urine passes from the bladder into the allantoic cavity. Normally, the urachus closes at the time of parturition, but incomplete closure is the most common malformation of the equine urinary tract. Patent urachus occurs more commonly in foals than in other

domestic species.[30] Greater than average length or partial torsion of the umbilical cord has been suggested to cause tension onthe attachment of the umbilical cord to the body wall. The result is dilation of the urachus and subsequent failure to close at birth.[70,71,114,117,118] Patent urachus results in a persistently moist umbilicus after birth, from which urine may leak as drips or as a stream during micturition. One must distinguish this malformation from septic omphalitis, which also can result in urine leakage from the umbilicus within a few hours to days after birth. Patent urachus has been referred to as a congenital problem 1180
and the latter as an acquired one, but both may result in urine leakage from the urachus from birth. Neither is 1181
life threatening, but local sepsis often is accompanied by more severe illness, including septicemia or localized infection, particularly in joints.

The congenital patent urachus traditionally has been treated with frequent (2 to 4 times daily) chemical cauterization of the urachus with swabs dipped in a concentrated phenol or 7% iodine solution or with silver nitrate applicators.[119] Because the urachus may close spontaneously in a number of cases, and because these agents desiccate and irritate tissue (and may predispose to infection), the rationale for this approach has been questioned.[118] In a study comparing the effects of disinfectant solutions on the bacterial flora of the umbilicus of normal foals, use of a 7% iodine solution was observed to cause rapid desiccation of the umbilical tissue and subsequent development of a patent urachus when the stump fell off a few days later.[120] Consequently, in the absence of apparent infection, no local treatment may be indicated specifically, but affected foals frequently are given antibiotics prophylactically. For acquired patency (which may be associated with local infection or septicemia), broad-spectrum antibiotic therapy is indicated, and resolution of the systemic disease may be accompanied by elimination of the umbilical infection and closure of the urachus. Chemical cauterization is contraindicated with local sepsis because it may increase the risk of urachal rupture and development of uroperitoneum.[121] If one observes no decrease in urine leakage after 5 to 7 days of medical therapy or if ultrasonography reveals abnormalities of multiple structures in the umbilicus,[122,123] surgical exploration and resection of the urachus and umbilical vessels may be indicated. In a retrospective study of 16 foals treated for sepsis of umbilical cord remnants, six of nine (67%) survived after surgical resection and antibiotic treatment, whereas only three of seven (43%) survived after antibiotic treatment alone.[124] Although this series of 16 foals often is cited in support of surgical intervention, one should note that the series studied a small number of foals and that the cases were evaluated over 10 years (1975 to 1985), during which time many aspects of neonatal care improved. In a more recent retrospective report of 33 foals with umbilical remnant infections, no difference in survival was observed between foals treated with antibiotics combined with surgical resection or with antibiotic therapy alone.[123] Further, emphasis was placed on the insensitivity of palpation of the umbilicus in detection of umbilical remnant infection (compared with ultrasonographic examination) and the poor outcome of cases in which the umbilical vein was involved. In addition to the possibility of omphalitis leading to urachal rupture and development of uroperitoneum, urachal leakage also may occur into the abdominal musculature and subcutaneous tissues and lead to swelling and cellulitis of the ventral abdominal wall.[125] Both instances require surgical intervention. Finally, trauma or tearing of the urachus also can lead to umbilical evagination of the urinary bladder,[126] which can result in partial or complete obstruction of urine flow, and surgical correction is indicated.

17.2

17.2—Renal Physiology

Harold C. Schott, II

The kidneys perform two essential functions in the maintenance of homeostasis: elimination of nitrogenous and organic waste products and control of body water content and ion composition. In addition, the kidneys are important endocrine organs that produce renin, erythropoietin, and the active form of vitamin D, and they also play an important role in the degradation and excretion of a number of other hormones, including gastrin and parathormone. To gain an understanding of the pathophysiologic alterations associated with renal disorders in horses, one must first review some aspects of normal renal physiology in this species.

17.2.1

Production and Elimination of Nitrogenous and Organic Wastes

The two most commonly recognized waste products excreted in urine are urea and creatinine, but many other nitrogenous or organic wastes are produced each day and subsequently are eliminated by the kidneys (Box 17.2-1).[1]

17.2.1.1

UREA METABOLISM

A molecule of urea is produced in the liver from two ammonium ions that are liberated during catabolism of amino acids. For each urea molecule the carbon atom is derived from bicarbonate. One ammonium ion is cleaved from an amino acid via an α-ketoglutarate-dependent transamination coupled to oxidative deamination of glutamate. The second ammonium ion is derived from aspartate in the urea cycle.[2] Urea synthesized in the liver is released into the blood, and clearance by the kidneys represents the major pathway (75% to 100%) of excretion. Extrarenal urea excretion includes losses in sweat and through the gastrointestinal tract. With normal intestinal function, enteric excretion is minimal because of enterohepatic recirculation (reabsorption of ammonia from the degradation of urea by bacterial ureases and subsequent reformation of urea in the liver).[3]

In human beings, inborn errors of metabolism leading to deficiency of a specific transaminase or of one of the five enzymes of the urea cycle can result in accumulation of ammonia and other intermediates of amino acid catabolism. These disorders typically are inherited as autosomal recessive traits, and the consequence is moderate to severe mental retardation because the accumulated intermediates can be toxic to the central nervous system (ammonia) or can act as false neurotransmitters (aromatic amines).[1] Because urea production is limited in these disorders, blood urea nitrogen concentration (BUN) is often low.[2] Although such defects in metabolism appear to be rare in domestic animals,[4] development of encephalopathy in association with hyperammonemia has been recognized in horses.[5,6] Furthermore, in one report of two related Morgan weanling fillies, persistent hyperammonemia was suspected to be caused by a defect in a mitochondrial ornithine transporter similar to an autosomal recessive syndrome of hyperornithinemia, hyperammonemia, and homocitrullinuria in human beings (HHH syndrome).[7]

Blood urea nitrogen concentration depends on age, diet, rate of urea production, and renal function. For example, a low BUN typically is found in neonatal foals following an anabolic demand for amino acids.[8] Next, investigations of nitrogen use in ponies have demonstrated that urea production is proportional to dietary protein content. Similarly, urinary urea excretion increases in parallel with urea production.[9,10] As a result, with increased levels of dietary protein or when urea is supplemented in the diet, BUN may increase twofold or greater.[11–13]

In human beings and small animals, BUN is routinely higher in samples collected postprandially because diets are typically high in protein.[3] Postprandial elevation of BUN has not been described in horses or other herbivores. However, fasting leads to enhanced protein catabolism to meet energy demands and increased BUN in horses.[14,15] In ponies, however, BUN decreases with fasting.[16] This opposite response suggests 1184
differences in the metabolic responses of horses and ponies to anorexia, consistent with a greater capacity of 1185
ponies to mobilize and use fat during starvation. Other causes of protein catabolism, including fever, infection, trauma, myositis, burns, and corticosteroid therapy, also can produce an increase in BUN.[3] Finally, a decrease in renal blood flow (RBF) or renal function produces an increase in BUN. The former may occur with dehydration or during periods of anesthesia or exercise; the latter is a reflection of renal disease.[3] With short bouts of moderate to intensive exercise, BUN often does not change,[13,17] but during prolonged exercise, BUN can increase by 50% or more because of the combined effects of decreased RBF and protein catabolism.[18,19]

Most renal nitrogen excretion occurs in the form of urea in urine. One must recognize that urea excretionis completely passive and that the high concentrations achieved in urine are merely a consequence of medullary tonicity produced by the countercurrent-multiplier function of the loop of Henle. Thus although variations in dietary protein intake lead to parallel changes in urea excretion, the idea that low-protein diets decrease the work load on the kidney is a fallacy.[3] Urinary urea nitrogen concentrations can vary from as low as 50 mg/dlin neonatal foals or horses with primary polydipsia to greater than 2500 mg/dl in normal horses on high-protein diets. Total daily urea excretion usually ranges between 100 and 300 g per day in horses with normal renal function.

17.2.1.2 CREATININE METABOLISM

Creatinine is produced by the nonenzymatic, irreversible cyclization and dehydration of creatine. Creatine is produced indirectly from three amino acids in the kidney, liver, and pancreas and subsequently is transported to other organs such as muscle and brain, where it is phosphorylated to store energy in the form of phosphocreatine.[3,20] In human beings, 1.5% to 2% of the creatine pool is converted to creatinine daily and results in fairly constant excretion of creatinine within a given individual.[3] With normal renal function, a direct relationship exists between daily creatinine production, serum creatinine concentration (Cr), and creatinine excretion, all three being proportional to total muscle mass. The fact that Cr is 30% higher in human males than in females and that urinary creatinine excretion is correlated to body size across a wide range of animal species supports this relationship.[3,21] Creatinine is excreted principallyin urine, but sweat and the gastrointestinal tract are secondary routes of excretion.[3] In contrast to urea, enterohepatic recycling of creatinine does not occur, and the gastrointestinal tract may represent a major route of excretion when renal function is compromised. For example, in a group of azotemic human patients, between 15% and 65% of radiolabeled creatinine was found to be excreted through the intestine.[22] Creatinine excreted by this route is degraded rapidly by bacteriaso that little is found in feces.

Like BUN, Cr can vary with age, activity level, and renal function. In contrast, dietary protein intake has little influence on Cr in horses.[11] Newborn foals routinely have Cr values 30% to 50% higher than those measured in the mare, and values as high as 20 to30 mg/dl have been measured in some premature or asphyxiated foals.[8] These high values may result from limited diffusion of creatinine across the placenta. For example, the Cr in equine amniotic fluid collectedat term is proportionately much greater than urea nitrogen concentration (Cr, 10.1 mg/dl; urea nitrogen, 38.8 mg/dl).[23] If the foal appears healthy and all other laboratory values are within reference ranges, a serumCr value in the range of 5 to 15 mg/dl should not cause alarm. In most healthy foals with normal renal function, Cr decreases to values below 3.0 mg/dl within the first 3 to 5 days of life.[22] After the first few days of life, Cr is usually lower in foals than in adults[12] because of the combined effect of rapid growth and the fact that skeletal muscle comprises a smaller percentage of body weight in foals than in adult horses. Other nonrenal factors that may influence Cr include fasting, rhabdomyolysis or muscle wasting caused by disease, and exercise. Although fasting can increase the measured value for Cr, a substantial portion of this increase actually is due to other compounds (possibly ketones) that increase during fasting and are measured as noncreatinine chromagens in the commonly used Jaffe's colorimetric assay for Cr determination (see Chapter 17.3).[12,14,24] In contrast, the increase in Cr (up to 80% in some reports) associated with various types of exercise is likely the combined result of increased release of creatine from muscleand decreased urinary creatinine excretion during the exercise bout.[12,14,17–19]

Creatinine is filtered freely at the glomerulus and is concentrated to values of 100 to 300 mg/dl in equine urine, which results in a total daily urine excretion of 15 to 25 g of creatinine.[25,26] In comparison to urea, creatinine excretion is responsible for only one tenth as much urinary nitrogen excretion. Minor species and sex differences have been reported for renal tubular handling of creatinine with a weak proximal tubular secretory mechanism in human beings and male dogs (accounting for 7% to 10% of total urinary creatinine excretion).[3,20] To determine whether tubular secretion of creatinine occurs in equine kidneys, Finco and Groves fitted anesthetized ponies with ureteral catheters and performed simultaneous inulin and exogenous creatinine clearance studies.[27] Because inulin is filtered freely at the glomerulus and neither secreted nor 1185
reabsorbed by renal tubules, inulin clearance (Cl_{In}) provides a standard of comparison for creatinine 1186

clearance (Cl_{Cr}). Tubular secretion of creatinine should result in a greater value for Cl_{Cr} than for Cl_{In}, whereas the opposite should occur with tubular reabsorption of creatinine. To magnify any minor tubular secretion of creatinine, stop-flow studies were performed by temporarily occluding the ureteral catheters. During obstruction, tubular lumen pressure increased and tubular flow decreased. As a consequence, fluid remained in contact with tubular epithelium for a prolonged period, enhancing local tubular secretory or resorptive processes. Analysis of a series of urine samples collected after release of ureteral occlusion revealed no differences in tubular handling of inulin or creatinine, leading to the conclusion that creatinine neither was reabsorbed nor secreted by equine kidneys. In contrast, simultaneous measurement of endogenous Cl_{Cr} and Cl_{In} in several horses with chronic renal failure (author's unpublished observations) has revealed higher values for Cl_{Cr}, indicating that tubular secretion of creatinine may develop in horses as renal function declines (see Chapter 17.5). Whether significant excretion of creatinine occurs in sweat or through the gastrointestinal tract has not been investigated in horses.

17.2.1.3

METABOLISM OF OTHER NITROGENOUSAND ORGANIC COMPOUNDS

Although the kidneys excrete a number of nitrogenous and organic wastes in addition to urea and creatinine (see Box 17.2-1), these compounds are quantitatively unimportant in terms of nitrogen balance.[1] Two of the more commonly recognized molecules are ammonia and uric acid. In proximal tubular epithelial cells, ammonium ions and α-ketoglutarate are produced from glutamine. Subsequent metabolism of α-ketoglutarate results in generation of two bicarbonate molecules that are returned to the systemic circulation. Ammonium ions are secreted in exchange for sodium into the tubule lumen, where they remain trapped, because tubules are relatively impermeable to ammonium ions. Furthermore, because the pK_a for ammonia is greater than 9.0, most of the tubular ammonia remains in the form of ammonium ions, even in alkaline equine urine. Although ammonium ion excretion is of little significance in overall nitrogen excretion, it plays an important role in acid (hydrogen ion) excretion. In fact, glutamine metabolism and ammonium ion excretion can increase severalfold in response to metabolic acidosis.[28] Although urinary ammonium concentration is not measured routinely, one can estimate it because it is directly related to the urinary anion gap ($[Na^+ + K^+] - Cl^-$) in human patients with normal anion gap metabolic acidosis.[29] More important, impairment of this proximal tubular acid secretion pathway contributes to development of metabolic acidosis in patients with renal insufficiency.

Uric acid is a product of purine nucleotide degradation and is the major nitrogenous waste product formed in amphibians and reptiles. In mammals, however, uric acid excretion (mostly in the ionic form of urate) is unimportant in terms of overall nitrogen excretion.[30] Uric acid metabolism has received little attention in veterinary species with the exception of Dalmatian dogs. This breed exhibits high urate excretion rates and is predisposed to uric acid stone formation; however, this problem results from decreased hepatic uricase activity rather than any abnormality in renal urate handling.[31] Finally, hyperuricemia (leading to gout in human beings) also can be attributed to a lack of uricase activity in human tissues and greater renal reabsorption of urate compared with other mammalian species. Thus crystallization of urate in tissues appears to be limited to human beings.[30] Urate metabolism has been studied little in horses, although Keenan observed that plasma concentrations increased dramatically in response to exercise (from less than 1 μmol/L at rest to 150 to 200 μmol/L 1 hour after racing) and that these increases were accompanied by a transient increasein urinary urate excretion (from less than 40 μmol/L at rest to 250 to 1270 μmol/L after racing).[17]

The proximal tubule is also the major site of excretion (by tubular secretion) of a number of endogenous organic anions and cations.[30] The anions share the common pathway measured by *p*-aminohippurate clearance, the substance traditionally used to measure effective renal plasma flow (because more than 90% is excreted via this pathway). A number of exogenous compounds also are excreted via these pathways—acetazolamide, furosemide, probenecid, penicillin G, sulfadiazine, salicylate, atropine, cimetidine, and neostigmine. Thus administration of these compounds can interfere with tubular secretion of endogenous organic wastes or other exogenous products by healthy kidneys.[32] More important, pharmacokinetics of these products varies widely in patients with renal insufficiency. Combined with the fact that anion binding to plasma proteins is decreased with azotemia, dosing protocols of many medications may need to be readjusted for patients with renal failure.

17.2.2 Body Water and Electrolyte Balance

17.2.2.1 BODY FLUIDS: VOLUME AND COMPOSITION

Water accounts for at least 60% of total body mass, equivalent to 300 L in a 500-kg horse.[29–35] About 200 L of total body water is intracellular fluid, and the remaining 100 L is extracellular fluid. Extracellular fluid is divided between plasma (4% to 6% of body mass, ≈25 L), interstitial fluid and lymph (10% to 12% of body mass, ≈45 L), and transcellular fluid (6% to 10% of bodymass, ≈30 L, most of which is in the lumen of the 1186
gastrointestinal tract). Despite significant differences in ion composition (Table 17.2-1), the extracellular 1187
fluid and intracellular fluid compartments exchange water freely to maintain osmotic equilibrium.[36]

TABLE 17.2-1 Approximate Ionic Compositions (mEq/L) of Plasma, Interstitial Fluid, and Intracellular Fluid (Skeletal Muscle)

ELECTROLYTE	PLASMA	INTERSTITIAL FLUID	SKELETAL MUSCLE CELL
CATIONS

Total	147.6	150.6	190

Modified from Rose BD: Physiology of body fluids. In *Clinical physiology of acid-base and electrolyte disorders,* ed 3, New York, 1989, McGraw-Hill.

* This largely represents organic phosphates such as adenosine triphosphate.

From the values in Table 17.2-1 one can estimate the total amount of exchangeable sodium, potassium, and chloride in the body fluids of a 500-kg horse: approximately 16,000 mEq, approximately 28,800 mEq, and approximately 10,800 mEq, respectively (including gastrointestinal fluid ion contents). These values are accurate except for that of sodium, which may be twice as great; however, 40% to 50% is sequestered in bone and is not readily available to buffer sodium alterations in body fluids.[33–35] Thus the 16,000-mEq estimate is accurate for the exchangeable sodium content in body fluids. Similarly, one can estimate body fluid contents of calcium, magnesium, and phosphorus at approximately 1000 mEq (20 g), approximately 6875 mEq (84 g), and approximately 8150 mEq (140 g), respectively (excluding gastrointestinal fluid ion contents, because these vary with the amount and solubility of the dietary source). As for sodium, the values underestimate the total body content of calcium, magnesium, and phosphorus, because more than 99%, 70%, and 85% of these elements, respectively, are contained in the skeleton.[37]

17.2.2.2

WATER BALANCE

Appropriate water balance maintains plasma osmolality in a narrow range (270 to 300 mOsm/kg) and is achieved by matching daily water intake with water loss.[38–40] Water is provided from three sources: (1) free water intake (drinking), (2) water in feed, and (3) metabolic water (Table 17.2-2). Horses consume most of

the water by drinking (about 85%), but feed and metabolic water provide about 5% and 10% of daily water, respectively. Water can be lost by three routes: (1) in urine,(2) in feces, and (3) as insensible losses (evaporation) across the skin and respiratory tract (Table 17.2-3). Investigations of water balance have revealed a maintenance water requirement of 60 to 65 ml/kg/day or 27 to30 L/day for a 500-kg horse.[38,41] These values are consistent with traditional recommendations that 5 to 10 gallons/day of fresh water be provided to a stabled horse under mild environmental conditions.[42] Urinary and fecal water losses range from 20% to 55% and 30% to 55%, respectively, of the total daily water loss.[38,41,43,44] The remaining (insensible) 1187
loss accounted for up to 15% to 40% of daily water loss, despite mild ambient conditions and the lack of 1188
observed sweating in most studies of water balance.

TABLE 17.2-2 Water Balance in Hay-Fed Horses in a Cool Climate

WATER INTAKE (L)		WATER LOSS (L)	
Consumption	23.6	Feces	14.0

§ Water intake includes imbibed water (23.6 L), water in feed (1.1 L), and metabolic water (2.9 L).

Water drinking and urine production are the mechanisms by which water balance is finely tuned; however, they can vary widely between individual horses and also are affected by age, environmental conditions, level of exercise, and diet. Often, for example, neonatal foals consume milk in excess of 20% of their body massdaily,[45] which equates to fluid intake approaching250 ml/kg/day. Next, water intake by horses increased 15% to 20% when ambient temperature increased from 13° to 25° C.[46] Under conditions of high ambient temperature and humidity, urine concentration also may increase to conserve water, whereas fecal water content tends to remain fairly stable, at about 75% of fecal weight. Exercising horses, especially endurance horses and racing horses treated with furosemide, can increase water consumption by 100% to 200% to replace body water lost in sweat (and urine). Horses and ponies on all-roughage diets also drink more and have greater daily fecal water loss (because of greater daily fecal volume) than animals fed a large amount of concentrate or complete pelleted diets.[43,44] Diets high in nitrogen (protein) and calcium, such as legume hays, typically increase urine volume by 50% or more and are associated with a similar increase in urinary nitrogen excretion. These diets are also more digestible, so that fecal water excretion generally decreases because of a decrease in total fecal material.[9,14,43,44] Although high dietary levels of salt have been suggested to increase drinking and promote diuresis, no increase in water consumption or urine volume was observed in ponies fed 5 to 10 times the daily salt requirement (equivalent to about 350 g of sodium chloride for a 500-kg horse).[47] The effects of water access, continuous versus intermittent, have received less attention, although a recent study showed no difference in water balance in horses provided water 3 times daily compared with horses that had continuous access to water.[48] Furthermore, horses drink the most water within the hour after feeding,[49] and feral horses and ponies often drink only once or twice daily.[50] Thus horses are unlikely to require continuous access to water. An obvious exception is a patient with renal insufficiency that should have access to fresh water at all times.

Two main stimuli for thirst are increased plasma osmolality and hypovolemia or hypotension.[51] The former is mediated through osmoreceptors in the hypothalamus that have a high threshold for activation (about 295 mOsm/kg) in human beings. Hemodynamic stimuli are mediated by low- and high-pressure baroreceptors. Osmotic and hemodynamic stimuli can produce their dipsogenic effect in part by activating a local renin-angiotensin-aldosterone system in the central nervous system.[52,53]

Renal water reabsorption is controlled principally by the action of arginine vasopressin (antidiuretic hormone) on the collecting ducts.[54] Vasopressin is produced in the neurosecretory neurons of the supraoptic nuclei, packaged in granules, and transported down axons for storage in the neurohypophysis (pars nervosa or posterior pituitary). As for thirst, increases in plasma osmolality and hypovolemia or hypotension are the stimuli for vasopressin release. Osmoreceptors for vasopressin release also are located in the hypothalamus, adjacent to the osmoreceptors mediating thirst. Activation of these receptors is the signal for vasopressin release from the neurohypophysis. Furthermore, these osmoreceptors are not equally sensitive to all plasma solutes. For example, increases in plasma sodium concentration and infusion of mannitol are potent stimuli, whereas increases in plasma glucose and urea concentrations are weak stimuli. These differences have led to the suggestion that osmoreceptor activation is caused by an osmotic water shift that produces cell shrinkage (which would be greater for sodium and mannitol than for glucose or urea). Activation of osmoreceptors signaling vasopressin release also appears to have a threshold value; however, this threshold appears to vary highly between individuals. In addition, the threshold for vasopressin release in human beings is significantly

lower (270 to285 mOsm/kg) than that for thirst. Thus vasopressin release can be thought of as the initial line of defense against a mild increase in plasma osmolality, whereas thirst and drinking are secondary responses to even greater increases.

Studies in horses, ponies, and donkeys have demonstrated that increased plasma osmolality (induced by water deprivation or infusion of hypertonic saline) and hypovolemia (induced by furosemide administration) are stimuli for thirst.[48,54–58] Furthermore, after a period of water deprivation, dehydrated ponies, horses, and donkeys appear to be able to replace water deficits within 15 to 30 minutes of gaining access to water. The increases in plasma osmolality and vasopressin concentration associated with water deprivation also are corrected in this same period of time, indicating that imbibed water is absorbed rapidly fromthe gastrointestinal tract.[55] Although increases in plasma vasopressin concentration have been measured in horses and ponies during water deprivation,[55,59] vasopressinalso appears to be a "stress hormone" in equids, because substantially greater concentrations (tenfold greater than those induced by water deprivation) have been measured after application of a nose twitch, nasogastric intubation, or exercise.[60,61] Thus increases in plasma vasopressin concentration following water deprivation would be expected to vary in horses, and separating osmotic effects from stress effects may be difficult sometimes.

Once released, vasopressin acts on V_2-receptors on the basolateral membrane of collecting duct epithelial 1188

1189 cells, leading to insertion of water channels (transmembrane proteins) in the apical membrane.[51] These channels increase the water permeability of the apical membranes and lead to increased water reabsorption. Action of V_2-receptors is mediated by activation of adenyl cyclase and a stimulatory transmembrane G protein. Interestingly, V_2-receptor activation can be antagonized by activation of adjacent α_2-adrenoceptors and by a prostaglandin E_2–mediated effect on an inhibitory G protein.[62,63] Although effects of these antagonists vary with species and have not yet been studied in horses, the diuresis associated with administration of α_2-agonists to horses[64,65] likely may be attributable to vasopressin antagonism at the collecting duct.

As mentioned previously, most water drinking in equids occurs periprandially; thus feeding practices affect timing of water intake.[49] If a horse eats a large meal once or twice daily, both increased plasma sodium concentration and decreased plasma volume (because of a shiftof fluid into the bowel) stimulate thirst and vasopressin release. The result is a simultaneous increase in water intake and a decrease in urine output.[66] In addition, hypovolemia further stimulates activation of therenin-angiotensin-aldosterone system, which leads to enhanced renal sodium conservation as an additional means of restoring plasma volume. Although the increase in plasma sodium concentration with meal feeding is rather small (1% to 3%), the decrease in plasma volume is much greater (5% to 25%). The magnitudeof this fluid shift (and the degree of activation of the renin-angiotensin-aldosterone system) can be attenuated largely by feeding small meals 4 to 6 times throughout the day.[67,68] Thus more frequent feeding causes less perturbation of body fluids and likely has a protective effect against development of some forms of colic.

Although balance of daily water intake and outputis critical for maintenance of homeostasis, it warrants mention that equids tolerate water deprivation well.[69–75] For example, after horses were deprived of water for72 hours (which resulted in body weight loss in excess of 10%), most of the weight lost (90% of which was assumed to be water) was recovered within the first hour of being provided access to water.[72] Similarly, even greater body weight losses (approaching 20%) induced by water deprivation and desert walking in donkeys and burros were replaced largely within the first few minutes after water was provided.[70,71] Thus in

terms of water balance, equids (especially donkeys and burros) truly can be considered desert-adapted animals.[75,76] An important reason for their ability to tolerate water deprivation appears to be a substantial intestinal reserve of water and electrolytes that they call on during periods of dehydration for the maintenance of plasma volume.[77,78] Despite rapid fluid replacement by equids that have been dehydrated by water deprivation, horses that become dehydrated because of prolonged exercise or diarrheal disease (colitis) often do not drink. This behavior can be attributed to the fact that these conditions produce loss of body water and osmoles in the form of sweat or diarrhea. As a result, plasma osmolality does not increase and osmotic thirst stimulus is not produced. In human endurance athletes this state of mild to moderate dehydration that does not induce thirst has been called "voluntary" and "involuntary" dehydration,[79,80] and although less well-documented, a similar response appears to occur in endurance horses.[81] Another form of involuntary dehydration, which may be accompanied by increases in plasma osmolality and protein concentration, also has been described anecdotally in mares after foaling.

17.2.2.3 ELECTROLYTE BALANCE

Intake and loss of electrolytes also must be matched appropriately to maintain body content of electrolytes within narrow ranges. This balance is most important for the exchangeable ions (Na^+,K^+, and Cl^-) because these have minimal tissue (skeletal) reserves that can be called on during times of need. An exception is the fluid and electrolyte reserve in the lumen of the gastrointestinal tract, which may be able to provide replacement of 10% or more of the body content of these electrolytes.[78] Three sources provide electrolytes: feed, water (usually minimal amounts), and a number of dietary supplements. Electrolytes also can be lost by three routes: in urine, in feces, and in sweat (insensible losses; see Table 17.2-3). Investigations of electrolyte balance have revealed that most horses that eat predominantly hay or pasture grass ingest excess potassium and chloride. In contrast, sodium intake varies and with some diets may be marginal.[38,40,41] A maintenance requirement for sodium of 0.4 to0.8 mEq/kg/day or 200 to 400 mEq per day (6 to 12 g per day) for a 500-kg horse has been suggested[41,57]; however, exercising horses that may lose 500 to 1000 mEq of sodium per hour in sweat or are treated with furosemide have greater dietary requirements to replace such losses.[40] Thus addition of 50 to 75 g of common table salt (which provides 850 to 1275 mEq, because 1 g NaCl provides ≈17 mEq Na^+) is a safe and economical method of providing daily supplemental sodium and chloride to athletic horses.

The data from the water and electrolyte balance studies performed by Tasker[38] and by Groenendyk, English, and Abetz[41] (see Table 17.2-3) provide a good illustration of the capacity of the equine kidneys to conserve sodium when dietary intake is low (see Tasker's data at top) compared with when intake is unlimited (see
Groenendyk, English, and Abetz's data at bottom). Furthermore, these studies demonstrate that urinary 1189
excretion is the major route for loss of potassium and chloride. Although dietary intake of potassium is 1190
usually excessive, equine kidneys do not appear to have a great capacity to conserve potassium during periods of food and water deprivation or with anorexia associated with disease.[38,40,80] Thus urinary potassium concentration and total excretion can remain substantial in the face of decreased intake. Consequently, with decreased feed intake horses can develop significant total body potassium depletion and often benefit from supplemental dietary potassium (25 to 50 g per day of KCl provides 375 to 750 mEq, because 1 g KCl provides ≈15 mEq K^+).

In horses the stimuli for electrolyte intake (salt appetite) have received much less attention than stimuli for drinking. Houpt, Northrup, Wheatley, et al. found that horses that had marginal sodium intake (250 mEqper

day) and that were treated with furosemide ate more salt in the hours after treatment than did placebo-treated horses on the same diet[57]; however, salt intake (which was comparable for eating salt from a block or drinking a 0.9% sodium chloride solution) was excessive in both treatment groups (in excess of 100 g). Thus salt appetite, unlike water intake, is less closely regulated to balance intake with losses. In fact, when salt is available ad libitum, horses appear to consume more than their maintenance needs. The excess is eliminated by increased urinary sodium excretion. Although this apparently excessive salt appetite may seem inappropriate, one could consider it advantageous for exercising horses, which have a much greater daily salt requirement.[82]

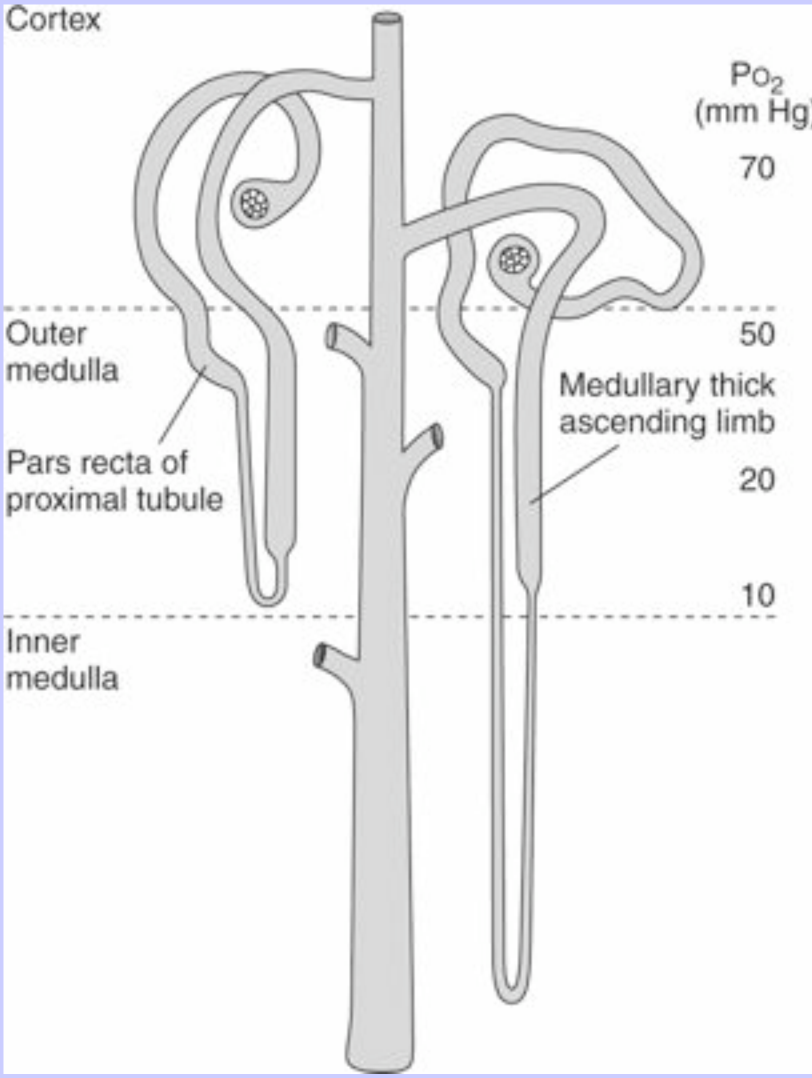
17.2.3 Renal Regulation of Body Water Content and Ion Composition

The kidneys are the organs responsible for fine tuning body water content and ion composition within narrow ranges. The important components of renal regulation of water and ion content include renal blood flow, glomerular filtration, and tubular modification of glomerular filtrate to produce the final urine.

17.2.3.1 RENAL BLOOD FLOW

At rest, the kidneys receive about 15% to 20% of the cardiac output, or about 7.5 to 10 L per minute for an average-size horse.[83,84] This high tissue perfusion, 500 to 600 ml/min per 100 g of kidney compared with 50 to 100 ml/min per 100 g of brain tissue, is necessary for the kidney to function as an effective filter and as a regulator of extracellular fluid composition. Furthermore, tubular reabsorption of glomerular filtrate requires energy. Because more than 99% of the filtrate is reabsorbed, the metabolic rate of the kidney is high (second only to that of the heart), and despite the fact that the kidneys account for less than 1% of body weight, they are responsible for about 10% of whole body oxygen use.[85] Next, RBF is distributed preferentially to the renal cortex. In fact, renal medullary blood flow, which is derived largely via the vasa recta that arise from the efferent arterioles of juxtamedullary glomeruli, accounts for less than 20% of total RBF.[84] Consequently, the renal medullary tissue normally functions in a hypoxic environment. Medullary hypoxia has been described as “an inevitable accompaniment of efficient urinary concentration” as a consequence of countercurrent exchange.[86] Although the latter mechanism would suggest that oxygen tension should decrease progressively toward the inner medulla, the lowest values, often no greater than 10 mm Hg, are found in the inner portion of the outer medulla, termed the *inner stripe* (Figure 17.2-1).[87] This finding can be explained by the substantial metabolic activity of epithelial cells lining the medullary thick ascending limb (mTAL) of the loop of Henle in the inner stripe. The sodium-potassium-adenosinetriphosphatase pumps (Na^+,K^+-ATPase) in the basal membrane of these cells are responsible for the greatest ATP use (and thereby oxygen consumption) in the medulla.[88] The combined effects of low oxygen delivery and a high rate of use 1190
produce the lowest oxygen tension in the inner stripe. Fortunately, several “protective” mechanisms exist to 1191
preserve medullary blood flow and tissue oxygenation during periods of renal hypoperfusion and include a preferential reduction in cortical blood flow along with redistribution of renal blood flow to the corticomedullary region, accumulation of adenosine with depletion of ATP, and production of prostaglandins (PGE_2 and PGI_2) and nitric oxide.[86–88] Of clinical importance is that the use of nonsteroidal antiinflammatory drugs in patients with poor renal perfusion can exacerbate tissue hypoxia because PGE_2 acts as a vasodilator and an inhibitor of Na^+,K^+-ATPase. In fact, the earliest lesions of analgesic nephropathy include degeneration and necrosis of mTAL cells before development of overt papillary necrosis.[88]

Figure 17.2-1 Schematic drawing of a nephron: in the outer medulla is the site of lowest intrarenal oxygen tension *(Po_2)* in the final *(straight)* portion of the proximal tubule and the medullary thick ascending limb of Henle's loop. Limited medullary blood flow and high metabolic rates make these outer medullary nephron segments the most susceptible to damage during periods of renal hypoperfusion.



Renal blood flow of horses has been measured bya variety of techniques including *p*-aminohippurate clearance (Cl_{PAH}, by classic clearance techniques involving timed urine collections and by plasma disappearance curves), clearance of radionuclides, microsphere injection, and use of ultrasonic Doppler flow

probes placed around the renal artery (Table 17.2-4).[83,84,89–105] The latter technique does not provide absolute blood flow values but rather measures changes in RBF from a baseline value.[102] Recently, plasma disappearance curves for ^{131}I-orthoiodohippuric acid and ^{99m}Tc-mercaptoacetyltriglycine have been validated in normal horses in an attempt to establish radionuclide techniques for rapid and noninvasive measurement of RBF in hospitalized horses.[100,105] Although values for RBF determined by these 1191
radionuclide techniques compared well with previous data (Table 17.2-5), their future use in a clinical setting 1192
likely will remain limited because of moderate expense and the need to perform serial measurements to provide clinically relevant information in patients with reduced renal function.[106]

TABLE 17.2-4 Reported Values for Effective Renal Plasma Flow and Renal Blood Flow in Horses and Ponies

NUMBER OF ANIMALS	METHOD[a]	EFFECTIVE RENAL PLASMA FLOW (MEAN ± SD/SE ml/min/kg [RANGE])	RENAL BLOOD FLOW (ml/min/kg)[b]	REFERENCE

8 ponies[e]	Microspheres	—	483 ± 79[f]	93
11 ponies[e]	Microspheres	—	670 ± 50[d, f]	94
3 horses (♀, ♂, and gelding)	Microspheres	—	535 ± 93[f]	99

9 horses[e]	Microspheres	—	589 ± 50[f]	101
4 gelding ponies	Microspheres	—	428 ± 49[f]	105

a $Cl_{Diodrast}$, Clearance of 3,5-diiodo-4-pyridine-N-acetic acid; $Cl131_{I\text{-}o\text{-}HA}$, clearance of ^{131}I-*o*-iodohippurate; Cl_{PAH}, clearance of *p*-aminohippurate; $Cl99_{mTc\text{-}MAG\text{-}3}$, $Cl99_{Tc\text{-}MAG3}$, clearance of ^{99m}Tc-mercaptoacetyltriglycine.

b Renal blood flow (RBF) values presented have been calculated from effective renal plasma flow (ERPF) data using extraction ratios (ERs) of 0.80 for diodrast and 0.91 for ^{131}I-*o*-iodohippurate and *p*-aminohippurate: RBF = (ERPF/ER)/(1-hematocrit); hematocrit was assumed to be 0.35.

c Other horses and ponies also were studied following bolus injection of ^{131}I-*o*-iodohippirate and yielded ERPF values of 16.93 ± 6.05 and 10.65 ± 2.73 ml/min/kg for ponies and horses, respectively; these values corresponded to a RBF of 8.6 ± 10.2 ml/min/kg in ponies and 18.0 ± 4.6 ml/min/kg in horses.

d Values estimated from figure.

e Sex not reported.

f Renal blood flow values for microsphere studies are expressed in units of milliliters per minute per 100 g of kidney tissue; a value of 500 ml/min/100 g would correlate to an RBF value of 18 ml/min/kg (or 3.6 and 9 L/min for a 200-kg pony and a 500-kg horse, respectively).

g Values reported are for ponies under general anesthesia (halothane in oxygen); these authors also reported that renal medullary blood flow was 2.6% to 18.8% of total RBF in two ponies.

	99mTc-diethylenepentaacetic acid determined by serial imaging at the body surface with a gamma camera.
b	Values taken from Knudsen.89
c	Values presented have been calculated from original data.
d	Low glomerular filtration rate (GFR) values were attributed to rapidly declining plasma inulin concentrations (nonsteady state conditions) during the urine collection periods.
e	Sex not reported.
f	Other horses and ponies also were studied following bolus injection of 125I-iothalamate and yielded GFR values of 5.39 ± 1.79 and 3.44 ± 1.11 ml/min/kg for ponies and horses, respectively.
g	Attempts at measuring GFR by plasma disappearance following bolus injection of inulin were unsuccessful.
h	Value presented is for control group; GFR was not different after phenylbutazone administration (1.36 ± 0.04 ml/min/kg) or phenylbutazone and furosemide administration (1.44 ± 0.12 ml/min/kg) but was reported to increase to 1.75 ± 0.16 ml/min/kg after water loading (25 L) and to 1.77 ± 0.18 ml/min/kg after water loading and phenylbutazone administration.
i	Ponies were anesthetized during the studies.
j	Mares studied before, during, and after 1.2 minimum alveolar concentration halothane anesthesia.
k	Value calculated from urinary clearance values for inulin and creatinine.
l	Despite correction for differences in depth (right kidney closer to lateral body surface than left kidney), the clearance of 99mTc-diethylenepentaacetic acid determined by serial imaging at the body surface with a gamma camera showed a greater (.60% total) GFR by the right kidney compared with the left kidney (.40% of total). Because similar differences have not been demonstrated in microsphere studies of renal blood flow (in which both kidneys receive equal blood flow), this technique requires further refinement before it can be used to provide accurate measures of GFR in horses.

Intrinsic and extrinsic factors play a role in the control of RBF. The former include autoregulation and action of renal nerves; the latter include vasoconstrictors (catecholamines, renin-angiotensin system, arginine vasopressin) and vasodilators (prostaglandins, dopamine, atrial peptides, bradykinin, adenosine, and nitric oxide).[107] Although not unique to the kidney, autoregulation of blood flow is a physiologic response that maintains cortical RBF in the normal range through a rather wide range of perfusion pressures (75 to 180 mm Hg in human beings). This response is thought to be independent of neural or hormonal mechanisms and is attributed to a myogenic response to changes in arterial wall tension. The local action of renal nerves or release of vasoconstrictor substances leads to an increase in renal vascular resistance that may occur in response to disease states (hypovolemic or endotoxic shock), drugs (particularly anesthetic agents), or physical stress (exercise). Renal blood flow may or may not decrease, depending on the degree of vasoconstriction. For example, renal vascular resistance increases during low-intensity exercise to divert a greater portion of the cardiac output to the working muscles. Thus the fraction of cardiac output delivered to 1192
the kidneys decreases; however, because cardiac output also increases in response to exercise, total RBF 1193
remains unchanged.[97] In contrast, during halothane anesthesia in ponies, redistribution of cardiac output occurs without an increase in cardiac output. Under these circumstances, renal vasoconstriction is accompanied by a decrease in renal blood flow to about 60% of the awake value at 1.0 to 1.5 minimal alveolar concentration of halothane. As the plane of anesthesia deepens (to 2.0 minimal alveolar concentration), a greater increase in renal vascular resistance (or degree of vasoconstriction) further

decreases RBF to about 25% of the awake value, likely because of further vasodilatation of other vascular beds and a mild decrease in cardiac output.[93] Although RBF was not measured, results of a recent study of prolonged (18 hours) anesthesia with sevoflurane are of interest in terms of probable renal hypoperfusion and damage.[108] After 10 hours of anesthesia an increase in urine production was accompanied by evidence of tubular dysfunction (e.g., glucosuria and enzymuria). Furthermore, microscopic lesions following anesthesia were limited to the more distal nephron (mTAL and distal tubule), providing support that these normally hypoxic nephron segments may be the first to succumb to prolonged hypoperfusion.

When RBF decreases, counteracting vasodilatory mediators usually are released in an attempt to ameliorate the decrease in RBF. The best studied of these vasodilatory mediators include renal prostaglandins (PGE_2 and PGI_2) and dopamine. Although the role of renal prostaglandins in the control of basal or resting RBF is thought to be insignificant, renal prostaglandins are important mediators of vasodilatation in response to a number of vasoconstrictive stimuli.[109] Furthermore, production of renal prostaglandins is several times
greater in medullary tissue, so that action of these mediators leads to a greater increase in inner cortical 1193
(region of juxtamedullary glomeruli) and medullary blood flow. As mentioned previously, one should not be 1194
surprised that the lesion associated with antagonism of prostanoid production by use of nonsteroidal antiinflammatory drugs is medullary or papillary necrosis.[110,111] With or without renal vasoconstriction, activation of dopamine receptors (DA_1 type) leads to renal vasodilatation. Because the receptors are located on most renal arterioles, blood flow increases in the renal cortex and the medulla. For this reason, dopamine infusions are touted to be of benefit in treating acute renal failure because this catecholamine has been shown to increase RBF and urine output by 30% to 190% in normal horses.[102]

17.2.3.2 GLOMERULAR FILTRATION

Approximately 20% of the blood entering the glomeruli passes through small pores in the filtration barrier into Bowman's capsule. The primary force driving filtration is glomerular capillary transmural hydraulic pressure. A relatively constant pressure across the glomerular capillary wall is maintained by greater resistance in the arteriole leaving the glomerulus (efferent arteriole) than in the arteriole entering the glomerulus (afferent arteriole). This difference in vascular resistance generates the hydraulic pressure that forces plasma water out of the glomerular capillaries.[112] The filtration barrier is made up of three layers: endothelium of the glomerular capillaries, basement membrane, and foot processes of the epithelial cells (podocytes) lining Bowman's capsule. The pore size of the filtration barrier, about 8 to 10 nm in diameter, prevents filtration of cells and larger proteins. As a result, the fluid that enters Bowman's capsule is an ultrafiltrate that is essentially identical to plasma except that it has less than 0.05% of the protein content of plasma. Interestingly, the diameter of albumin is about 6 nm, so its size should not prevent filtration. Glycosaminoglycans containing heparan sulfate and sialic acid residues impart a significant negative charge to the filtration barrier. Thus charge repulsion of albumin (which is similarly negatively charged) may be more important than molecular size in preventing significant loss of albumin into the filtrate; however, metabolic disturbances (metabolic acidosis) can neutralize the glomerular charge barrier, and one can observe transient proteinuria in the absence of structural damage to the glomerular barrier.[113]

By definition, *glomerular filtration rate (GFR)* is the volume of plasma filtered per unit of time and commonly is described in milliliters per minute per kilogram of body mass. The GFR of horses and ponies ranges from 1.6 to 2.0 ml/kg/min, with some authors reporting slightly higher values for ponies. This range is similar to those of other animals and human beings. For a 500-kg horse this value equals 800 to 1000 ml per minute or about 1200 to 1400 L per day. This value represents filtration of the total plasma volume 60 to 70

times per day. Because urine production is about 10 L per day, more than 99% of the glomerular filtrate is reabsorbed.

Like RBF, GFR has been measured in horses bya variety of techniques, including Cl_{In} (by classic clearance techniques), Cl_{Cr}, and clearance or plasma disappearance of radionuclides (see Table 17.2-5).* Plasma disappearance curves for ^{99m}Tc-diethylenetriaminopentaacetic acid (^{99m}Tc-DTPA) have been documented to compare well in normal horses with Cl_{In} (the gold standard).[100] Although this technique is less expensive than ^{131}I-orthoiodohippuric acid clearance for estimating RBF,[106] clinical use is limited by availability of nuclear medicine capabilities and expense (because one must take multiple measurements to assess disease progression or response to treatment). Recently, Gleadhill, Marline, Harris, et al. described use of a three blood sample technique to estimate GFR by plasma disappearance of ^{99m}Tc-DTPA.[124] Interestingly, rather than expressing GFR on the basis of per kilogram of body mass or a body surface area, they suggested that GFR should be compared with extracellular fluid volume. Because one also can use plasma activity of ^{99m}Tc-DTPA to estimate extracellular fluid volume, one can make this estimate of GFR using ^{99m}Tc-DTPA alone. Standardization of GFR based on extracellular fluid volume is attractive and warrants further consideration because it eliminates the effect of variable body composition (e.g., specifically differences in body fat) when expressing GFR based on body mass. The authors subsequently used this method to estimate the decrease in GFR accompanying exercise.[125]

The mechanisms responsible for control of RBF (autoregulation, neural input, hormonal factors) also play a role in control of GFR. In addition, GFR is affected further by factors such as plasma protein concentration (oncotic pressure) and alterations in the filtration barrier. As discussed previously, a balance exists between that action of vasoconstrictor and vasodilator substances during periods of decreased RBF. Interestingly, GFR decreases less than RBF with moderate to severe renal vasoconstriction. This sparing effect on GFR has long been attributed to greater vasoconstrictive effects of angiotensin II on efferent arterioles compared with afferent arterioles.[126] Such a response could increase the glomerular capillary transmural hydraulic pressure driving filtration and would be manifested by an increase in filtration fraction. In fact, the latter response hasbeen documented in exercising horses.[97] More recently, however, other vasoconstrictors (endothelins) and vasodilators (endothelium-derived relaxing factors, nitric oxide) have been shown to play a role in the 1194
control of glomerular capillary hemodynamics and filtration, so that a singular role for angiotensin II is likely 1195
an oversimplified explanation for the sparing effect on GFR.[127]

17.2.3.3 RENAL TUBULAR FUNCTION

Once the glomerular filtrate enters the renal tubule, it is modified extensively in the process of becoming the final product excreted into the renal pelvis. A complete review of renal tubular function is beyond the scope of this text; however, a few general concepts warrant mention, and a number of specific aspects are addressed elsewhere in this chapter. First, most glucose, amino acid, electrolyte, and water reabsorption occurs across epithelial cells lining the proximal tubule; however, these substances arenot all reabsorbed to the same extent. For example, this tubule segment is responsible for reabsorption of essentially all filtered glucose and amino acids, about 90% of filtered bicarbonate, about 70% of filtered sodium, and about 60% of filtered chloride.[128] Furthermore, at the end of the proximal tubule fluid is no more concentrated than it was in Bowman's space. Tubular sodium concentration is unchanged, whereas tubular chloride concentration actually has increased (because of preferential bicarbonate reabsorption). Despite limited modification of

these tubular fluid components, net reabsorption of between 60% and 80% of the total filtered load of sodium, chloride, and water occurs within the proximal tubule. Proximal tubular epithelial cells are also responsible for secretion of ammonium ions and a number of organic anions and cations, as described previously.

Tubular fluid passing into the loop of Henle becomes progressively more concentrated (hypertonic) as it travels to the inner medulla because the descending limb is permeable to water, urea, and electrolytes (the latter to a lesser degree).[129] In contrast, the ascending limb is relatively impermeable to water but actively reabsorbs sodium, chloride, and potassium via the apical $Na^+/K^+/2Cl^-$ cotransporter (blocked by furosemide), which is coupled to Na^+,K^+-ATPase on the basolateral membrane. As a result, fluid leaving this nephron segment is actually less concentrated (hypotonic) than the original filtrate. The loop of Henle is responsible for reabsorption of an additional 15% to 20% of filtered sodium and chloride, along with addition of urea to the tubular fluid. More important, Henle's loop is responsible for generation of the medullary osmotic gradient via countercurrent multiplication. This function results from the combined effects of different permeability characteristics of the descending and ascending limbs of the loop of Henle and active removal of sodium and chloride in the ascending limb.

The distal tubule is quantitatively less important in reabsorption of electrolytes and water; however, the distal tubule is the nephron segment in which the final qualitative changes in urine occur.[130] For example, the distal tubule is an important site of calcium, potassium, and acid excretion. The latter two typically are exchanged for sodium under the influence of aldosterone. Tubule fluid passes from the distal tubule into the outer or cortical collecting ducts, which are impermeable to urea. In addition to further modification of fluid in the cortical collecting ducts, tubular urea concentration increases steadily as water is removed (under the influence of vasopressin) as fluid travels to the inner medulla. In contrast, in the absence of vasopressin (as with diabetes insipidus), the collecting ducts are impermeable to water and produce hypotonic urine. The collecting ducts remain impermeable to urea (which accounts for up to 50% of the osmoles in urine) except for the innermost medullary segments, which allow urea to be recycled into the interstitium for maintenance of the medullary osmotic gradient.

Reabsorption of glomerular filtrate by renal tubules requires a close association with the vascular system that carries reabsorbed solute and water to the circulation. Proximal tubules are adjacent to peritubular capillaries, which have a tremendous capacity to accommodate the massive flux of solute and water across proximal tubule epithelial cells. Equally important in maintenance of the medullary osmotic gradient are the vasa recta, hairpin capillaries that travel deep into the renal medulla in association with loops of Henle derived from the population of juxtamedullary nephrons. Blood flow through these capillaries is typically slow, allowing for countercurrent exchange of solute in the medullary interstitium, which is necessary for generation and maintenance of medullary hypertonicity. Urea leaving the descending limb of Henle and being recycled across the innermost portion of the medullary collecting duct is responsible for about half of this medullary hypertonicity.

These basic aspects of tubular function have a number of important clinical implications. First, proximal tubule epithelial cells have a high metabolic rate. Although most of the proximal tubule is in the more highly perfused renal cortex, renal hypoperfusion leads to a relative hypoxia surrounding these cells because of ongoing metabolic activity. Consequently, the proximal tubule is highly susceptible to injury when cortical blood flow is reduced (e.g., with hypovolemia or other states accompanied by a decrease in RBF). Second, as discussed before, the renal medulla receives only a small fractionof the total RBF, leading to a normally hypoxic local environment. Thus any degree of renal hypoperfusion also is accompanied by exacerbation of medullary hypoxia, especially in the inner stripe because of the metabolic activity of epithelial cells lining

the mTAL. In fact, in cases of acute renal failure in human beings, histologic examination of renal tissue 1195
actually may show more severe lesions in the more distal nephron (mTAL) rather than in the proximal 1196
tubule.[131] Recognition of this more distal tubular damage has also led to consideration of therapeutic interventions to reduce damage to this nephron segment during periods of poor renal perfusion (e.g., continuous infusion of furosemide to decrease the metabolic activity of the mTAL). Third, despite the fact that the distal tubule and collecting ducts are responsible for reabsorption of less than 5% of the total glomerular filtrate, a decrease in reabsorption of only 1% to 2% can be quantitatively significant and can lead to dramatic polyuria (see Chapter 17.9). Next, generation of a maximal medullary concentration gradient requires slow flow of tubular fluid for countercurrent multiplication and slow flow of blood through the vasa recta to maximize countercurrent exchange. Thus conditions that increase tubular flow rates (high-volume intravenous fluids) or increase vasa recta blood flow (endogenous PGE_2 and PGI_2 production consequent to renal hypoperfusion) compromise the medullary concentration gradient (partial medullary washout) and lead to production of more dilute urine with increased urinary sodium concentration (and excretion).

A final aspect of tubular function that appears to be unique to horses among the domestic species is excretion of calcium. Equine urine is well recognized as being cloudy and viscid. These qualities can be attributed to the large amount of calcium excreted in normal equine urine, largely in the form of calcium carbonate crystals, and mucus secreted by glands in the renal pelvis and proximal ureter that acts to “lubricate” the lower urinary tract to minimize adherence of crystal to the epithelium lining the ureters, bladder, and urethra. Although the nature of this unique tubular calcium excretion has been studied little in horses, one report of the role of vitamin D in calcium and phosphorous homeostasis in horses suggested that this vitamin/hormone was less important in horses than in other species.[132] This fascinating difference between horses and other species evaluated by large animal internists clearly warrants further investigation.

17.2.3.4 EXCRETION OF SOLUTE AND WATER

Renal function traditionally is thought of in terms of glomerular filtration, tubular modification of the filtered fluid, and excretion of the final urine. This concept accommodates excretion of nitrogenous and organic wastes and the major aspects of regulation of body water content and ionic balance. Urine concentration and volume also are affected by solute excretion, and another way to think about renal function is in terms of total solute and water excretion. For example, a horse could produce 6 L of urine daily with an osmolality of 900 mOsm/kg to excrete 5400 mOsm of solute or, if the solute load were doubled to 10,800 mOsm, the horse could produce 12 L of urine with an osmolality of900 mOsm/kg to eliminate the additional solute. Thus urine osmolality reflects the ability of the kidney to dilute or concentrate the final urine but does not necessarily provide an accurate estimate of the “quantitative ability” to excrete solute or retain water. One assesses these functions by calculating the osmolal (C_{osm}) and free water clearances (C_{H2O}).[133] Like other clearances, these calculations require measurement of urine flow (via timed urine collection) and measurement of plasma and urine osmolality.

These measures of renal solute and water handlingare conceptualized by considering urine to have two components: (1) that which contains all the urinary solute in a solution that is isosmotic to plasma (C_{osm}, usually expressed in milliliters per minute or liters per day), and (2) that which contains free water without any solute (C_{H2O}, also expressed in milliliters per minute or liters per day). The sum of these two components is the actual urine flow rate in milliliters per minute or liters per day. Because urine is typically more concentrated than plasma, C_{H2O} typically has a negative value, indicating water conservation. In fact, the inverse of free water clearance is termed *renal water reabsorption*. Returning to the foregoing example,

excretion of the 5400 mOsm would require production of 18 L of urine that is isosmotic with plasma (using a value of 300 mOsm/kg for plasma). However, because 6 L of concentrated urine actually was produced during the period measured, the kidneys quantitatively have reabsorbed 12 L of free water per day. In contrast, despite production of urine with an identical urine osmolality (900 mOsm/kg), excretion of 10,800 mOsm would require production of 36 L of urine isosmotic with plasma. Free water clearance would be 30 L per day (i.e., 30 L per day of free water would be reabsorbed by the kidneys). Thus although concentrated urine always will have a negative C_{H2O} value, indicating renal water reabsorption, and dilute urine always will have a positive value for C_{H2O}, indicating renal water excretion, quantitative assessment of renal solute and water handling requires measurement of osmolal and free water clearances.

Excretion of free water by the kidney occurs by generation of hypotonic tubule fluid in the ascending limb of Henle's loop, and the amount or volume of free water produced depends on the amount of tubule fluid presented to that segment. Free water consequently is excreted by keeping the collecting ducts relatively impermeable to water (lack of vasopressin). Assessment of C_{H2O} is most helpful in patients with hyponatremia and hypoosmolality that cannot be attributed to another primary disease process (diarrhea or bladder rupture). For hyponatremia to develop, water excretion must be defective. For example, 1196
hyponatremia can develop with prerenal failure (hypovolemia) or with oliguric renal failure following a 1197
reduction in GFR and the amount of filtrate presented to the loop of Henle. Hyponatremia and hypoosmolality may also develop with use of loop diuretics because less free water is generated in the ascending limb of Henle's loop because of blockade of the apical $Na^+/K^+/2Cl^-$ cotransporter (smaller amounts of solute are removed). A final cause of true hyponatremia may be the syndrome of inappropriate vasopressin secretion or syndrome of inappropriate antidiuretic hormone secretion. Although the latter condition has not been documented in horses, occasionally it may play a role in the development of hyponatremia in a foal.[134]

17.3 17.3—Examination of the Urinary System

Harold C. Schott, II

17.3.1 History and Physical Examination

To begin the evaluation of a horse with urinary tract disease, one should collect a complete history and perform a thorough physical examination. Important historical information includes duration and type of clinical signs, number of horses affected, diet, medications administered, and response to treatment. One also should assess water intake and urine output. For example, owners may mistake pollakiuria (frequent urination) for polyuria (increased urine production), and distinguishing between the two is helpful for forming a diagnosticplan. Pollakiuria frequently occurs in females during estrus or in either sex of horse with cystic calculi or cystitis. In contrast, polyuria more often accompanies renal disease, pituitary adenoma, behavior problems (primary polydipsia), diabetes insipidus, or diabetes mellitus. Astute owners may note increased thirst after exercise or a change in urine character, such as a clearer stream, to support polydipsia and polyuria.

One can determine water intake over 24 hours by turning off any automatic watering devices and providing a known volume of water to the horse.[1] Water intake can vary widely with environmental conditions, level of activity, and diet (see Chapter 17.2), so that repeated measurements over several 24-hour periods may be more rewarding in documenting average daily water consumption. Urine output, which should range between 5 and 15 L in a horse with normal renal function, is more difficult to determine. One can apply a urine collection harness for 24-hour urine collections[2–5]; alternatively, one can use an indwelling Foley catheter attached to a collection apparatus to quantify urine output in mares. Although horses used for research tolerate these devices fairly well, the devices have limited application to clinical patients. One can construct a practical collection device for geldings and stallions by cutting off the bottom of a large plastic bottle, padding it, and fitting it over the prepuce. One covers the opening of the bottle with a rubber tube and clip, and one can remove urine every few hours.[6] During the collection period, horses usually are tied or restrained in stocks to minimize interference with the collection device.

The most common presenting complaints for horses with urinary tract disease are weight loss and abnormal urination. Other clinical signs vary with the cause and site of the problem and may include fever, anorexia, depression, ventral edema, oral ulceration, excessive dental tartar, colic, or scalding or blood staining of the perineum or hindlegs. Although lumbar pain and hindlimb lameness have been attributed to urinary tract disease, a musculoskeletal problem is the usual cause of these clinical signs. Decreased performance may be an early presenting complaint for renal disease, but poor performance likely results from changes associated with uremia (mild anemia and lethargy) rather than from renal pain. Occasionally a horse with urolithiasis or renal neoplasia may have a history of recurrent colic. Prolonged or repeated posturing to urinate and dysuria or

hematuria would be important findings to implicate the urinary tract as the probable source of abdominal painin such patients.

In addition to a thorough physical examination, one should include rectal palpation in the evaluation of all horses with suspected urinary tract disease. One should palpate the bladder to determine size, wall thickness, and presence of cystic calculi or mural masses. If the bladder is full, one should palpate the bladder again after bladder catheterization or voiding. One can palpate the caudal pole of the left kidney for size and texture. The ureters generally are not palpable unless enlarged or obstructed by disease, but one should palpate the dorsal abdomen (retroperitoneal course of ureters) and trigone to determine if they are detectable. Dilation of a ureter may occur with pyelonephritis or ureterolithiasis, and in mares palpation of the distal ureters through the vaginal wall may be more rewarding. One also should palpate the reproductive tract to assess whether a reproductive problem could be causing the clinical signs.

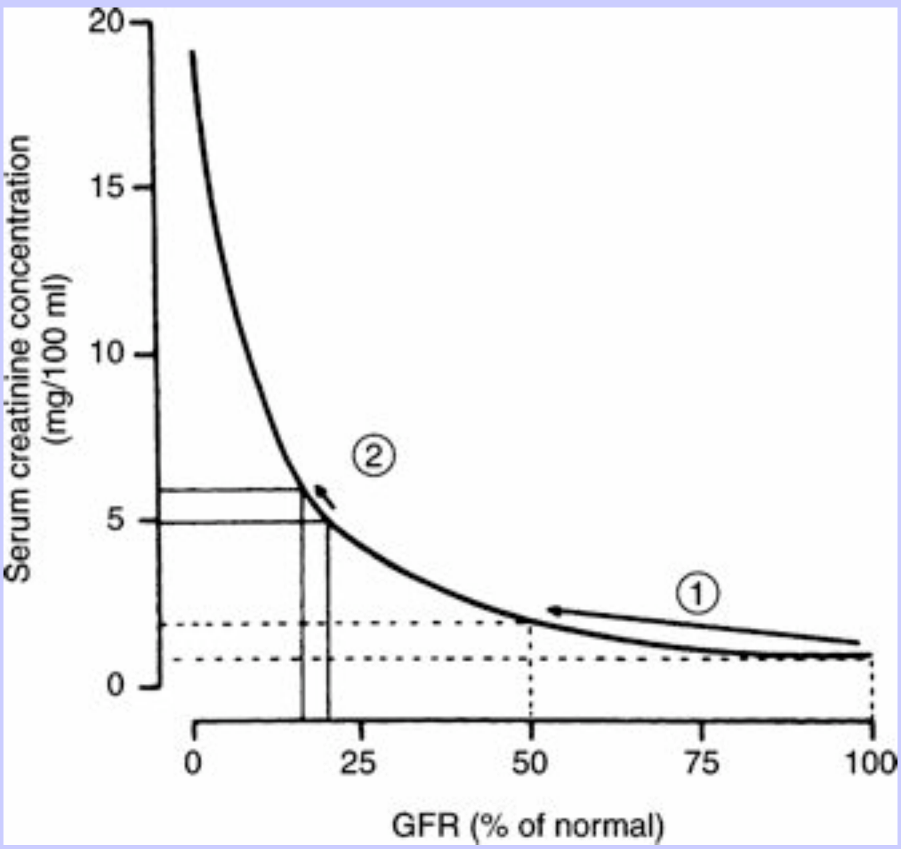
17.3.2 Hematology and Serum Biochemistry

A complete blood count that reveals an elevated white blood cell count and total protein or fibrinogen concentration would support an inflammatory or infectious disease process. One may observe mild anemia (packed cell volume 20% to 30%) consequent to decreased erythropoietin production and a shortened red blood cell life span in horses with chronic renal failure.

Blood urea nitrogen (BUN) and serum creatinine (Cr) concentrations are the most commonly used indexes of renal function, specifically glomerular filtration rate (GFR).[7–9] One must remember that BUN and Cr do not increase until the majority of nephrons (generally considered about 75%) become nonfunctional.[10] Although this commonly used percentage is based on studies of partially nephrectomized laboratory animals, several clinical reports in which unilateral nephrectomy was used successfully to manage disorders of the upper urinary 1200
tract support a similar renal reserve capacity in horses.[11–15] In addition, renal function remained within normal 1201
ranges and animals maintained body weight after experimental unilateral nephrectomy in ponies[16] andin horses (R. DeBowes, personal communication, 1991). Thus measurement of BUN and Cr is of little use in evaluating early or minor changes in GFR. Once elevated, however, small increases in BUN and Cr are more sensitive indicators of further deterioration in GFR, for one can intrepret doubling of BUN or Cr as a 50% decline in remaining renal function (Figure 17.3-1).

One can measure urea by a variety of methods that are categorized broadly as direct or indirect analyses.[7,8] The direct method is the diacetyl monoxime reaction, in which urea reacts with diacetyl after hydrolysis of diacetyl monoxime to diacetyl and hydroxylamine. One determines urea concentration spectrophotometrically by measuring the yield of the yellow diazine reaction product. Indirect analysis is based on enzymatic conversion of urea to ammonia and carbonic acid by urease. Several methods exist for subsequently determining ammonia concentration, and the one used most often is the enzyme-coupled reaction with glutamate dehydrogenase. Although the term "*blood* urea nitrogen" is widely accepted, one must remember that the actual measurement reported is the urea concentration in serum or plasma.

Figure 17.3-1 Relationship between glomerular filtration rate *(GFR)* and serum creatinine. When renal function is normal, a large decrease in glomerular filtration rate (as with acute renal failure) results in a minor increase in serum creatinine *(arrow 1)*. In contrast, when renal function is decreased (as with chronic renal failure), a much smaller decrease in glomerular filtration rate results in a similar increase in serum creatinine *(arrow 2)*. (From Brezis M, Rosen S, Epstein FH: Acute renal failure. In Brenner BM, Rector FC, editors: *The kidney*, ed 4, vol 1, Philadelphia, 1991, WB Saunders.)



One also can assay Cr by several methods, but the one used most often is the Jaffe's reaction, which is a colorimetric assay based on the formation of a complex between creatinine and alkaline picrate.[7–9] Unfortunately, a number of other substances in plasma or serum contribute to the yellow color, which leads to a 20% overestimation of actual Cr in human beings and in horses.[17] These noncreatinine chromagens include glucose, pyruvate, acetoacetate, fructose, uric acid, and ascorbic acid. Interference by noncreatinine chromagens is greatest when Cr is in the normal range, which leads to a high coefficient of variation in repeated

measurements of the same sample. With azotemia, Cr measurement by the Jaffe's reaction becomes more accurate because the contribution from noncreatinine chromagens does not increase significantly (noncreatinine chromagens are responsible for less than 5% of the color development when Cr is greater than 5.0 mg/dl). Noncreatinine chromagens do not interfere significantly with urine Cr measurement.

In addition to the factors discussed in the preceding section that influence urea and creatinine metabolism (see Chapter 17.2), spurious increases in Cr may be reported in various metabolic disorders or after administration of certain cephalosporin antibiotics.[8] When such increases in Cr are thought to be factitious, one can measure *true* Cr by several methods, which include use of an automated analyzer that distinguishes creatinine and noncreatinine chromagens by their different rates of color development or performance of the creatinine imidohydrolase enzyme assay. The latter yields ammonia, which can be quantified by colorimetric methods. As an example, Cr measured by the Jaffe's reaction increased 16% after horses were fasted for 3 days; however, when serum was analyzed by the enzymatic method, no increase in Cr was detected.[17] In addition to spurious increases in Cr, other substances can cause spurious decreases in serum Cr. The most common one is bilirubin, which, when greater than 5.0 mg/dl, may decrease measured Cr by 0.1 to 0.5 mg/dl.[8]

The reporting of serum or plasma urea and creatinine concentrations also varies between different countries. In the United States, BUN and Cr are reported in milligrams per deciliter, whereas in other parts of the world they are reported in standard international units of millimoles per liter and micromoles per liter, respectively. One can convert BUN from milligrams per deciliter to millimoles per liter and Cr from milligrams per deciliter to micromoles per liter by multiplying by 0.357 and 88, respectively.[8]

Azotemia is the term used to describe an elevation in BUN and Cr; thus it is strictly a laboratory abnormality. 1201
Azotemia can be prerenal in origin, because of decreased renal perfusion; may be attributable to primary renal 1202
disease; or may accompany obstructive diseases or disruption of the urinary tract (postrenal azotemia).[10,18] Thus one should interpret BUN and Cr in light of hydration status of the patient, presenting complaint, and physical findings. In general, animals with prerenal azotemia tend to have smaller increases in BUN and Cr than animals with intrinsic renal failure, whereas animals with postrenal failure may have the greatest degree of azotemia.[19] Unfortunately, BUN and Cr can cover a wide range of values for all three categories of azotemia; thus specific ranges do not identify the type of azotemia.[19–22] In an attempt to characterize azotemia better, use of the BUN/Cr ratio also has been examined. In theory the ratio should be higher for prerenal azotemia (because of increased reabsorption of urea with low tubule flow rates) and postrenal azotemia (because of preferential diffusion of urea across peritoneal membranes in cases of uroperitoneum) than for azotemia associated with intrinsic renal failure. As for categoric values for BUN and Cr, BUN/Cr ratios measured in azotemic dogs with naturally occurring diseases were distributed over wide, nondiscriminatory ranges for all three types of azotemia.[19,20] In horses the BUN/Cr ratio more often has been used to separate acute renal failure from chronic renal failure. In the acute form of renal failure, Cr tends to increase proportionately more than BUN, leading to a BUN/Cr ratio of lessthan 10:1.[23] In contrast, with chronic renal failure, the BUN/Cr ratio often exceeds 10:1. Although a clear explanation for this difference has not been established, the difference may be related to different volumes of distribution for urea and creatinine. Urea, a nonpolar molecule, diffuses freely into all body fluids, whereas creatinine, a charged molecule, likely requires longer to diffuse out of the extracellular fluid space. Thus a sudden decrease in renal perfusion leads to a greater increase in Cr than in BUN. Muscle breakdown or damage, as with rhabdomyolysis, may be an additional factor contributing to the rapid increase in serum Cr. Furthermore, the BUN/Cr ratio value provides only a suggestion of the duration of azotemia in horses, for one can find exceptions for acute and chronic renal failure. Finally, the BUN/Cr ratio

also may be useful in assessing adequacy of dietary protein intake in cases of chronic renal failure (see Chapter 17.5).[24]

The terms *prerenal azotemia* and *prerenal failure* describe the reversible increase in BUN and Cr associated with renal hypoperfusion.[10,18,22,25] Although these terms are entrenched firmly in human and veterinary medical literature, they likely contribute to the failure to recognize the renal damage that accompanies a number of medical and surgical conditions. Lack of recognition is attributable to the large renal functional reserve. In fact, in many cases of prerenal failure, one can demonstrate altered glomerular and tubule function by proteinuria and cast formation, impaired concentrating ability, and changes in electrolyte excretion.[26,27] Although such functional alterations are usually reversible, a degree of permanent nephron loss can occur and could explain the finding of microscopic evidence of renal disease in as many as one third of equine kidneys examined.[28] Thus considering prerenal failure as a transient and reversible period of compromised renal function that can lead to permanent but clinically silent decreased renal functional mass may be more appropriate. Furthermore, periods of decreased renal blood flow or prerenal failure are accompanied by a number of compensatory renal responses that are mobilized to preserve renal blood flow (autoregulatory response of the afferent arterioles) and GFR (increase in filtration fraction because of angiotensin II–mediated efferent arteriolar constriction). In addition, increased intrarenal production of vasodilatory prostaglandins (PGE_2 and PGI_2) is an important response to renal ischemia that maintains or even increases medullary blood flow (see Chapter 17.2). Thus one also can consider prerenal failure as a period of decompensation from the numerous renal compensatory responses to hypoperfusion.[29]

Prerenal azotemia traditionally is differentiated from intrinsic renal failure by assessing urinary concentrating ability. With prerenal azotemia, maintenance of urinary concentrating ability is demonstrated by a urine specific gravity greater than 1.020 and urine osmolality exceeding 500 mOsm/kg. In contrast, urinary concentrating ability typically is lost with intrinsic renal failure, and urine specific gravity and osmolality are less than 1.020 and 500 mOsm/kg, respectively, in the face of dehydration.[30] Such assessment is challenging, however, because it is valid only when performed on urine collectedbefore initiation of fluid therapy or administration ofany of a number of medications (α_2-receptor agonists, furosemide) that can affect urine flow and concentration.[31–34] In addition to these measures of urinary concentrating ability, urine/serum ratios of osmolality, urea nitrogen and creatinine concentrations, and fractional sodium clearance may provide useful information to differentiate prerenal azotemia from intrinsic renal failure (Table 17.3-1).[30,31] For example, urine/serum Cr ratios exceeding 50:1 (reflecting concentrated urine) and fractional sodium clearance values less than 1% (indicating adequate tubule function) would be expected in horses with prerenal azotemia, whereas ratios less than 37:1 and clearance values greater than 0.8% were reported in a group of horses determined to have primary renal disease.[30] Although these values can be helpful, the data in Table 17.3-1 illustrate that renal 1202
hypoperfusion is accompanied by a progressive loss of concentrating ability, because the ranges of these ratios 1203
tend to be lower for horses with prerenal azotemia than for clinically normal horses. Thus these data also support the concept that the progression from prerenal failure to intrinsic renal failure is associated with decompensation of the intrarenal responses to hypoperfusion.[29] Clinically, this decompensation is recognized as persistence of azotemia, whereas prerenal azotemia rapidly resolves(by 30% to 50% within 24 hours and completely by72 hours) in response to fluid therapy and other supportive treatments.

TABLE 17.3-1 Diagnostic Indexes That May Be Useful for Separating Prerenal From Renal Azotemia in Horses

DIAGNOSTIC INDEX	NORMAL HORSES	PRERENAL AZOTEMIA	RENAL AZOTEMIA
Urine osmolality (mOsm/kg)	727–1456	458–961	226–495
Uosm/Posm	2.5–5.2	1.7–3.4	0.8–1.7
UUN/PUN	34.2–100.8	15.2–43.7	2.1–14.3
UCr/PCr	2.0–344.4	51.2–241.5	2.6–37.0
FCl_{Na}	0.01–0.70	0.02–0.50	0.80–10.10

Modified from Grossman BS, Brobst DF, Kramer JW et al: Urinary indices for differentiation of prerenal azotemia and renal azotemia in horses, *J Am Vet Med Assoc* 180:284, 1982.

Uosm, Urine osmolality; *Posm,* plasma osmolality; *UUN,* urine urea nitrogen; *PUN,* plasma urea nitrogen; *UCr,* urine creatinine; *PCr,* plasma creatinine; FCl_{Na}, fractional sodium clearance.

In patients at risk for developing acute renal failure, including horses with serious gastrointestinal disorders, or rhabdomyolysis and in those receiving nephrotoxic medications, serial assessment of urine specific gravity or osmolality, sodium concentration, and fractional sodium clearance may be useful in identifying significant changes in renal function before the onset of azotemia. Similarly, if one determines urine flow rate during a timed urine collection period, assessment of renal water reabsorption (free water clearance; see Chapter 17.2) can be a sensitive predictor of impending renal failure.[35–37] Unfortunately, monitoring of these parameters often is complicated by use of intravenous fluid support in such patients. Although intravenous fluids can complicate interpretation of many of these indexes of renal function, Roussel, Cohen, Ruoff, et al.[31] found that the urine/plasma osmolality ratio remained greater than 1.7:1 in healthy horses receiving 20 L of an intravenous polyionic solution over 4 hours. Thus serial measurement of urine specific gravity or osmolality may provide useful information for patients at high risk for acute renal failure.

One usually suspects postrenal azotemia resulting from obstruction or disruption of the urinary tract based on clinical signs, including dysuria and renal colic. With bladder rupture, however, some affected foals and adult horses continue to void urine although progressive abdominal distention usually accompanies development of uroperitoneum. One most often confirms urinary tract disruption by measuring a twofold or greater value for peritoneal fluid creatinine concentration compared with serum creatinine concentration. Occasionally in a foal with a urachal problem or a gelding with a disrupted urethra, postrenal azotemia may be accompanied by considerable swelling in the abdominal wall or in the prepuce, respectively.

In addition to screening for azotemia and concentrating ability, the laboratory database should include serum electrolyte, protein (albumin and globulin) and glucose concentrations, and muscle enzyme activity.[8,18,21–25] Hyponatremia and hypochloremia are common in horses with renal disease. Serum potassium concentration may be normal or may be elevated in cases of acute or chronic renal failure. Hyperkalemia is often most extreme and most serious with urinary tract disruption and uroperitoneum. Calcium and phosphorus concentrations vary in horses with renal disease. Hypercalcemia and hypophosphatemia often occur in horses with chronic renal failure, especially when they are fed alfalfa hay (see Chapter 17.5), whereas hypocalcemia and hyperphosphatemia are more common with acute renal failure. With protein-losing glomerulopathies,

albumin tends to be lost to a larger extent than the higher-molecular-weight globulin. One can find low total protein and albumin concentrations in severe cases of chronic renal disease, whereas other horses may have an increased globulin concentration consistent with a chronic inflammatory response. Hyperglycemia (values greater than 150 to 175 mg/dl) following stress, exercise, sepsis, pituitary adenoma, or diabetes mellitus can result in glucosuria.[38,39] Finally, when pigmenturia is a complaint, muscle enzyme activity measurements are helpful in differentiating myoglobinuria from hematuria or hemoglobinuria.

17.3.3 Urinalysis

One should perform urinalysis whenever one suspects urinary tract disease. One can collect urine as a midstream catch during voiding, via urethral catheterization, or via cystocentesis in foals. Unlike cows, horses cannot be stimulated easily to urinate, but they often urinate within a few minutes after being placed in a freshly bedded stall. Manual compression of the bladder during rectal palpation may stimulate urination after the rectal examination is completed. One should evaluate color, clarity, odor, viscosity, and specific gravity at the time of collection.[40,41] Normal equine urine is pale yellow to deep tan and often is turbid because of the large amounts 1203
of calcium carbonate crystals and mucus. Urine appearance commonly changes during urination, especially 1204
toward the end of micturition, when more crystals tend to be voided. If pigmenturia or hematuria is present, noting the timing and duration of passage of discolored urine may help localize the source. Pigmenturia throughout urination is most consistent with myonecrosis or a bladder or kidney lesion, whereas passage of discolored urine at the start or end of urination more often occurs with lesions of the urethra or accessory sex glands (see Chapter 17.8).

17.3.3.1 ASSESSMENT OF URINE CONCENTRATION

Urine specific gravity is a measure of the number of particles in urine and is a useful estimate of urine concentration. Although determination of specific gravity with a refractometer is quick and easy (one should not use reagent strips to measure specific gravity in horses),[40] one must recognize that urine concentration is determined most accurately by measurement of urine osmolality because the presence of larger molecules in urine, such as glucose or proteins, leads to overestimation of urine concentration by assessment of specific gravity. Clinically, overestimation is a problem in patients with diabetes or heavy proteinuria.[42] Urine specific gravityis used to separate urine concentration into three categories: (1) urine that is more dilute than serum (hyposthenuria or specific gravity less than 1.008 and osmolality less than 260 mOsm/kg); (2) urine and serum of similar osmolality (isosthenuria or specific gravity of 1.008 to 1.014 and osmolality of 260 to300 mOsm/kg); and (3) urine that is more concentrated than serum (specific gravity greater than 1.014 and osmolality greater than 300 mOsm/kg). Althoughurine of most normal horses is concentrated (3 to 4 times more concentrated than serum with specificgravity of 1.025 to 1.050 and an osmolality of 900 to 1200 mOsm/kg), occasionally a normal horse produces dilute or highly concentrated urine. For example, in response to water deprivation of 24 to 72 hours' duration, horses with normal renal function often produce urine with a specific gravity greater than 1.045 and an osmolality greater than 1500 mOsm/kg.[43–45] In contrast, foals typically have hyposthenuric urine consequent to their mostly milk diet.[46] Although the constant polyuria decreases the ability of the neonate to generate a large osmotic gradient in the medullary interstitium, dehydrated foals still can produce urine with a specific gravity greater than 1.030. With chronic renal insufficiency the ability to produce concentrated (specific gravity greater than 1.025) or dilute (specific gravity less than 1.008) urine is lost. Thus horses with chronic renal failure typically manifest isosthenuria. As discussed previously, urine specific gravity is helpful in differentiating prerenal from renal azotemia in horses that exhibit dehydration or shock following a number of disorders.

17.3.3.2 REAGENT STRIP ANALYSIS

The pH of equine urine is usually alkaline (7.0 to 9.0).[40,41,47] Vigorous exercise or bacteriuria can resultin acidic pH. Bacteriuria can impart an ammonia odor to the urine secondary to breakdown of urea by bacteria with urease activity. Concentrate feeding generally decreases urine pH toward the neutral value.[47] Similarly, the more dilute the urine sample is, the closer the pHis to 7.0. The dilute urine produced by foals typically is neutral to mildly acidic and is relatively free of crystalline material. Interestingly, calcium oxalate crystals are more prevalent in urine of foals than in that of adults.[48] Occasionally, one detects aciduria in a dehydrated or anorectic horse. Although aciduria typically has been attributed to metabolic acidosis, many patients actually may have hypochloremic metabolic alkalosis accompanied by paradoxical aciduria. The mechanism for paradoxical aciduria is likely similar to that described in ruminants with abomasal outflow obstruction.[49] Briefly, after all chloride has been reabsorbed from the glomerular filtrate, further sodium reabsorption occurs by exchange with (excretion of) potassium or hydrogen ions. Thus paradoxical aciduria is most likely to occur with concomitant hypokalemia or whole-body potassium depletion.

Commercially available urine reagent strips can yield false-positive results for protein when one tests alkaline samples. Thus one can assess proteinuria better by performing the semiquantitative sulfosalicylic acid precipitation test or by specific quantification with a colorimetric assay (such as the Coomassie brilliant blue dye method[50] or other assays that are used routinely on cerebrospinal fluid). In normal mares a mean value of 3.2 mg/kg(1.6 g) per day and a range of 3.6 to 22.3 mg/kg(1.8 to 11.2 g) per day for urinary protein excretion have been reported by Schott, Hodgson, and Bayly[51] and by Kohn and Strasser,[52] respectively. These values translate into urinary protein concentrations of less than 100 mg/dl in most normal horses. Comparison of the quantitative protein result (milligrams per deciliter) to urine creatinine concentration (milligrams per deciliter) in the form of a urine protein/creatinine ratio also is recommended. This technique is more practical because it obviates timed urine collection. Although a normal range hasnot yet been reported for horses, values exceeding 1.0:1 and 3.5:1, respectively, are considered above normalfor dogs[53] and indicate nephrotic range proteinuria in human beings.[8] Thus a urine protein/creatinine ratio greater than 2:1 likely supports significant proteinuria in an equine patient. Proteinuria may occur with glomerular disease, bacteriuria, or pyuria or may transiently follow exercise.[51] 1204

1205 Normal equine urine should not contain glucose. Although the renal threshold for glucose has not been evaluated thoroughly in horses, an early study byLink suggested that the threshold may be lower (about 150 mg/dl) than that of small animals and human beings.[54] Thus glucosuria can accompany hyperglycemia associated with the causes described previously or with administration of dextrose-containing fluids or parenteral nutrition products.[38,39] In addition, glucosuria may accompany sedation with α2-agonists or exogenous corticosteroid administration.[32,33] When one detects glucosuria in the absence of hyperglycemia, one should suspect primary tubule dysfunction. Glucosuria more often has been detected in horses with acute renal failure (mostly in experimental models of nephrotoxicity) than in those with chronic renal disease. Unlike ruminants, ketones rarely are detected in equine urine, even in advanced catabolic states or with diabetes mellitus. A positive result for blood on a urine reagent strip can reflect the presence of hemoglobin, myoglobin, or intact red blood cells in the urine sample. Evaluation of serum for hemolysis and of urine sediment for red blood cells, combined with an ammonium sulfate precipitation test to detect myoglobin,[55] can be rewarding in differentiating between these pigments (see Chapter 17.8). Finally, occasionally one detects bilirubinuria on reagentstrip analysis of equine urine. Bilirubinuria is associated with intravascular

hemolysis, hepatic necrosis, and obstructive hepatopathies. In most instances, one more commonly detects hemolysis and hepatic disease by abnormal biochemical data such as elevated serum bilirubin concentration and increased hepatic enzyme activity.

17.3.3.3

SEDIMENT EXAMINATION

Sediment examination is probably the most underused diagnostic technique available for evaluation of urinary tract disorders in horses. In human beings, sediment examination has been demonstrated to be a useful predictor for occurrence and severity of acute renal failure.[56] Unfortunately, a major limitation is that one should examine sediment within 30 to 60 minutes after collection. To perform sediment examination, one centrifuges 10 ml of fresh urine (usually in a conical plastic tube) at 1000 rpm for 3 to 5 minutes. One discards the supernatant urine (or uses it for quantitative protein determination) and resuspends the pellet in the few drops of urine remaining in the tube. One transfers a drop of sediment to a glass slide and applies a coverslip. One first examines the sediment at low power to evaluate for casts and subsequently at high power to quantify erythrocytes, leukocytes, and epithelial cells and to determine whether bacteria are present. Casts are molds of Tamm-Horsfall glycoprotein and cells that form in tubules and subsequently pass into the bladder. They are rare in normal equine urine but may be associated with inflammatory or infectious processes. Casts are unstable in alkaline urine; thus one should evaluate sediment as soon as possible after collection to ensure accurate assessment. One should see fewer than five red blood cells per high-power field in an atraumatically collected urine sample. Increased numbers of urinary red blood cells can result from inflammation, infection, toxemia, neoplasia, or exercise (see Chapter 17.8). Pyuria (more than 10 white blood cells per high-power field most often is associated with infectious or inflammatory disorders and normal equine urine should have few bacteria, if any. The absence of bacteria on sediment examination does not rule out their presence, however, and one should perform bacterial culture of urine collected by catheterization or cystocentesis (foals) when one suspectscystitis or pyelonephritis. Finally, equine urine is rich in crystals. Most of these are calcium carbonate crystals of variable size, but calcium phosphate crystals and occasionally calcium oxalate crystals also are visible in normal equine urine (Figure 17.3-2).[40,41,57] Addition of a few drops of a 10% acetic acid solution may be necessary todissolve crystals for accurate assessment of urine sediment.[40]

17.3.3.4

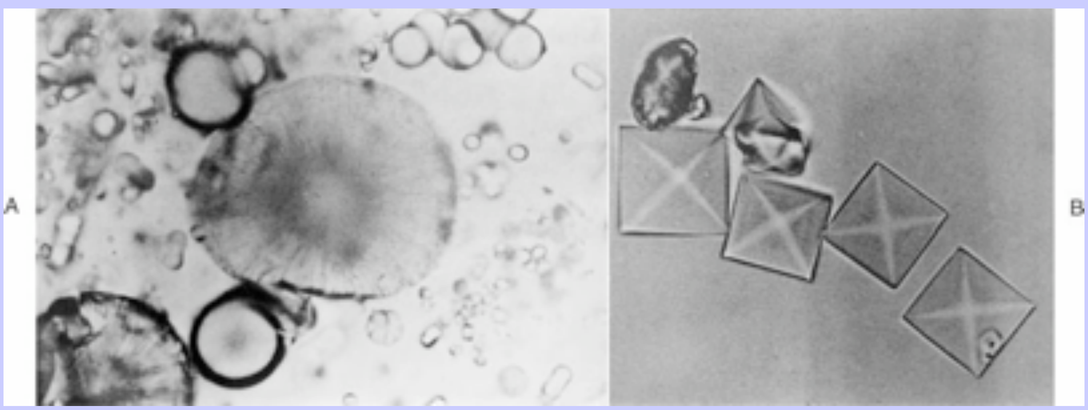
ENZYMURIA

Renal tubules are metabolically active, being responsible for absorption or excretion of a wide range of substances. Transport of these compounds is facilitated by a number of enzymes, which are found in large amounts in lysosomes within or in the brush borders of tubular epithelial cells. Regular turnover of these cells and release of endocytotic vesicles and lysosomes into the tubular lumen results in activity of enzymes in urine (enzymuria).[58] A number of substances that are filtered at the glomerulus (including bile acids, aminoglycoside and cephalosporin antibiotics, mannitol, dextrans, radiographic contrast media, and heavy metals) are taken up via endocytosis into proximal tubular epithelial cells. Endocytotic vesicles combine with lysosomes and substances that are not broken down by lysosomal enzymes subsequently are extruded into the tubule lumen through evacuation of residual bodies.

Inflammation or necrosis of tubular epithelial cells results in elevated urinary activity of lysosomal and brush border enzymes. Because proximal tubular epithelial cells are the most metabolically active of all kidney cells, they are particularly susceptible to ischemic injury. Furthermore, they can be injured similarly by exposure to large quantities of nephrotoxins in glomerular filtrate. As a result, determination of the activities

of certain urinary enzymes can provide evidence of tubular damage several days before azotemia may 1205
develop.[59–62] Additional contributors to increased urinary enzyme activity include (1) low-molecular-weight 1206
enzymes such as amylase that normally are filtered by glomeruli and reabsorbed inthe proximal tubules, (2) postrenal genitourinary tract epithelia that usually contribute a negligible amountto the overall urinary enzyme activity (unless they become neoplastic), and (3) secretions from accessory sex glands. Contributions from the latter explain why intact males tend to have higher urinary activities of lactate dehydrogenase (LDH) and *N*-acetyl-β-D-glucosaminidase (NAG).

Figure 17.3-2 Crystals commonly observed in equine urine sediment (original magnification ×160). **A**, Large, round calcium carbonate crystals (*center* and *lower left*) and smaller calcium phosphate crystals *(oblong)*. **B**, Calcium oxalate dihydrate crystals. (Reproduced from Osborne CA, O'Brien TD, Ghobrial HK et al: Crystalluria: observations, interpretations, and misinterpretations, *Vet Clin North Am Small Anim Pract* 16:45, 1986.)



Although more than 40 enzymes have been detected in urine of different species, only a few appear to be of diagnostic relevance. To be of clinical use, a urinary enzyme must have measurable activity in the kidney; its activity must lie within a fairly narrow range in urine of healthy animals; it must be sufficiently large (molecular weight >60,000) so as not to be filtered freely across the glomerulus; and its activity must increase early enough during the course of renal injury to permit institution of corrective treatment. Finally, the activity of the urinary enzyme should remain fairly stable in urine for several days without the need for special processing. In human beings and dogs, a number of enzymes, includingNAG, LDH, β-glucuronidase, alanine aminopeptidase, alkaline phosphatase (ALP), leucine aminopeptidase,γ-glutamyltransferase (GGT), and kallikrein have been demonstrated to be sensitive indicators of renal damage.[59–61,63,64] With respect to horses, normal values have been established for activities of GGT, ALP, NAG, LDH, and kallikrein.[65–69] Attempts to assay aspartate aminotransferase and alanine aminotransferase activities were unsuccessful in normal horse urine.[66]

Alkaline phosphatase and GGT are membrane-associated enzymes found primarily in the brush border of the proximal tubular epithelium.[60–64,70] Their activity in distal tubular epithelium is negligible.[13] These enzymes have activity in other tissues, but because they are not filtered by the glomerulus, elevated activity in urine in the absence of significant proteinuria is presumed to originate from the kidneys. Measurable activity in normal urine is attributed to cell turnover.[60] Lactate dehydrogenase is a more ubiquitous tubular epithelial enzyme, being as active in the distal tubules and medullary papillae as in proximal tubular epithelium.[63–70] *N*-acetyl-β-D-glucosaminidase is a proximal tubular lysosomal enzyme.[60–70] Only GGT, ALP, LDH, and NAG have been assayed in the urine of horses known to have, or thought to have, some form of renal dysfunction. Determination of NAG activity can be difficult in normal equine urine because of its alkalinity, and normal values may be less than detectable assay limits when one uses a spectrophotometric, rather than a fluorometric, method.[71–74] Published normal activities (expressed per gram of creatinine) for these enzymes in equine urineare GGT: 0-25 IU/g Cr; ALP: 0-28 IU/g Cr; LDH:0-12 IU/g Cr; and NAG: less than 1 IU/g Cr (<2 IU/L urine). Comparison with creatinine concentration, which is relatively constant, results in less volume-related variation and allows interpretation of a randomly collected specimen (compared with a urine sample obtained during a timed collection period).[65,75,76] 1206

1207

Factors one must consider when measuring urinary enzyme activities include conditions under which the urine sample has been stored, urinary pH, diurnal variation, gender- and age-related variations, and other naturally occurring inhibitors or promoters of enzyme activity in urine (albumin, mucoproteins, proteolytic agents, amino acids, and ammonia). Although these factors have received limited study respecting equine urine, it has been documented that freezing can decrease activity of all enzymes, especially GGT. Furthermore, the colder the temperature, the more rapid the loss of enzyme activity.[65] To obtain the most accurate results, one should refrigerate samples (4° C) and assay them within 72 hours of collection. In species that have a slightly acidic or neutral urinary pH, assay of NAG is considered one of the most valuable diagnostic tests available. However, its activity appears to be susceptible to pH changes. In human beings receiving nephrotoxic medications, NAG activity in urine became undetectable at pH values greater than 8.[77] Similarly, NAG activities were undetectable (less than 2 IU/L) in urine of normal horses.[78] In a study of monensin toxicosis in horses, NAG activity increased as urinary pH decreased.[67] Certain amino acids and ammonia further act as inhibitors of lysosomal enzymes such as ALP and NAGin the urine of human beings, dogs, and rats,[79,80] and techniques have been developed to remove these agents from the urine by gel filtration before assay of their activity.[81]

Theoretically, assessment of changes in the urinary activity of selected enzymes may assist the clinician in identifying the segment of the nephron suffering the greatest dysfunction or damage. Although NAG, GGT, and ALP are associated primarily with proximal tubular epithelium, LDH usually is associated with distal tubular epithelial cells. Increases in urinary GGT and ALP activity have been induced experimentally in horses receiving gentamicin and neomycin for 5 to 10 days.[82,83] Increases also have been measured in horses with diarrhea, acute abdominal crises, and endotoxic shock. In the latter instances, enzymuria was assumed to indicate tubular damage following ischemia. Five consecutive days of furosemide administration also produced moderate increases in GGT and ALP activity, with ALP increasing more rapidly.[78] However, 48 hours of water deprivation failed to induce any changes in GGT, ALP, or LDH activity.[69] Similarly, no change in urinary LDH activity was observed in horses administered phenylbutazone (8.8 mg/kg p.o.) daily for six days.[69]

Although increases in urinary enzyme activities generally indicate acute tubular damage, one must interpret urine enzyme/Cr ratios carefully. Threshold values above which elevations are significant have not been well documented, although one study reported that a GGT/Cr value greater than 25 IU/g indicated tubular damage.[65] In contrast, in a study of gentamicin-induced nephrotoxicity in pony mares, Hinchcliff, McGuirk, and MacWilliams[82] measured GGT/Cr values exceeding 100 IU/g several days before measuring an increase in serum creatinine concentration. Furthermore, one frequently may measure GGT/Cr values between 25 and 100 IU/g in horses receiving gentamicin at recommended doses. Similar to gentamicin pharmacokinetics, enzymuria in these horses has been highly variable and these horses have not been recognized to be at risk of developing acute renal failure. Although enzymuria likely reflects a degree of tubular damage in these patients, one should interpret increases in GGT/Cr values between 25 and 100 IU/g with caution, whereas increases greater than 100 IU/g are more likely to be clinically significant.

Horses with chronic renal disease may have normal or reduced enzyme activities that reflect cellular changes that occur in the nephron in response to chronic inflammation. Just as BUN and Cr concentrations may be normal during the early stages of renal disease, urinary enzyme activities may not reflect accurately renal dysfunction later in the disease course when results of blood tests and urinalysis are more likely to be abnormal. A possible reason for this phenomenon is that substantial destruction of tubular epithelium occurring early in the disease leaves fewer epithelial cells to be an ongoing source of elevated enzyme activities. Alternatively, regenerating tubular epithelial cells may be more refractory to the effects of the toxin.

All in all, determination of urinary enzyme activities has failed to gain acceptance as a routine measure of renal tubular damage in most equine hospitals. This lack of acceptance can be attributed to the high sensitivity for detection of subclinical renal tubular damage. For example, although a urine GGT/Cr ratio elevated to a value of 75 supports tubular damage, it does not provide the clinician a quantifiable risk for development of acute renal failure. Thus as a single measurement, the ratio is of limited use in deciding whether one should discontinue use of a nephrotoxic medication (e.g., gentamicin). In contrast, more dramatic elevations of the GGT/Cr ratio may precede development of azotemia and could be a useful warning that one may need to discontinue a medication or, at a minimum, prolong the dosing interval. Until values for urinary enzyme activities are reported for a larger number of equine patients with various diseases, the true value of assessing urinary enzyme activity will remain unclear.

17.3.3.5 FRACTIONAL CLEARANCE OF ELECTROLYTES

Urinary electrolyte losses, which reflect tubular function, can be expressed as excretion rates (total amount of 1207
electrolyte excreted during a given time period, expressed as milliequivalents per minute) or as clearance 1208
rates. Determination of clearance rates uses the same clearance concept to measure GFR. In brief, a clearance rate (Cl_A) is a measure of the volume of plasma that is cleared completely of the substance in question (A) during a given time period. One calculates the Cl_A by performing a timed urine collection (to determine urine flow in milliliters per minute) and measuring the concentration of the desired substance in plasma and urine (creatinine or inulin for determination of GFR)[8]:

$$Cl_A = \frac{\text{Urine [A]}}{\text{Plasma [A]}} \times \text{Urine flow}$$

As with protein, urinary clearance of many substances, including electrolytes, often is compared with that of creatinine.[8] Basically, a substance that is filtered mostly across the glomerulus but is neither reabsorbed nor secreted by renal tubules (inulin) will have a clearance rate similar to that of creatinine. In contrast, a substance that is poorly filtered (larger molecule) or reabsorbed to a great extent by renal tubules (sodium or chloride) will have a lower clearance value than that of creatinine. Similarly, clearance values for substances that are eliminated by filtration and tubular secretion (potassium) may exceed that measured for creatinine. An advantage of comparing the clearance of a substance (A) to creatinine clearance (expressed as a fraction of creatinine clearance) is that it obviates the need to perform a timed urine collection, for the urine flow factor is cancelled out in the calculation:

$$\frac{Cl_A}{Cl_{Cr}} = \frac{\dfrac{\text{Urine [A]}}{\text{Plasma [A]}} \times \text{Urine flow}}{\dfrac{\text{Urine [Cr]}}{\text{Plasma [Cr]}} \times \text{Urine flow}}$$

that, by rearrangement and expression as a percentage becomes

$$\frac{Cl_A}{Cl_{Cr}} = \left(\frac{\text{Plasma [Cr]}}{\text{Urine [Cr]}} \times \frac{\text{Urine [A]}}{\text{Plasma [A]}}\right) \times 100$$

This calculation is called the fractional creatinine clearance value.[8,84] More often, however, the term *fractional excretion* has been used to describe this value. Although most sources recommend that blood and urine samples be collected at the same time for determination of fractional clearance values, serum electrolyte and creatinine concentrations are usually stable (except in patients with prerenal azotemia or acute renal failure), so one can use blood values measured within a few days of the urine sample in the clearance calculations. Consequently, leaving a specimen cup for the client to use to collect a voided sample is acceptable and obviates bladder catheterization in many cases.

As previously discussed (see Chapter 17.2), the equine kidneys function to conserve more than 99% of filtered sodium and chloride ions. In contrast, potassium ions are conserved poorly except during periods of whole-body potassium depletion (anorexia, prolonged exercise). Thus normal fractional clearance values areless than 1% for sodium but are considerably higher for potassium (Table 17.3-2).[30,41,45,52,85–94] Increases in fractional sodium and chloride clearance values may reflect an appropriate renal regulatory response to dietary excess, as with psychogenic salt consumption.[95] Alternatively, increases in fractional clearance values specifically for sodium and phosphorous also can be early indicators of renal tubule damage[30,96–98]; however, one must interpret results of these calculations in light of fluid therapy because fractional clearance values can be increased artifactually in horses receiving intravenous polyionic solutions.[31] Similarly, medication (furosemide) or light exercise also can result in increased urine flow and fractional sodium and chloride clearance values.[99]

The kidneys play an important role in equine calcium and phosphorus homeostasis, and renal loss of these ions varies with dietary intake. Thus fractional clearances of calcium and phosphorous also have been used to assess adequacy of dietary intake.[86–88,90,92,100–105] Although diet is evaluated more appropriately on a herd basis by analyses of hay and concentrates, fractional clearances may be useful in individual animals or when feed analysis is impractical (e.g., forage consists of pasture). Determination of fractional calcium and

phosphorus clearances has received limited study with a focus on young racing horses.[100–105] For example, excessive dietary phosphorus intake (which can lead to nutritional secondary hyperparathyroidism) leads to increased fractional clearance of phosphorus. Evaluation of fractional calcium clearance is hampered by the fact that most of the calcium in equine urine is in the form of calcium carbonate crystals. To measure the urinary calcium concentration reliably, one must collect the entire contents of the bladder during voiding or via catheterization to ensure collection of the initial crystal-poor and final crystal-rich fractions. Subsequently, one treats a well-mixed aliquot of urine with acetic acid or nitric acid to solubilize the crystals.[92] In one report, fractional calcium and phosphorus clearance values greater than 2.5% and less than 4% were considered consistent with adequate dietary intake (adequate calcium intake with phosphorus intake that was not excessive).[101] Unfortunately, because the ranges for fractional calcium and phosphorus clearances can be wide in normal horses (see Table 17.3-2), measurement of these clearances may not be sensitive enough to detect minor dietary imbalances.

Determination of fractional electrolyte clearance values also has been advocated in the evaluation of horses 1208
with recurrent rhabdomyolysis.[106–108] Low sodium and potassium clearances have been reported in some 1209
affected horses. Whether these low fractional clearance values reflected total body electrolyte depletion (as a consequence of repeated bouts of exercise in hot weather or repeated furosemide administration) or a true physiologic predisposition to rhabdomyolysis was not determined. Nevertheless, low fractional clearance values document the need for electrolyte supplementation in equine athletes. Harris and Snow also described another population of horses that exhibited recurrent rhabdomyolysis that had increased fractional phosphorus clearance and was reported to respond to dietary supplementation with ground limestone.[107] Thus although determination of fractional electrolyte clearances may be helpful in the evaluation of horses with recurrent rhabdomyolysis, only a small portion of affected horses are likely to show significant clinical improvement in response to dietary electrolyte supplementation alone.

NR, Not reported.

* Values calculated from data provided.

† Fractional clearance of potassium may exceed upper limit on high potassium diets; a fractional clearance of phosphorus exceeding 4% suggests excessive dietary intake; and a fractional clearance for calcium should exceed 2.5% with adequate intake.

‡ Low range attributed to low urine potassium concentrations determined by ion specific electrodes.

§ Fractional clearance value for magnesium reported at 7 to 30.

Finally, the methodology used to determine fractional electrolyte clearances should be standardized because several factors may lead to erroneous results. For example, a note of caution is warranted when ion-specific electrodes (instead of a flame photometer) are used to measure urinary potassium concentration, for components of animal urine can interfere with the ion-specific electrode and lead to spurious low values. One usually can avoid this problem by performing the analysis on urine diluted with water.[109] Next, as mentioned

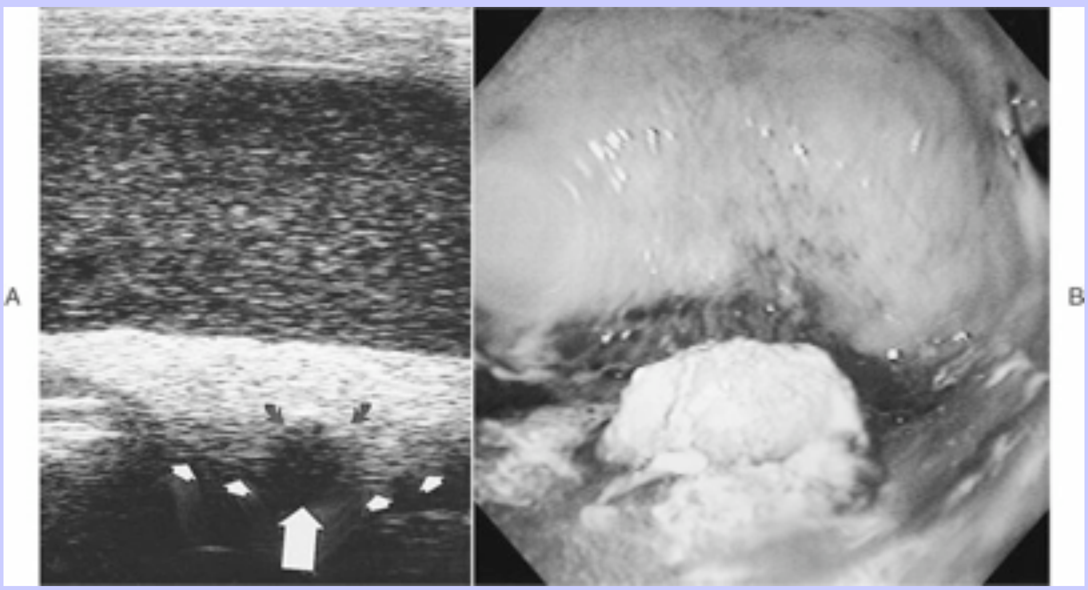
previously, light exercise may increase urine flow rate and sodium excretion.[99] Thus "spot" urine samples are best collected in the morning before feeding and exercise. Recently, McKenzie, Valberg, Godden, et al. compared fractional electrolyte clearance values between single-sample spot urine collections to 24-hour volumetric urine collections over 3 days in horses receiving diets varying in cation-anion balance.[94] They found substantial variation in fractional clearance values within individual horses over the 3-day study despite feeding of a consistent diet. When they assessed the effect of the differing diets, fractional clearance values for sodium, potassium, and chloride were generally similar when calculated using urine electrolyte concentrations determined in spot urine samples or well-mixed 24-hour collection samples. However, they found greater variability with fractional clearance values for calcium and magnesium. The fact that they detected considerable variability should not be surprising when one remembers that fractional clearance 1209
values are a calculation using four measurements (creatinine and electrolyte concentrations in plasma/serum 1210
and urine). Thus small variations in each measured value have the potential to magnify error in the final calculation. All in all, this study should serve as a reminder that determination of fractional electrolyte clearances is only one of the diagnostic tools one should use to evaluate patients with renal disease or recurrent rhabdomyolysis or to assess diet in a group of horses.

17.3.4 Imaging Techniques

17.3.4.1 ULTRASONOGRAPHY

One can perform ultrasonographic examination of the urinary tract transrectally or transabdominally.[110–117] Bladder imaging is performed best transrectally using a 5-MHz probe. One must remember the character of equine urine while imaging the bladder, for the urine will be an inhomogeneous, echogenic fluid because of the presence of mucus and crystals. The latter can appear as echogenic sediment in the ventral aspect of the bladder, and ballotting the bladder may cause this echogenic material to swirl in the bladder. One also can confirm the presence of a cystic calculus because calculi have a highly echogenic surface and produce an acoustic shadow (Figure 17.3-3). Similarly, one may image and palpate masses in the bladder wall during the examination.

Figure 17.3-3 Transrectal ultrasonographic and cystoscopic images of the bladder of a Miniature horse mare with recurrent cystitis and urolithiasis. **A**, The ultrasonographic image shows a layer of echogenic crystalline material in the ventral aspect of the bladder (*small, white arrows* outline ventral bladder wall) and presence of a small cystolith (outlined by *small black arrows* and *large white arrow*). **B**, After lavage of the urine sediment, cystoscopy confirmed presence of a small urolith, which was amenable to removal by digital manipulation.

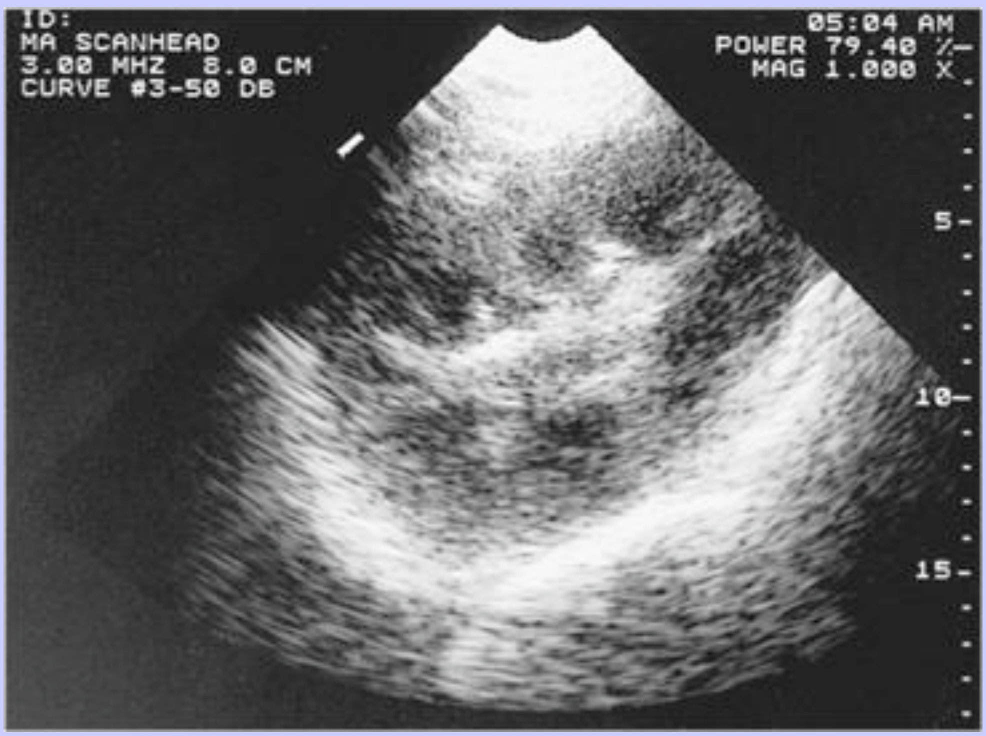


The right kidney is triangular or horseshoe shaped and is imaged best transabdominally via the dorsolateral extent of the last two or three intercostal spaces (Figure 17.3-4). The left kidney is somewhat a more typical bean shape, lies deep to the spleen, and can be imaged via the last two intercostal spaces or via the paralumbar fossa. Because the left kidney is deeper than the right kidney, it can be difficult to image completely and is examined best with a 2.5- or 3-MHz probe. One should assess systematically the size and shape of both kidneys, architecture, and echogenicity of the parenchyma, including imaging the kidneys in dorsal, sagittal, transverse, and transverse oblique anatomic planes.[115] In a full-size horse the right kidney should not measure more than 15 cm in the longest axis, whereas the left kidney may measure up to 18 cm if imaged in longitudinally.

In acute renal failure the kidneys may be normal or enlarged, and abnormalities of parenchymal detail are not often detected. When present, abnormal findings may include perirenal edema, widening of the renal cortex, and loss of a distinct corticomedullary junction.[111,112,114,116–118] Chronic renal failure can result in decreased kidney size, irregular surfaces, and increased echogenicity because of renal fibrosis. Cystic or mineralized areas in renal parenchyma can be associated with chronic renal disease or congenital anomalies. 1210

Although uncommonly recognized, distinct curvilinear hyperechoic bands in the outer renal medulla parallel to the corticomedullary junction have been imaged in foals and adults horses with renal disease attributable to acute or chronic phenylbutazone toxicity.[117,119,120] This finding, termed the *medullary rim sign*, is thought to resultfrom damage (and possible secondary mineralization) to the inner stripe of the outer medulla, the location of highly metabolically active nephron segments including the distal extent of the proximal tubule and the thick ascending limb of Henle's loop. Calculi in the renal pelvis generally cast an acoustic shadow and can resultin hydronephrosis of the affected kidney (Figure 17.3-5).[111,112,114] Occasionally, one cannot image one or both kidneys because of a gas-filled bowel between the kidney and abdominal wall. Reexamination at a later time generally is required for successful imaging in such cases. In addition, administration of high rates of fluid therapy, especially in foals, can lead to iatrogenic pyelectasia (fluid distention of the renal pelvis).[117,121] One should use caution so as not to interpret this mild distention of the renal pelvis falsely as evidence of ureteral or lower urinary tract obstruction. 1211

Figure 17.3-4 Transabdominal ultrasonographic image of a normal right kidney: the renal medulla is more echolucent than the renal cortex, except for the renal pelvis, which varies in echogenicity.



17.3.4.2 RADIOGRAPHY

Radiography rarely is used to evaluate urinary tract disease in adult horses. One usually can obtain diagnostic radiographs of the urinary tract only in foals or Miniature horses. Excretory urography using intravenous contrast material or pyelography using contrast agent delivered into the renal pelvis under ultrasonographic

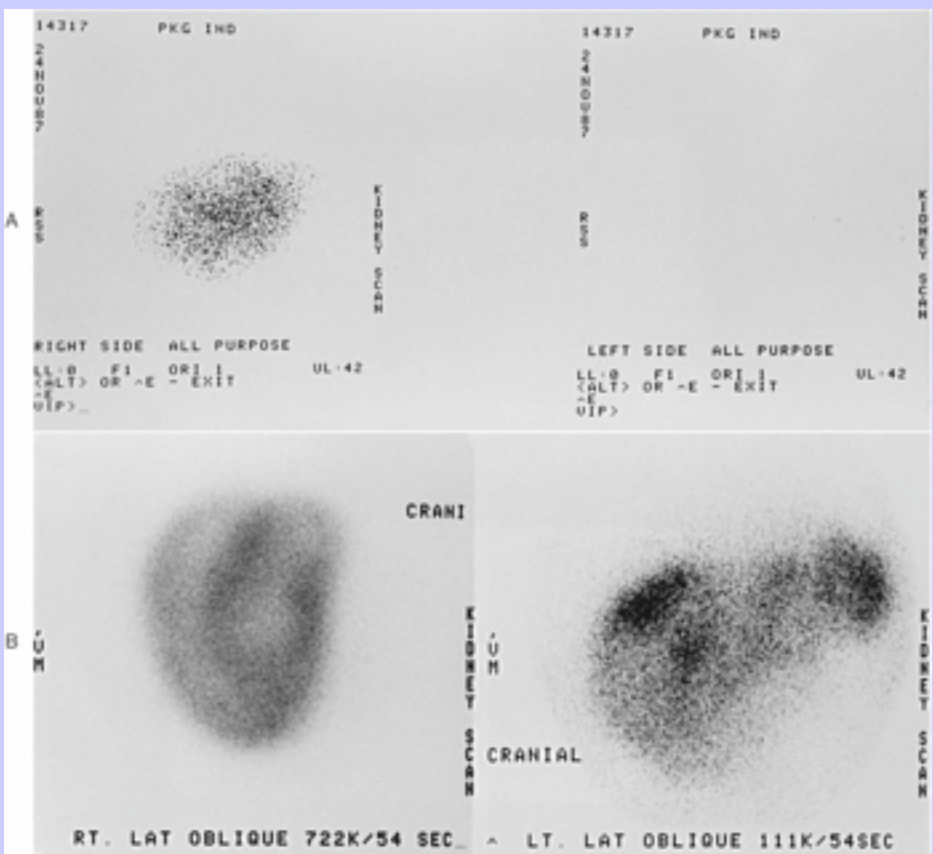
guidance may be useful to identify a nonfunctional or hypoplastic kidney or an ectopic or torn ureter.[122,123] The latter procedure may be more rewarding, but both require general anesthesia to be performed safely. One also can use retrograde contrast studies to evaluate the ureters in mares[124]; however, they have been used most often in foals suspected of having an ectopic ureter or a ruptured bladder. Contrast radiographic studies alsocan help to identify strictures or masses in the urethra or bladder, but endoscopy is generally more useful for these problems. In small animals, abdominal survey radiographs are most useful for assessing kidney size and shape, whereas ultrasonography provides more information about parenchymal changes associated with renal disease.[125] Thus use of a standardized protocol for ultrasonographic evaluation of the equine kidneys should provide essentially the same amount of information as the combined use of survey radiography and ultrasonography in small animal patients.[115]

Figure 17.3-5 Transrectal ultrasonographic image of the left kidney of a mare with nephrolithiasis and hydronephrosis. The nephrolith has an echogenic surface and produces an acoustic shadow. The echolucent crescent moon-shaped structure is a fluid-filled remnant of the renal parenchyma, consistent with hydronephrosis.

17.3.4.3 NUCLEAR SCINTIGRAPHY

Nuclear scintigraphy is an additional imaging modality often used to assess renal anatomy and function in human beings and small animals. One can use various radionuclides and pharmaceuticals, depending on the type of scintigraphic examination being pursued.[126–128] In fact, scintigraphy is used routinely for quantitative measurement of GFR in these species. Walsh and Royal compared use of renal scintigraphy (using 99-metastable technetium tagged to diethylenetriaminopentaacetic acid, which is similar to inulin in that it is neither secreted nor reabsorbed after filtration) for measurement of GFR in horses but found greater 1211
variability compared with GFR values measured by plasma disappearanceof inulin or the same radionuclide 1212
(^{99m}Tc-DTPA).[129] Nevertheless, renal scintigraphy using ^{99m}Tc-DTPA can provide qualitative information about renal function and is the only method currently available for assessing split renal function (assessing individual kidney function) in horses. Renal scintigraphy also has been performed with ^{99m}Tc tagged to glucoheptanate (taken up by the proximal tubule epithelial cells to provide anatomic detail) or mercaptoacetyltriglycine (MAG_3, which is similar to *p*-aminohippurate because it is eliminated by proximal tubular secretion) to provide qualitative information about renal anatomy and function (Figure 17.3-6).[130,131] 1212
Thus one may use renal scintigraphy to document the presence of a functional kidney in horses when 1213
multiple ultrasonographic examinations have been complicated by interfering bowel or when one desires information about individual kidney function.

Figure 17.3-6 Renal scintigraphic images of horses with renal disease. **A**, Renal scintigraphic image using *99m*Tc-diethylenetriaminopentaacetic acid revealed absence of functional left renal tissue, compared with an image of the right kidney, in a stallion with chronic renal failure. A nonfunctional hypoplastic left kidney was found on necropsy examination. **B**, Renal scintigraphic image using Technetium-99m-glucoheptonate (^{99m}Tc-GH) in a gelding with unilateral left-sided pyelonephritis revealed inhomogeneous uptake of the radionuclide and lesser count emission over the same time compared with the normal right kidney. The scintigraphic study, which provided anatomic and functional information, supported pursuit of unilateral nephrectomy, rather than prolonged antibiotic administration, as the treatment of choice for this horse.



17.3.4.4

ENDOSCOPY

Endoscopy of the urinary tract is a useful diagnostic aid when the complaint is abnormal urination.[40,132–134] A flexible endoscope with an outside diameter of 12 mm or less and a minimum length of 1 m is adequate for examination of the urethra and bladder of an adult horse of either sex. One should sterilize the endoscope before endoscopy of the lower urinary tract. Tranquilization of the patient is recommended, and one should clean the distal end of the penis or the vulva thoroughly. One passes the endoscope as one passes a catheter, using the air control intermittently to inflate the urethra or bladder. Normal urethral mucosa is pale pink with longitudinal folds. When dilated with air the mucosa flattens and may appear redder than normal, and a prominent submucosal vascular pattern may be apparent. Passage of a catheter before endoscopy (for sample collection orto empty the bladder) can produce mild irritation and erythema of the urethral mucosa, and one should not mistake these for abnormal findings. One should examine the regions of the ischial arch (where the urethra begins to widen into the ampullar portion) and of the colliculus seminalis (in the roof of the pelvic urethra just distal to the urethral sphincter) closely, for these are common sites of posturination or postbreeding hemorrhage in geldings or stallions (see Chapter 17.8). Subsequent passage of the endoscope through the urethral sphincter and air distention allows evaluation of the bladder for calculi, inflammation, and masses (see Figure 17.3-3). Viewing the ureteral openings in the dorsal aspect of the trigone can help determine the source of hematuria or pyuria (see Chapter 17.8). A small volume of urine should pass from each ureteral opening approximately once each minute or more frequently if the horse is well hydrated or has been sedated with an α_2-agonist. One can perform ureteral catheterization to obtain urine samples from each kidney by passing sterile polyethylene tubing via the biopsy channel of the endoscope. Additionally, one can take biopsy samples of masses in the bladder or urethra.

17.3.5

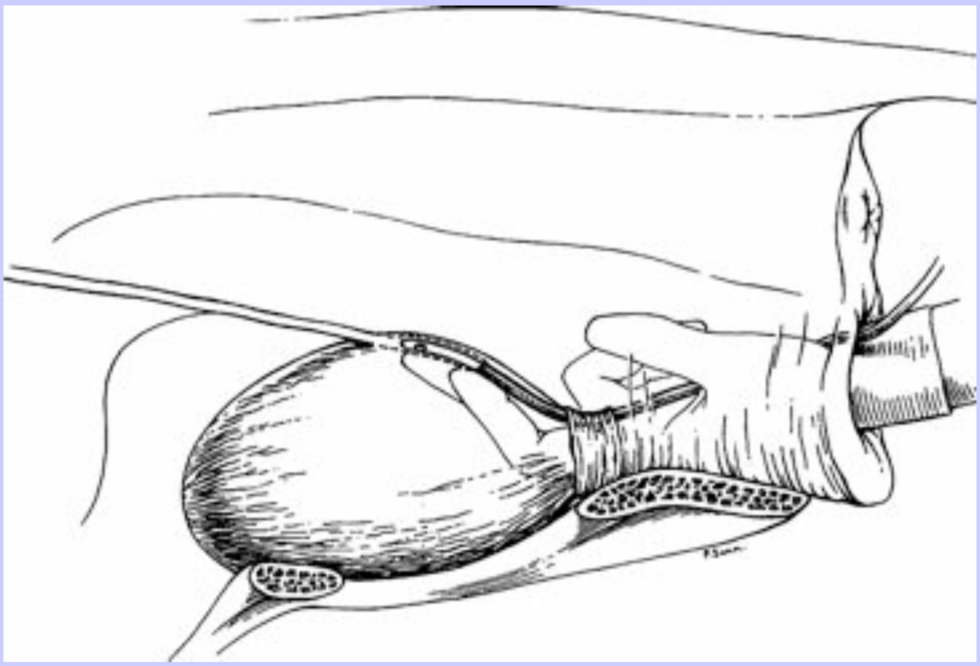
Specialized Diagnostic Techniques

17.3.5.1

URETERAL CATHETERIZATION

With development of high-resolution videoendoscopic equipment, retrograde instrumentation of the bladder, ureter, and renal pelvis rapidly is replacing surgical exploration for diagnostic evaluation and therapeutic management of urinary tract disorders in human beings and dogs.[135–138] Similarly, retrograde ureteral catheterization and instrumentation can be a valuable technique for evaluation and treatment of horses with unilateral disorders of the upper urinary tract.[139–141] In addition to localization of unilateral renal hemorrhage, pyelonephritis, and neoplasia, ureteral catheterization further enables retrograde pyelography.[124] As mentioned previously, one may perform this technique successfully in male and female horses during cystoscopic examination.[40,132–134]

Figure 17.3-7 Manual placement of a polypropylene catheter into the ureter of a mare. (From Schott HC, Hodgson DR, Bayly WM: Ureteral catheterisation in the horse, *Equine Vet Educ* 2:140, 1990.)



In mares, one also can catheterize the ureters manually without endoscopic guidance.[142] After preparation of the vulva, one catheterizes the bladder and drains the urine. One removes the bladder catheter and dilates the urethra manually until two fingers can be passed intothe bladder. One can palpate the ureteral orifices dorsally as small, soft projections. This done, one places a catheter between the fingertips, passes it through the urethra, and directs it into the ureter (Figure 17.3-7). A relatively rigid catheter with a rounded end (No. 8 to 10 French polypropylene catheter) facilitates passage into the ureter. After advancing the catheter 5 to 10 cm into the ureter, one attaches a syringe to the other end of the catheter and collects a urine sample. During sampling, one holds the catheter in place and occludes the ureteral opening with the fingertips to minimize loss of urine around the catheter.

17.3.5.2 WATER DEPRIVATION AND THE ANTIDIURETIC HORMONE CHALLENGE TEST

Water deprivation is a simple test to determine whether hyposthenuric polyuria is caused by a behavior problem such as primary (psychogenic) polydipsia or results from central or nephrogenic diabetes insipidus.[6] 1213
One should not perform a water deprivation test in an animal that is clinically dehydrated or azotemic. One 1214
should perform a baseline urinalysis (sample collected by catheterization to empty the bladder at the start of the test) and measure BUN, Cr, and body weight before removal of water (food does not necessarily need to be removed, but this may help prevent gastrointestinal complications of water deprivation). One measures urine specific gravity and weight loss after 12 (usually overnight) and 24 hours. Horses with normal renal

function typically produce urine with a specific gravity greater than 1.045 and an osmolality greater than 1500 mOsm/kg in response to water deprivation of 24 to 72 hours in duration.[43–45] Practically, one can stop the test when urine specific gravity reaches 1.025 or greater. Furthermore, one should stop the test if more than 5% of body weight is lost or clinical evidence of dehydration becomes apparent. With long-standing primary polydipsia, affected horses may not be able to concentrate urine fully (to a specific gravity greater than 1.025) because of partial washout of the medullary interstitial osmotic gradient. Extending the test period beyond 24 hours for such patients offers little benefit; however, affected horses should respond more favorably to water deprivation (producing urine with a higher specific gravity) after a period of partial water deprivation (termed a *modified water deprivation test*) during which daily water intake is restricted to 40 ml/kg for several days, which should allow time for restoration of the medullary interstitial osmotic gradient.[6] Horses with central or nephrogenic diabetes insipidus cannot concentrate urine in response to a water deprivation test.[6,143–145] When one suspects these problems, one should monitor patients every few hours, for significant dehydration may ensue within6 hours of water deprivation.

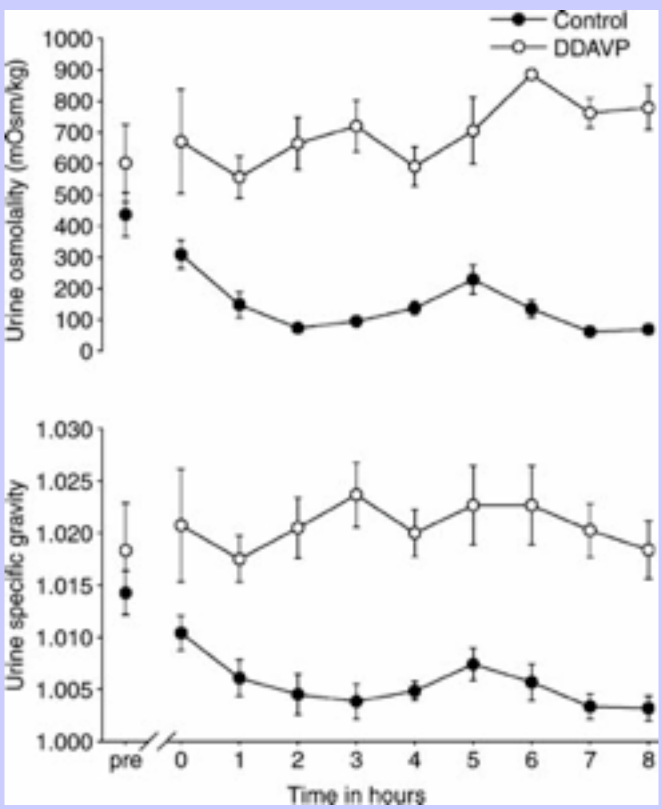
In the absence of azotemia or clinical signs of early renal failure, inability to concentrate urine in responseto water deprivation supports a diagnosis of diabetes insipidus; however, the test does not distinguish between the neurogenic and nephrogenic forms of the disorder. One can differentiate these by exogenous administration of vasopressin (antidiuretic hormone).[143–145] Until recently, the most commonly used form of exogenous antidiuretic hormone was a water insoluble tannate of the antidiuretic factor arginine vasopressin that was extracted from the posterior pituitary and suspended in peanut oil (Pitressin tannate). However, this preparation is no longer available. Currently, two approaches exist for performing an antidiuretic hormone challenge test. First, one can administer aqueous synthetic vasopressin (20 U/ml for intramuscular or subcutaneous injection) as an intravenous infusion (5 U [0.25 ml] added to 1 L of a 5% dextrose solution and administered intravenously at a rate of 2.5 mU/kg over 60 minutes [~250 ml to a 500-kg horse]) or an intramuscular injection (0.5 U/kg). An increase in urine specific gravity to 1.020 or greater after 60 to 90 minutes would be the expected response, whereas failure to increase urine concentration would support nephrogenic diabetes insipidus. Second, one can use desmopressin acetate (DDAVP), a synthetic analogof arginine vasopressin. Administration of desmopressin acetate is considered the safer diagnostic technique in small animals because the change in structure of this vasopressin analog has decreased pressor actions and less effect on visceral smooth muscle compared with an enhanced antidiuretic effect. One microgram of desmopressin acetate has an antidiuretic activity of 4 U of arginine vasopressin. The author and coworkers recently validated use of desmopressin acetate as a replacement for the antidiuretic hormone challenge test in normal horses. In this study, we diluted the nasal spray form of desmopressin acetate (0.1 mg/ml DDAVP) in sterile water and administered 0.05 μg/kg intravenously (25 μg, equalto 100 U of antidiuretic activity, to a 500-kg horse) to horses that had polyuria induced by repeated nasogastric intubation with water for 3 days preceding desmopressin acetate challenge. Urine was collected for 8 hours after desmopressin acetate administration and an increase in urine specific gravity to values greater than 1.020 was observed from 2 to 7 hours after desmopressin acetate administration (Figure 17.3-8, unpublished data). Furthermore, desmopressin acetate administration had no effect on heart rate or systemic blood pressures. These data demonstrate that intravenous administration of desmopressin acetate is a safe and useful diagnostic tool for evaluation of horses with diabetes insipidus.

A final test for evaluating polyuria and polydipsia isan intravenous challenge with hypertonic saline (Hickey-Hare test).[146] The goal is to produce an increase in plasma osmolality, which should trigger release of endogenous vasopressin. One protocol for the test would be to measure plasma osmolality and endogenous vasopressin concentrations before and within 30 minutes after administration of 1 to 2 ml/kg of a 7.5% sodium chloride solution. A normal response, expected in horses with primary polydipsia, would be

concurrent increases in plasma vasopressin concentration and urine specific gravity. Horses with nephrogenic diabetes insipidus also would respond with an increased plasma vasopressin concentration; those with neurogenic diabetes insipidus would not. Urine specific gravity would not be expected to increase in response to hypertonic saline administration with either form of diabetes insipidus. One could evaluate plasma vasopressin concentrations similarly before and at the end of a water deprivation test.[147,148] Unfortunately, however, assays for plasma vasopressin concentration are not currently available at commercial laboratories. Thus pursuit of this diagnostic test requires cooperation of a research laboratory. 1214

1215

Figure 17.3-8 Urine osmolality and specific gravity in six horses administered 0.05 μg/kg desmopressin acetate (DDAVP, open circles) or placebo (filled circles) intravenously at time 0. The horses had polyuria induced by repeated nasogastric intubation with water (40 ml/kg) twice daily for 3 days preceding desmopressin acetate challenge and again 4 hours after administration of desmopressin acetate. Urine was collected for 8 hours after treatment, and an increase in urine specific gravity to values greater than 1.020 was observed from 2 to7 hours after desmopressin acetate administration (author's unpublished data).



17.3.5.3 QUANTITATIVE MEASURES OF RENAL FUNCTION

As mentioned previously, azotemia does not develop until more than 75% of nephrons cease to function; therefore measurement of BUN and Cr, although readily available, provides a poor reflection of smaller declines in renal function. A number of methods are available to quantitate renal function in horses.[40,149] Basically, these tests can be separated into plasma disappearance curves or clearance studies involving use of timed urine collections. Generation of plasma disappearance curves requires collection of an initial blood sample, intravenous administration of one of a number of compounds (inulin, creatinine, sodium sulfanilate, phenolsulfonphthalein [phenol red], or radionuclides), and collectionof another series of blood samples over the subsequent 60 to 90 minutes.[129,150–155] One can express resultsin terms of an elimination half-life in minutes or as clearance values in milliliters per kilogram per minute. Mean elimination half-lives of 39.5 ± 4.4, 32.8 ± 4.1, and 16.4 ± 2.3 minutes have been reported for sodium sulfanilate, $^{99m}Tc\text{-}MAG_3$, and phenolsulfonphthalein, respectively, in healthy horses.[150,151,155] The difference in these values can be explained in part by the fact that $^{99m}Tc\text{-}MAG_3$ and phenolsulfonphthalein are eliminated mostly by tubular secretion and consequently are cleared more rapidly from plasma than is sodium sulfanilate (eliminated mostly by glomerular filtration). Plasma elimination half-times are most useful when measured sequentially throughout the course of renal disease;for example, Bertone, Traub-Dargatz, Fettman, et al.[156] reported a progressive increase in the sodium sulfanilate elimination half-time from 90 to 150 minutes during a 240-day course of chronic renal failure in a horse with polycystic kidney disease.

When one uses plasma disappearance curves of a substance to estimate GFR, the compound being used must meet all the requirements of a filtration agent[152–154]: (1) no significant binding to plasma proteins, (2) ability to be filtered freely across the glomerulus, and (3) absence of tubular reabsorption or secretion. The gold standard compound is inulin More traditionally, GFR has been measured by timed urine collection periods (to measure urine flow rate) and measurement of plasma and urine concentrations of a test compound that meetsthe listed requirements.[8,149] Several protocols exist for performing urine clearance studies. Ideally, the urine collection period should span 24 hours, although for practicality, one may use shorter collection periods.[6,149] For all protocols, one documents the bladder as being empty at the start of the collection period by catheterization or observation of voiding. One collects all urine produced during the study period and pools it into one sample. One again should empty the bladder via catheterization at the end of the collection period, record the total volume of urine produced, and assay an aliquot of the pooled urine sample for the test substance. Similarly, one measures the concentration of the test substance in a blood sample collected near the midpoint of the urine collection period. For urine collections of 12 to 24 hours, endogenous creatinine is the test substance used because it is the only one that does not have to be given by steady intravenous infusion during the collection period. GFR is calculated as the clearance of creatinine,

$$\mathrm{GFR} = \frac{\mathrm{Urine}\ [\mathrm{Cr}]}{\mathrm{Plasma}\ [\mathrm{Cr}]} \times \mathrm{Urine\ flow}$$

with the modification that the result usually is divided by body mass (in kilograms) to express GFR in term of milliliters per minute per kilogram. Although endogenous creatinine is a convenient test substance, its use typically underestimates GFR because noncreatinine chromagens in serum artifactually increase the value in 1215

the denominator.[149] Similarly, significant tubular secretion of creatinine can be one of the compensatory 1216
responses to renal failure. This can lead to overestimation of GFR calculated using endogenous creatinine clearance. Despite these limitations, the endogenous creatinine clearance technique for measurement of GFR

can provide useful information, especially when it is performed on several occasions during the course of renal failure (see Chapter 17.5).

To avoid the limitations of endogenous creatinine clearance as a measure of GFR, one can administer a number of filtration markers (inulin, creatinine, radionuclides) as an intravenous infusion throughout the urine collection period.[153,154,157–162] One starts the infusion as a bolus to increase the plasma concentration of the test substance to the desired level (for example, the desired plasma concentration for exogenous creatinine is 5 to10 mg/dl, to minimize the influence of noncreatinine chromagens) and subsequently continues a steady infusion throughout the remainder of the collection period. One usually performs this type of study for a shorter period with the horse restrained in stocks. One should empty the bladder of the horse at the start of the study and collect urine after two or three 30-minute intervals. One should pass a catheter and empty the bladder completely at the end of each 30-minute period. Alternatively, one can use an indwelling bladder catheter for the entire collection. After one measures urine volumes, one assays an aliquot of each urine sample and a blood sample collected at the midpoint of each urine collection period for the test substance and calculates GFR as the mean value for the two or three collection periods. For all practical purposes, these types of GFR measurements (with the exception of exogenous creatinine clearance) usually are limited to research studies, because commercial laboratories do not offer inulin assays. One also can use this shorter protocol for GFR determination using endogenous creatinine as the test substance, without the need for an intravenous infusion. The results of a number of studies measuring GFR in normal horses were presented in the previous section of this chapter (see Chapter 17.2).

17.3.5.4 RENAL BIOPSY

Renal biopsy is a useful diagnostic technique for identifying the affected region of the nephron, the type of lesion, and the chronicity and severity of disease.[8,163–166] Although biopsy is a safe procedure when performed with ultrasonographic guidance, it has risks, including perirenal hemorrhage or hematuria and, less commonly, penetration of bowel. In human beings, perinephric hematomas are common and have been detected in 57% to 85% of patients the day after biopsy. Microscopic hematuria occurs in virtually all patients for the first couple of days after biopsy, and gross hematuria occurs in 5% to 10% of patients. Most of these complications are inconsequential, but in 1% to 3% of patients the complications have resulted in the need for postbiopsy transfusions.[8] Similarly, in a group of seven normal horses subjected to renal biopsy, postbiopsy macroscopic and microscopic hematuria occurred in five animals. Furthermore, perirenal hemorrhage was a prominent finding during necropsy examination of five of these animals (including one examined 27 days after biopsy tissue was collected).[166] Thus renal biopsies remain controversialin human and equine renal failure patients.[167–169] Renal biopsies should be approached with caution and are indicated only when the results would alter the therapeutic plan or prognosis. Information about the effect of renal biopsy results on therapy and outcome of renal disease in human beings is limited; however, in one prospective study, biopsy results were found to influence physicians' decisions on about half of cases when the technique was performed.[170] In general, renal biopsy is pursued more aggressively in human beings with acute renal insufficiency than in those with chronic renal insufficiency, especially when it is difficult to determine the type of renal disease based on results of urinalysis and sediment examination.[8] In the equine patient, one performs a renal biopsy with the horse sedated and restrained in a stocks. Penetration of the needle (a Tru-cut biopsy needle or, preferably, a triggered biopsy device) into the renal parenchyma is imaged sonographically by triangulating the ultrasound beam with the biopsy instrument and the kidney or by determination of the site and depth of biopsy needle placement via ultrasonographic imaging immediately before biopsy. One should place the tissue collected in formalin for histopathologic and electron microscopic

evaluation. One can collect additional samples for bacterial culture and for immunofluorescence testing (placed in Michel's medium or quick frozen after coating with a preservative such as Tissue-Tek). One should determine appropriate sample processing beforehand by contacting the pathologist who will examine the biopsy samples.

Although renal biopsy results could provide useful diagnostic and prognostic information about the type of renal disease in horses with acute renal failure (e.g., glomerulonephritis, tubular necrosis, and interstitial nephritis), they have been used more often to document the presence of chronic disease in horses with chronic renal failure. In most cases of chronic renal failure, one cannot detect the inciting cause unless it can be associated with a historical event or immunofluorescence testing is pursued. This limitation can be attributed to the fact that significant renal disease develops before onset of azotemia. Pathologic lesions are widespread at this point, and involvement of all nephron segments and the interstitium often leads to the 1216
interpretation of end-stage kidney disease. In occasional cases the results may help separate infectious 1217
(pyelonephritis) or congenital (renal dysplasia) causes from nonspecific causes of renal failure. Although such results could be useful in the therapeutic approach to these patients, one should consider the limitations and risks of renal biopsy before performing this technique in horses with chronic renal failure.

17.3.5.5 URODYNAMIC PROCEDURES

Cystometrography and urethral pressure profiles are used to evaluate detrusor and urethral muscle function, respectively. Both techniques involve measurement of intraluminal pressure during inflation of the bladder or urethra. These techniques have been useful for diagnosis of myogenic and neurogenic disorders of the bladder and urethra in dogs and human beings.[171] The procedures have been performed experimentally in normal horses and ponies,[172–174] but little information is available about use of these techniques in clinical cases (see Chapter 17.12).

17.4 17.4—Acute Renal Failure

Warwick M. Bayly

Acute renal failure (ARF) is a clinical syndrome associated with abrupt reduction in glomerular filtration rate (GFR). Sustained reduction in GFR is associated with failure of the kidneys to excrete nitrogenous wastes causing azotemia and with disturbances in fluid, electrolyte, and acid-base homeostasis. The human medical literature is full of various terms and definitions for different forms of ARF. Veterinary medical definitions are simpler. Basically, ARF can result from decreased renal perfusion without associated cell injury (prerenal failure); obstruction or disruption of the urinary outflow tract (postrenal failure); or ischemic or toxic damage to the tubules, tubular obstruction, acute glomerulonephritis leadingto a primary reduction in the filtering capacity of the glomeruli, or tubulointerstitial inflammation and edema. Any of these intrarenal causes can be associated with intrinsic renal failure. Prerenal azotemia and ischemic tubular insults or necrosis represent a continuum, the former resulting in the latter when perfusion is compromised sufficiently to result in death of tubule cells.[1] Classically, ARF has been associated with oliguria and occasionally with anuria, and these are certainly the most commonly noted clinical signs associated with this disease in horses; however, nonoliguric forms of ARF, particularly intrinsic renal failure, exist and are characterized by slower development of azotemia, lower peaks in serum creatinine concentrations, more subtle increases in urinary sodium clearance, and a more rapid recovery of renal function in response to treatment. Nonoliguric renal failure seems to be diagnosed rarely in horses, although it is not uncommon to recognize mildly azotemic horses that have apparently normal urine output. In some cases, localized proximal tubule damage and reduced solute reabsorption actually may lead to enhanced distal delivery of filtrate, which may result in polyuric ARF.

In horses, ARF is usually prerenal or renal in origin and most often is caused by hemodynamic or nephrotoxic insults.[2] With the exception of bladder rupture in the neonate, postrenal failure is uncommon in horses. Identification and correction of the cause of ARF is important, for in the early stages of failure renal dysfunction is frequently reversible, whereas established ARF often requires extensive supportive care and carries a guarded prognosis. By identifying patients at increased risk and attempting to interrupt the cycle of events leading to ARF, one possibly may reduce the incidence of this condition.

17.4.1 Causes

Prerenal failure is associated with conditions that result in decreased cardiac output or increased renal vascular resistance, or both, and is the most common cause of reversible azotemia. In horses the most common causes of reduced cardiac output (and therefore reduced renal perfusion) are associated with diarrhea, endotoxemia, acute

blood loss, septic shock, and prolonged exercise. The resultant reductions in renal blood flow (RBF), GFR, and urine output usually result in azotemia and retention of water and electrolytes. Anesthesia also may decrease cardiac output enough to result in a degree of prerenal azotemia. Nonsteroidal antiinflammatory drugs (NSAIDs) also can precipitate prerenal azotemia in patients with decreased RBF.[3] Although prostaglandins play only a minor role in maintenance of RBF in the normal state, PGE_2 and PGI_2 are important vasodilatory mediators of RBF under conditions of reduced renal perfusion. Thus administration of NSAIDs to dehydrated or toxemic patients may contribute further to renal hypoperfusion by exacerbating a decrease in RBF. In some cases this may be sufficient to produce ischemic renal parenchymal damage also, thus causing intrinsic renal failure. Generally, the parenchymal lesion associated with NSAID toxicity is medullary crest or papillary necrosis. Such lesions develop because the renal medulla normally receives much less blood flow than the renal cortex, and consequently is much more susceptible to NSAID-induced changes in RBF.

In human beings, intrinsic renal diseases that lead to ARF generally are categorized according to the primary site of injury: tubules, interstitium, glomeruli, or vessels.[1] Acute tubular necrosis (ATN) is the form of intrinsic renal failure recognized most often in horses, interstitial and primary glomerular disease being recognized occasionally and vascular disease almost never. Ischemia, especially when associated with microvascular coagulation (which often leads to irreversible cortical necrosis[4]), and nephrotoxins probably are the most common causes of equine ATN. Important nephrotoxins include aminoglycoside antibiotics and NSAIDs. Less commonly, ATN develops following exposure to endogenous pigments (myoglobin or hemoglobin), heavy metals such as mercury (contained in some counterirritants), or vitamin D or K_3.[5–8] Use of aminoglycosides, particularly gentamicin, is a common cause of equine ATN.[9] Toxicity is a result of damage to proximal tubular epithelial cells that is mediated by impaired cell organelle function. Administration of potentially nephrotoxic agents such as NSAIDs or furosemide (which can exacerbate hypovolemia) can increase the risk of aminoglycoside nephrotoxicity. 1221

1222

Myoglobinuria and hemoglobinuria have been associated with development of ARF in horses (pigment nephropathy).[10] Myoglobinuric nephrosis can follow exertional rhabdomyolysis, heat stroke, or extensive crush injuries. Causes of intravascular hemolysis and hemoglobinuria include incompatible blood transfusions, immune-mediated hemolytic anemia, fulminant hepatic failure, and toxicosis from ingesting onions (*Allium* species) or withered red maple leaves *(Acer rubrum)*. Although the mechanism of pigment-induced renal injury is still ill understood, increased hydroxyl radical formation associated with reduction of ferrous iron compounds and tubular obstruction by casts of heme proteins are likely contributing factors. That pigment nephropathy is uncommon in well-hydrated horses suggests a possible link to renal perfusion. Myoglobin and hemoglobin have been suggested to induce renal vasoconstriction.

Acute interstitial nephritis often is not recognized but is believed usually to result from an allergic reaction to drugs such as the β-lactam and sulfa antibiotics. Autoimmune and embolic or ascending bacterial infections also may be associated with the condition, which is characterized by edema and inflammatory cell infiltration of the interstitium. Tubules frequently contain white and red blood cells, which pass into the lumen through the disrupted tubular basement membrane.

Glomerulonephritis often is identified post mortemin aged horses[11,12] and apparently is most often immune mediated. Glomerulonephritis often results in subacute or nonoliguric renal failure. Although the condition is theoretically reversible with immunosuppressive agents, in horses such undertakings are usually impractical and rarely are tried for long.

Postrenal obstructive failure can develop following disease of the renal pelves, ureters, bladder, or urethra. The severity of the failure depends on the extent of the obstruction. Frequently, problems are not recognized in horses until urine output obviously is reduced or renal function is impaired to the point that systemic problems are manifested. Although a neurogenic bladder can cause a functional obstruction, postrenal failure in horses most often results from intraluminal blockage by uroliths, which can cause obstruction anywhere in the urinary outflow tract.[13,14] Other possible intraluminal causes include neoplasia or stricture formation. Extraluminal obstructive lesions such as retroperitoneal tumors or adhesions or bladder displacements also occasionally are associated with development of postrenal failure.

17.4.2 Pathophysiology

The pathophysiology of equine ARF has receivedlittle study, and the mechanisms at work are assumed essentially to be the same as those identified in experimental studies of other animal species. Several mechanisms have been demonstrated to be involved in the development of ARF, the actual pathogenesis being complex and depending somewhat on the cause of the disease. Multiple factors probably operate in different combinations at different times and in different nephrons. These different mechanisms are discussednext in relation to the type of failure with which theyare associated (i.e., prerenal, intrinsic, and postrenal failure).

The pathophysiology of prerenal failure and ischemic ARF tend to involve the same processes. Toxins that cause ATN also share many pathophysiologic features with ischemic ARF.[15] The heterogeneity of intrarenal blood flow is an important factor in the development of this condition. The kidneys are particularly susceptible to ischemic and toxic injury because of their unique anatomic and physiologic features. Although they receive approximately 20% of the cardiac output, only about 10% to 20% of total RBF reaches the medulla via the vasa recta. This low medullary blood flow is necessary to ensure a functional countercurrent mechanism in this region of the kidney; however, low blood flow also creates a large corticomedullary oxygen gradient and renders the renal medulla hypoxic and highly susceptible to ischemic injury. Conversely, the renal cortex receives 80% to 90% of total RBF and is particularly susceptible to toxins.

Hypovolemia triggers compensatory systemic and renal responses. The systemic responses include activation of the autonomic nervous system and renin-angiotensin system and release of antidiuretic hormone. Peripheral vasoconstriction is one of the effects of these responses. Renal responses to decreases in circulating blood volume have several phases. Initially, tubular reabsorption of sodium and water increases and is mediated by nerves and hormones. Reabsorption usually is associated with reduced clearance of urea and an associated increase in serum urea nitrogen concentration in the face of preservation of GFR, which in turn maintains the plasma creatinine concentration in the normal range. More severe hypovolemia overcomes renal autoregulation, RBF being redistributed from the cortex to the medulla and GFR thus declining. The renal circulatory changes further enhance tubule solute reabsorption in the face of the decreased GFR. The net effect is production of small amounts of concentrated urine, a high urine/plasma creatinine ratio, and low fractional sodium clearance.[16]

A further reduction in RBF results in a syndrome considered intermediate between the prerenal and intrinsic
ischemic forms of ARF. Urine concentrating ability apparently is disrupted earlier than is sodium reabsorptive 1222
capability, with the result that urine osmolality decreases and output increases, but fractional sodium clearance 1223
stays low. Patients may appear to be mildly polyuric.[17] With more severe or prolonged renal hypoperfusion and ischemic insult, urinary sodium and fractional sodium clearance start to increase and the animal develops nonoliguric, and then oliguric, ARF. These changes are associated with progressively more severe tubule necrosis as the ARF progresses from prerenalto renal. The more severe the insult, the poorer the prognosis.

Intrarenal vasoconstriction is caused by an imbalance between vasoconstrictive and vasodilating factors (systemic or local) that act on small renal vessels in particular. These mediators include the vasodilator nitric oxide and the constrictor endothelin. Hypercalcemia is associated with increases in free calcium in the vascular smooth muscle and leads to enhanced vascular tone. Vasopressin and angiotensin II also have been shown to induce significant vasoconstriction under certain experimental conditions, as have endotoxins and myoglobin. Some nephrotoxins—gentamicin, heavy metals, and radiographic contrast agents—can cause renal vasoconstriction in addition to having direct toxic effects on the proximal tubules.[18–20]

Prostaglandins E_2 and I_2 are potent mediators that are responsible for a critical vasodilating response in the face of reduced RBF when activation of the renin-angiotensin system alone would result in further vasoconstriction. Increases in circulatory concentrations of angiotensin II stimulate synthesis of these renal prostaglandins. Consequently, the vasoconstrictive effects of stimulating the renin-angiotensin system usually are blunted somewhat by concomitant increases in PGE_2 and PGI_2; however, in the face of increased angiotensin II and simultaneous inhibition of prostaglandin synthesis (e.g., because of an NSAID), a significant increase in renal vascular resistance results.[21]

The reduction in GFR associated with reduced renal perfusion is associated with a number of mechanisms involving the glomeruli, vasculature, and tubules. In the initial phases a reduction in glomerular capillary hydrostatic pressure is associated with a net drop in RBF and a rise in renal vascular resistance. The latter phenomenon usually is associated with afferent arteriolar vasoconstriction and efferent arteriolar vasodilation and initially is reversible with volume expansion. Later (2 days or more), restoration of RBF does not necessarily improve GFR, and a drop in RBF is associated with a disproportionately greater drop in GFR.[22] Even when vasoconstriction is reversed, GFR may not improve; this reflects loss of RBF autoregulation. This disproportionate reduction in GFR suggests a fall in the ultrafiltration coefficient of the glomeruli following a reduction in total filtering area. The mechanism for this is unclear butmay be associated with increases in angiotensin II concentration, for this agent is known to induce mesangial contraction and a drop in the ultrafiltration coefficient.[23]

In addition to the aforementioned vascular changes that can affect GFR, the possible effects on GFR in the juxtamedullary region of even mild changes in RBF warrant specific mention. The glomeruli and adjacent straight portion of the proximal tubule and thick ascending limbs of Henle's loops in this region are apparently particularly susceptible to hypoxia (i.e., ischemia) because of their high oxygen requirements. Swelling of endothelial and tubule cells following prolonged ischemia in this region results in increased vascular resistance and continued compromise of the medullary circulation, even when cortical RBF has been restored.[15,24]

Glomerular filtration rate also can be compromised significantly by obstruction of tubular lumina by casts of cellular debris and inflammatory cells. Increased intratubular pressure decreases the net driving pressure for glomerular filtration in the same way that obstruction of the urinary outflow tract ultimately can lead to a lower GFR. One of the reasons that agents that accelerate the solute excretion rate (e.g., furosemide and mannitol) may be therapeutic adjuncts has been that they are believed to help disperse these luminal blockages.

Tubuloglomerular feedback is a regulatory mechanism that lowers GFR whenever solute (most notably sodium chloride) concentrations at the macula densa are increased. In ARF, impaired transport in the thick ascending limb of the loop of Henle in the context of preserved glomerular response to signals from the macula densa, results in a decrease in GFR. This feedback is a normal protective mechanism mediated principally by the renin-angiotensin system, although prostaglandin, intracellular calcium, and adenosine may play a role in signal transmission or regulation. In essence the mechanism serves to prevent massive fluid losses associated with a

reduction of tubular reabsorptive capacity; however, in cases of renal hypoperfusion and ischemia, the effect is the opposite, for basically the feedback mechanism exacerbates the effects of already reduced RBF.

Proximal tubule cells undergo morphologic changes early in cases of ischemia. They lose their brush borders and polarity, and the integrity of their tight junctions is disrupted, probably following alterations in the actin and microtubular cytoskeletons.[25,26] Under these conditions the glomerular filtrate is able to leap back to the peritubular circulation, thus reducing the net (or effective) GFR. This mechanism is thought to be an important source of GFR reduction only in more severe cases of ischemia or nephrotoxin exposure. 1223

Tubule cells involved in solute reabsorption have a high metabolic rate and a high demand for oxygen. The existence of the corticomedullary oxygen gradient makes these cells vulnerable to the effects of hypoxia and ischemia, the thick ascending limb of the loop of Henle in the outer medulla being most susceptible.[27] Early in ischemic and toxic ARF, decreases in adenosine triphosphate (ATP) and adenosine diphosphate tissue levels occur with associated elevations in adenosine monophosphate and inorganic phosphate concentrations. Much of the adenosine monophosphate is broken down further to adenosine and then to xanthine. Adenosine is a potent constrictor of cortical blood flow and probably enhances the effect of the tubuloglomerular feedback system. Depletion of ATP in tubular cells inhibits cell volume regulation, and the resultant swelling probably contributes to luminal obstruction and increased vascular resistance. Redistribution of Na^+,K^+-ATPase from the basolateral to the apical membrane of the tubule cells reduces the ability of the cells to extrude sodium into the peritubular fluid and circulation.[28] Redistribution of integrins to the apical surface contributes to the breakdown of tight junctions.[29] Depletion of ATP in tubule cells also leads to an increase in cytosolic calcium concentration. In addition to being a vasoconstrictor, calcium activates proteases and phospholipases, interferes with mitochondrial energy metabolism, and can break down the cytoskeleton.[1,30] Administration of calcium channel blockers has helped ameliorate ARF in some experimental situations.[31] 1224

Reperfusion of renal tissue after a period of ischemia is associated with rapid production of oxygen free radicals and with significant tissue damage. Xanthines, neutrophils, phospholipase A_2, mixed-function oxidases, and mitochondrial electron transport are associated with the production of these oxidants.[32] Phospholipase A_2 hydrolyzes phospholipids in cell and mitochondrial membranes to free fatty acids and lysophospholipidsand produces arachidonic acid. Arachidonate in turn is converted to eicosanoids that are vasoconstricting and chemotactic for neutrophils.[33] Cell membranes are particularly susceptible to phospholipase activity following reperfusion. Reperfusion injury is a major consideration in transplant surgery; however, the role it playsin the pathogenesis of prerenal and ischemic ARF isnot clear.

Many of the cellular biochemical and structural changes that occur along with the ischemic form ofARF are also important parts of the pathogenesis ofATN associated with exposure to nephrotoxins. Toxin-associated dysfunction and necrosis of cells result in increased tubular pressure and a decreased glomerular capillary hydrostatic pressure gradient. Loss of reabsorptive capability triggers tubuloglomerular feedback and further reduces GFR by lowering RBF following vasoconstriction and a decrease in the glomerular ultrafiltration coefficient. Transepithelial backleak of solutes into the circulation further interferes with the excretory function of the kidneys.

17.4.2.1 ACUTE TUBULAR NECROSIS

Many agents are recognized to have potential nephrotoxic effects.

Aminoglycoside-induced renal toxicity results from accumulation of these agents within the renal cortex. Streptomycin is the least nephrotoxic of the aminoglycosides, whereas gentamicin and kanamycin are intermediate nephrotoxins. Neomycin is the most nephrotoxic. Most cases of aminoglycoside toxicity are associated with conditions that cause reduced renal perfusion because the healthy kidney usually can tolerate some degree of aminoglycoside overdosing. After filtration at the glomerulus, aminoglycosides bind to phospholipase on the brush border of proximal tubules and subsequently are reabsorbed by pinocytosis. Accumulation of these antibiotics interferes with lysosomal, mitochondrial, and Na^+,K^+-ATPase function by inhibiting phospholipase A activity. Binding to the brush border is saturable with the result that sustained exposure of the proximal cells to the drug (as with multiple daily dosing regimens) results in greater accumulation of the drug and increased nephrotoxicity. As a result, once daily dosing may attenuate the risk of nephrotoxicosis while maintaining or improving therapeutic efficacy (because it results in higher peak concentrations).[34,35] Many mild cases of aminoglycoside toxicity notably are associated with nonoliguric ARF and therefore may go unrecognized in horses.

Some cephalosporins, such as cephaloridine, have considerable nephrotoxic potential. These agents cause necrosis because of mitochondrial toxicity following accumulation of the antibiotic in the cell.[36]

Not all cases of ATN are caused by direct toxic changes in tubule cells. For instance, whether myoglobin and hemoglobin are truly nephrotoxic is still debatable. The principal characteristics of pigment nephropathy caused by these agents are tubule obstruction and reduced RBF (caused by the direct vasoconstrictor effects of the pigment). Whether obstruction is physical, caused by pigment accumulation, or reflects aggregation of sloughed cells is not clear. Myoglobin tends to be associated with nephropathy more frequently than hemoglobin. Patients often quickly become oliguric, presumably because of the widespread tubule obstruction.

17.4.2.2 ACUTE INTERSTITIAL NEPHRITIS

To distinguish between drug-induced ATN and acute interstitial nephritis can be difficult, and the latter rarely is diagnosed in horses. Making a distinction may be a particular problem when continued use of 1224
antibiotics is indicated. With ATN one may alter the dosing regimen, whereas with interstitial nephritis, 1225
short-term corticosteroid therapy is often of benefit in human beings. Interstitial nephritis often is marked by eosinophiluria and eosinophilia and is more likely to be associated with the presence of red cells than is ATN. The exact immune mechanism by which interstitial nephritis develops is unclear, although it is thought most likely to be caused by delayed cell-mediated hypersensitivity or the presence of antitubule basement membrane antibodies.[37] The prognosis is usually grave in horses with acute interstitial nephritis.

17.4.2.3 ACUTE GLOMERULONEPHRITIS

Acute glomerular nephropathy is rare in horses, but when it occurs, it usually is manifested by the nephrotic syndrome, although hematuria and oliguria sometimes are apparent. Deposits of γ-globulin and complement are found along the basement membrane (global form) or in the mesangial area (mesangioproliferative form).[38] Group C streptococcal antigens have been identified along with equine glomerulonephritis, and equine infectious anemia viral antigen-antibody complexes have been recognized in the glomeruli of horses that were not in renal failure.[12,39] Deposition of immune complexes activates the complement cascade. Formation of C_3b and C_5a causes platelet aggregation and attracts neutrophils. Tissue damage results from deposition of

complement per se and from inflammation associated with neutrophil activation and release of reactive oxygen radicals, proteases, elastases, and other lysozymes. These enzymes, plus platelet-activating factor and leukotriene B_4, increase vascular permeability and upregulate expression of adhesion molecules, thus promoting further inflammation.[33] Severe reduction in GFR results from large drops in the glomerular permeability coefficient, which is associated with the widening of Bowman's spaces following inflammation and deposition of immune complexes.

The pathophysiology of postrenal ARF was referred to previously. Basically, increases in ureteral pressure for any reason result in GFR reduction because of a drop in the glomerular capillary hydrostatic pressure gradient, some tubular backleaking, a decrease in the glomerular permeability coefficient, and ultimately, a reductionin RBF.

17.4.3 Clinical Signs

In most horses with hemodynamically mediated (i.e., prerenal or ischemic) ARF, clinical signs are usually referable to the primary problem, such as acute colic or enterocolitis, sepsis, coagulopathies, rhabdomyolysis, or heavy metal poisoning, rather than to renal dysfunction. Therefore the predominant clinical signs are often dehydration (with or without diarrhea), depression, and anorexia. Other signs can include tachycardia, hyperemic mucous membranes, pyrexia, mild abdominal pain, and laminitis. Because clinical signs usually relate to the inciting problem, ARF may not be suspected or detected unless the veterinarian specifically evaluates renal function as part of the workup for a more obvious disease. In general, the clinical manifestations of ARF reflect the systemic effects of toxic substances usually excreted in the urine (i.e., uremia generally is reflected by anorexia and depression), urinary tract dysfunction, and derangements of fluid, electrolyte, and acid-base balance. One may observe signs of encephalopathy in horses with severe azotemia.

Although oliguria is considered the hallmark of ARF, urine production in horses varies. Oliguria frequently occurs in the early stages of hemodynamically mediated ARF and is the most frequently reported clinical sign that is related directly to urinary tract dysfunction. As outlined in the section on pathophysiology, however, nonoliguric and polyuric stages of prerenal and intrinsic ARF also can be associated with renal hypoperfusion. Anuria is rare. Nonoliguric or polyuric ARF also can be associated with exposure to nephrotoxins (ATN), and polyuria is common during the recovery phase of ARF, regardless of its cause. The magnitude of azotemia tends to be lower in nonoliguric than in oliguric ARF, possibly indicating less severe damage in the former condition. Similarly, nonoliguric ARF is associated with a more favorable prognosis.

Patients with ARF often are treated initially with large volumes of intravenous or oral fluids for the primary disease. In these cases, oliguria may progress to polyuria. When significant renal damage has been sustained, persistence of oliguria in the face of fluid administration usually is manifested as failure to produce a significant volume of urine in response to fluid therapy. The degree of change of azotemia also is minimal in the initial 24 to 36 hours of treatment. If one does not monitor these patients carefully, fluid retention may lead to development of subcutaneous and pulmonary edema. Soft feces caused by fluid retention also may be apparent in patients with oliguric ARF.

Postrenal or obstructive uropathy usually is characterized by mild to severe abdominal pain and pollakiuria and stranguria (see Chapter 17.7).

17.4.4 Diagnosis

Increases in plasma urea nitrogen and creatinine concentrations (i.e., azotemia) are frequently the initial findings that suggest compromised renal function. Azotemia simply reflects a reduction in GFR; it has almost no differential diagnostic value. After establishing recent development of azotemia, the equine internist must proceed systematically to differentiate between six possible syndromes associated with ARF: prerenal ARF, ischemic ARF, ATN, acute interstitial nephritis, acute glomerulonephritis, and obstructive (postrenal) ARF. A useful way to go about this is first to try to rule out pre- and postrenal ARF. If this is possible, the patient must have a type of intrinsic ARF and one can direct further diagnostic efforts to identifying the disease subtypes. 1225 1226

As described in greater detail later (see Urolithiasis), the diagnosis of postrenal obstructive disease usually is based on a combination of clinical signs, history, and the results of rectal palpation, ultrasonography, and urinary tract endoscopy. The frequency and volume of urination can vary with these cases, and total obstruction causes anuria. Salt and water reabsorption often are impaired as the problem persists, which results in hyponatremia (i.e., plasma sodium concentrations in the low normal range). Although the mechanisms for this sodium wasting arenot completely clear, the wasting apparently is related to impaired function of the ascending limb of Henle's loop and an increased medullary blood flow following prostaglandin release. Both of these events greatly diminish the magnitude and effect of the medullary countercurrent concentrating mechanisms. Prostaglandin also directly inhibits the effect of antidiuretic hormone.[40]

Measurement of specific gravity in the azotemic horse is a commonly practiced means of detecting prerenal ARF. In these cases the value is usually greater than 1.025 and often as high as 1.055. In human beings, one can use a number of reliable indexes to differentiate renal azotemia from prerenal azotemia[41–43] that are basedon urine osmolality and the ratio of urine to plasma osmolality (U/P_{osm}), urine sodium concentration and fractional sodium clearance, and ratios of urine to plasma urea concentrations (U/P_{UN}) and urine to plasma creatinine concentrations (U/P_{Cr}). Fractional sodium clearance in particular is a good indicator of solute reabsorption and proximal tubule function, whereas U/P_{Cr}, and to a lesser extent U/P_{UN}, are useful indexes of the ability of the tubules to reabsorb water. The utility of these indexes in horses also has been investigated and has been shown to have considerable differential diagnostic value.[16] Although these tests are discriminatory, some degree of overlap occurs between them respecting prerenal and parenchymal or intrinsic problems. One also must bear in mind that these indexes do not allow differentiation between intrinsic and postrenal disease. A number of horses with prerenal (nonoliguric) ARF have urine osmolality less than 360 mOsm. A small percentage of horses in prerenal ARF have U/P_{Cr} less than 30 (usually greater than 50) and fractional sodium clearance greater than 0.80% (usually less than 0.50%), most likely because of the unrecognized existence of tubule damage before volume depletion or because of a natriuretic effect of some treatments such as diuretics or intravenous fluids. Natriuresis is particularly likely to be induced along with bicarbonate administration because sodium cations are lost with unreabsorbed bicarbonate anions. In these cases the determination of the fractional chloride clearance may be a better indicator of the response of the kidney to hypoperfusion.

No parameter reliably differentiates between prerenal and ischemic ARF because of the pathophysiologic continuum between these diseases. At one end is reduced GFR with preserved tubule function and concentrating mechanisms. This form of disease is readily reversible with appropriate therapy. Additional or more prolonged decreases in GFR lead to disturbances in tubule function and slower reversal of damage, until the other end of the spectrum is reached, in which complete and irreversible loss of renal function occurs. Assessment of urine specific gravity before initiation of fluid therapy is helpful in differentiating prerenal from renal failure. As normally functioning kidneys would preserve salt and water maximally in response to a

transient decrease in RBF with prerenal failure, so urine specific gravity and osmolality are greater than the values associated with serum, whereas the urine produced by horses with intrinsic ARF is often isosthenuric (specific gravity less than 1.020). In a clinical situation, assessment of the response to fluid therapy is the most practical way to differentiate prerenal failure from intrinsic forms of ARF. Azotemia caused by prerenal problems should resolve quickly with replacement of fluid deficits and restoration of renal perfusion. In prerenal failure, volume repletion also should restore renal function, with the result that the magnitude of azotemia should decrease by 50% or more during the first day of therapy. In contrast, fluid therapy usually does not lead to prompt resolution of azotemia associated with intrinsic problems. Application of the measurement of U/P_{Cr} and U/P_{UN} ratios is limited to use on urine samples collected before initiation of fluid therapy or the first urine sample voided after fluid therapy has been started.

In prerenal ARF, electrolyte and acid-base abnormalities generally reflect problems caused by a primary disease (e.g., enterocolitis, colic, blood loss). Most frequently, horses are mildly acidotic, hyponatremic, and hypochloremic. Plasma concentrations of potassiumand calcium vary according to what disease is causing renal hypoperfusion. Potassium concentration also is affected to some extent by urine output, hyperkalemia being most common in association with oliguria and anuria.

The technique for biopsy of the left kidney has been well-described.[44] The main indication of kidney biopsyis 1226
to help differentiate between types of intrinsic renal disease when one thinks that this distinction will have 1227
therapeutic and prognostic relevance. One often can diagnose ischemic failure and ATN without biopsy. The primary complication associated with the biopsy procedure is renal hemorrhage, which can be severe. Ultrasonographic guidance and use of a spring-loaded biopsy instrument may reduce the risk of complications. Ultrasonography also allows biopsy of the right kidney. As the knowledge of equine renal physiology and pathology improves and advances in molecular genetics lead to techniques that supplant or supplement standard histopathologic methods, the diagnostic usefulness of renal biopsy may increase. For example, biopsy results may dictate the use of immunosuppressive agents in the treatment of some forms of renal parenchymal disease (e.g., interstitial nephritis).

Identification of subtypes of intrinsic ARF often depends on analysis of urine and urine sediment. The availability of a history of exposure to ischemic insults or potential nephrotoxins such as aminoglycosides certainly helps in this regard, but determination of the severity of the condition and its prognosis still generally relies on the analysis of urine. Ischemic tubule disease is similar to ATN. In both cases a slight to moderate proteinuria with specific gravities usually less than 1.020 and urine osmolality less than 350 mOsm occurs. Fractional sodium clearance is nearly always greater than 1.0, regardless of urine output. Granular casts frequently are visible, particularly with ATN. Enzymuria and phosphaturia are frequently prominent early in the course of ATN.[45,46] Plasma sodium and chloride concentrations are usually low. Plasma concentrations of calcium and inorganic phosphate vary greatly: increases, decreases, and normal values are possible, depending on the diet of the horse, the nephrotoxin, and the location and severity of damage to the nephron.[39,45]

One must remember that GFR is reduced in cases of ATN and is most likely caused by the increase in presentation of sodium and chloride at the macula densa following dysfunction of proximal sodium reabsorption. Stimulation of the macula densa results in release of renin and local production of angiotensin II, thus increasing renal vascular resistance and lowering RBF. The low GFR may mask the absolute magnitude of the damage in tubule function; however, if one studies renal sodium reabsorption carefully over time in cases of ATN, this defect appears to improve more rapidly than that of GFR.[47]

Acute interstitial nephritis often is not recognized in horses; however, in a study conducted about 20 years ago, the condition was diagnosed in approximately one eighth of all human patients who needed renal biopsy for diagnosis of unexplained ARF.[48]

The disease is characterized by edema and diffuseor focal patches of interstitial inflammation. In human medicine, the number of drugs, toxins, and infectious agents known to induce this disease is growing. No reason exists to believe that similar agents are not capable of causing the same disease in equids. Inflammatory cells surround the tubules and can move between epithelial cells into tubule lumina. As a result, white blood cell casts are common. The leukocytes are also capable of disrupting the tubule basement membrane, making cell repair much less likely, and this is an important distinguishing feature between ATN and interstitial nephritis. With the former disease the basement membrane usually stays intact. Reduction of GFR and azotemia probably result from the interstitial edema, intratubular obstruction, and release of vasoactive agents.

Acute interstitial nephritis and ATN have similar fractional sodium clearance, U/P_{Cr}, and U/P_{osm} values; however, the urine sediment may be different for each disease. Sterile pyuria and microscopic hematuria commonly occur with interstitial nephritis, although red blood cell casts are rare. Mild proteinuria and eosinophiluria are also common. Eosinophiluria generally seems to be limited to renal interstitial disease, mainly drug-induced interstitial nephritis but also chronic pyelonephritis and systemic lupus erythematosus.[49,50] Eosinophiluria may or may not be accompanied by eosinophilia. Eosinophils in equine urine should be easy to observe using Wright's stain, given the alkaline nature of the fluid. Occasionally, fevers are believed to be associated with the development of interstitial nephritis. This clinical sign is relatively nonspecific and might be misleading if the animal is being treated with antibiotics for an infection. What one might see with close monitoring of the patient is an initial reduction or resolution of the fever after the onset of antimicrobial therapy followed by recurrence of the fever and development of azotemia. If this happens, acute interstitial nephritis should be on the rule-out list.

Acute glomerulonephritis usually is characterized by the nephrotic syndrome. Proteinuria is moderate to severe, and the urine usually is concentrated. Urine osmolality and U/P_{osm} are comparable with the values with prerenal ARF and are higher than those values normally seen in ATN. Urinary sodium concentration and fractional sodium clearance tend to be much lower than with other intrinsic renal and postrenal causes of ARF. The ratios of U/P_{UN} and U/P_{Cr} are often similar to those associated with prerenal failure and higher than those in ischemic, tubular, interstitial, or postrenal disease. Renal tubular secretion of creatinine is increased in glomerulonephritis, with the result that serum creatinine concentrations may not rise quickly and urea nitrogen-to-creatinine ratios stay high, as they frequently do with prerenal problems. Therefore although urinary indexes should make possible differentiation of acute glomerulonephritis from other parenchymal and postrenal 1227
diseases, they overlap much with those associated with prerenal ARF. One is going to differentiate ARF caused 1228
by acute glomerulonephritis from that caused by hypoperfusion based on the significant proteinuria and red cell numbers usually associated with the former disease. Red cell casts are more common with glomerulonephritis than with other intrinsic causes of ARF. Some causes of postrenal ARF also may manifest red cell casts, but the proteinuria is not normally as great in those situations.

17.4.5 Treatment

Initially, treatment of horses with ARF should focus on reversing the inciting or underlying cause and correcting fluid and electrolyte imbalances. Early identification of patients at risk and prevention of problems by rapid restoration and accurate maintenance of intravascular fluid volume, glomerular filtration, and urine

production, with fluids and possibly diuretics, is obviously preferable to treatment. The importance of prevention cannot be overstated. One should correct initial fluid deficits over the first 6 to 12 hours of treatment. Physiologic saline or a balanced electrolyte solution is the fluid of choice unless the patient is hypernatremic, as may be the case in prerenal ARF or acute glomerulonephritis. In the event of hypernatremia, a solutions of 0.45% sodium chloride and 2.5% dextrose is recommended. The addition of 50 to 100 g of dextrose per liter of fluid to saline or polyionic fluids helps address the caloric needs of anorectic horses. If fluid administration is begun early in the course of the disease or if the problem is not severe, diuresis should result. When this occurs, one should maintain intravenous fluid therapy at 40 to 80 ml/kg per day until serum creatinine concentration decreases dramatically. One then reduces the rate of fluid administration to 10 to 20 ml/kg per day until the creatinine concentration is normal or the horse is eating and drinking adequately.

In the event that the horse remains oliguric 10 to12 hours after starting fluid therapy, administration of dopamine in 5% dextrose slowly (3 to 5 μg/kg/min) may improve RBF and urine output. One should monitor blood pressure during dopamine infusion because the drug can induce significant hypertension. One should discontinue administration of dopamine if blood pressure starts to rise. One can attempt to restart the infusion at a lower rate when pressure has returned to normal. Blood pressure also may increase because of overhydration of oliguric patients who are receiving isotonic fluids. Regular monitoring of body weight, hematocrit, and serum total protein concentration, central venous pressure, and lung sounds is important if one is to avoid problems caused by overhydration.

The use of diuretic agents such as mannitol and loop diuretics to treat ARF is controversial. Furosemide and ethacrynic acid are the loop diuretics most commonly used. Furosemide is a particularly potent short-acting agent that acts by blocking the $Na^+/K^+/2Cl^-$ cotransporter in the ascending limb of the loop of Henle. In addition to promoting diuresis, cotransporter inhibition also may protect these tubule cells by reducing their metabolic rate and thus oxygen demand in the face of limited oxygen availability following hypoperfusion. To be effective, loop diuretics must gain access to the tubule lumina. Therefore loop diuretics may be of limited value in prerenal or ischemic problems, although the potential protective effect of furosemide on the especially vulnerable cells of the thick ascending limb may warrant its administration. Loop diuretic administration also may exacerbate or induce volume depletion in cases of ARF that are characterized by isosthenuria or polyuria (such as early ATN), thus making the condition worse and rendering the patient more susceptible to the effects of nephrotoxins such as gentamicin. Loop diuretics appear to be most beneficial when used in cases characterizedby tubule obstruction (e.g., pigmenturia) because the diuretic-induced increase in solute retention apparently helps flush these blockages and casts from the tubules.

Although loop diuretics have no direct effect on GFR, 20% mannitol (0.25 to 1.0 g/kg) given over 15 to20 minutes may help combat oliguria by increasing RBF and GFR. The increase occurs following reductions in plasma protein concentration and oncotic pressure. These changes in turn result from the systemic effects of the increase in intravascular osmolality induced by the mannitol. Mannitol also may induce synthesis of the vasodilator PGE_2 and release of atrial natriuretic peptide, which also would increase RBF and GFR. Once filtered, the agent also acts as an osmotic diuretic, thus decreasing urine solute concentration and boosting urine volume. Consequently, mannitol also can be effective in treating conditions characterized by tubular obstruction and swelling of tubule cells.

Hyperkalemia is uncommon in equine ARF, exceptin some postrenal cases. When present, hyperkalemia is usually mild and responds to administration of potassium-free intravenous fluids. When hyperkalemia (greater than 6.5 mEq/L) persists, correction of any associated acidosis with sodium bicarbonate and/or administrationof glucose (up to 10% solution) usually helps. In the worst or most refractory cases, insulin may be necessary.

Potassium supplementation (potassium chloride 20 to 40 mEq/L) may be necessary during the polyuric phase of recovery from ARF.

Calcium metabolism often is disrupted in cases of equine ARF, with hypocalcemia and hyperphosphatemia or hypercalcemia and hypophosphatemia having been reported variously. Hypercalcemia usually resolves witha 1228
switch to a grass or grass-hay diet and with time. Hypocalcemia probably results for a number of reasons, 1229
including skeletal resistance to parathyroid hormone during the early stages of ARF and deficiency of1,25-dihydroxycholecalciferol, which results from downregulation of renal 1,25-hydroxylase by the hyperphosphatemia, dysfunction of this enzyme following renal parenchymal damage, or both.[46,51] Hypoalbuminemia and enhanced deposition of calcium in injured tissues, as can occur in cases of rhabdomyolysis, are other factors to consider. Administration of a calcium salt as part of the intravenous fluid therapy protocol is usually sufficient to correct this.

Severe uremia often decreases red blood cell life span and induces platelet dysfunction. Consequently, anemia (possibly also caused by decreased production of erythropoietin) and bleeding tendencies may be associated with ARF. These conditions may require treatment with transfusions, synthetic erythropoietin, or conjugated estrogens.

Because aminoglycoside toxicity is one of the more commonly recognized causes of equine ARF,[4,9,52] continued aminoglycoside use in horses with ARF warrants specific attention. Gentamicin and amikacin are the aminoglycoside antibiotics most often used in equine practice, and their pharmacokinetics have been well studied in healthy animals. Large interindividual and age variations occur in the volume of distribution and clearance of these drugs in normal horses, and this variability is even greater in diseased horses. Therefore when a patient with ARF requires aminoglycoside antibiotics, monitoring serum trough concentrations of the drugto adjust the dosing interval is strongly indicated, for it provides the best protection against exacerbating renal damage. Renal dysfunction associated with aminoglycoside toxicity usually is indicated by an increase of at least 0.3 mg/dl in serum creatinine concentration. When this occurs, one should consider discontinuing therapy or increasing the dosing interval. One must remember that changes in urine sediment and development of enzymuria, mild proteinuria, glucosuria, and decreased urine-concentrating ability develop a number of days before serum creatinine concentration increases and are good indicators of the development of aminoglycoside nephrotoxicity. One usually can address the problem successfully by maintaining or increasing intravenous fluid therapy to guard against renal hypoperfusion and by appropriately adjusting the dosing interval with the antibiotic.

17.4.6 Prognosis

The prognosis for equine ARF depends on the underlying cause, the duration of renal failure, the response to initial treatment, and the development of secondary complications such as diarrhea, thrombophlebitis, and laminitis. Generally speaking, the duration of ARF before beginning therapy is the most important determinant of prognosis. Of the primary causes of ARF, severe ischemic failure and acute interstitial nephritis probably carry the worst prognosis in horses. ARF of any cause, however, should be associated with a reduced or poor prognosis in the event that early interruption of the pathophysiologic events leading to the ARF is not achieved or that the animal displays prolonged oliguria or anuria (longer than 12 hours) after institution of vigorous therapy. Most cases of postrenal ARF carry a favorable prognosis, provided the initiating disease is treated successfully. When discussing prognosis with horse owners, practitioners always must bear in mind that a successful outcome is not always associated with complete return of normal function. Many horseslive long after a bout of ARF but never fully regain theability to concentrate urine as well as they did beforethe disease;

or else they remain constantly polyuric. Acute tubular necrosis, following nephrotoxicity in particular, carries a favorable prognosis when tubule basement membranes remain intact.

17.5 17.5—Chronic Renal Failure

Harold C. Schott, II

17.5.1 Predisposing Conditions

Chronic renal failure (CRF) is recognized infrequentlyin horses. For dogs and cats the prevalence of CRF has been reported to be 0.9% and 1.6%, respectively,[1] whereas the Veterinary Medical Data Base at Purdue University reported that only 515 of 442,535 horses admitted to participating veterinary teaching hospitals during the years 1964 through 1996 had CRF (prevalence of 0.12%). In actuality, this may be an underestimate, because when a diagnosis of CRF is established for a horse, the horse likely may be destroyed without presentation to a veterinary teaching hospital. As in dogsand cats, CRF appears to be a greater problem in older horses: the prevalence increased to 0.23% in horses older than 15 years. The 0.51% prevalence for intact males older than 15 years of age also suggests that stallionsmay be at greater risk.

Although the clinical syndrome of CRF is uncommon, one widely cited abattoir study revealed that 16% of 45 horses examined had glomerular lesions on light microscopic examination and 42% (22 of 53 horses examined) exhibited deposits of immunoglobulin or complement on immunofluorescence staining of tissue samples.[2] Although these findings suggest that as many as one third of horses may show microscopic evidence of renal disease, only one of the horses in this survey exhibited signs of CRF. This disparity can be attributed to a large renal reserve capacity, for clinical signs ofrenal failure do not become apparent until two thirds to three fourths of functional nephrons have been lost.[3] Although this rule of thumb is based on studies of partially

nephrectomized laboratory animals, supportfor similar renal reserve capacity in horses is found in several clinical reports of unilateral nephrectomy used successfully to manage disorders of the upper urinary tract.[4–8] In addition, after experimental unilateral nephrectomy in ponies[9] and horses (R. DeBowes, personal communication, 1991), renal function remained within normal ranges and the animals maintained body weight.

Disorders of the kidneys leading to CRF may be congenital or acquired. In horses younger than 5 years with a history that includes no event that might have been complicated by acute renal failure, one should suspect a congenital renal disorder: renal agenesis, hypoplasia, dysplasia, or polycystic kidney disease.[10–23] Although each of these congenital abnormalities occasionally is recognized, acquired disease consequent to glomerular or tubular injury is more often the cause of CRF in horses.[24–30] Acquired disease is usually insidious in onset, and renal injury may have been initiated years earlier. Thus identifying the cause of CRF is challenging because many horses have evidence of advanced glomerular and tubular disease, termed *end-stage kidney disease*, by the time clinical signs of CRF develop. Nevertheless, knowing the various causes of CRF affords a better overall understanding of CRF in horses.

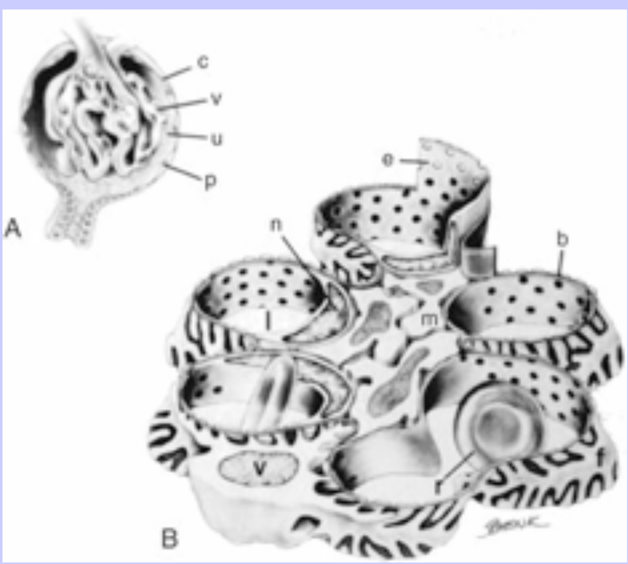
17.5.1.1 GLOMERULONEPHRITIS

Glomerular injury is a common precipitant of renal insufficiency and CRF in horses. Although immune-mediated glomerular injury is implicated most oftenin glomerulonephritis, glomerular integrity can be disrupted by a number of unrelated disease processes, including ischemia, toxic insults, and infection.[31] These mechanisms usually lead to significant vascular and tubulointerstitial changes in addition to glomerular injury. Thus the designation *glomerulonephritis* typically is reserved to denote renal disease of which immune-mediated glomerular damage is suspected to be the initiating factor in development of renal failure. Until the last decade, glomerulonephritis was considered a rare cause of CRF in domestic animals; interstitial nephritis was implicated more often.[32–34] Refinement of histologic examination with immunofluorescence staining techniques and electron microscopic examination of renal tissues has led to increased recognition of subclinical and clinically significant glomerulonephritis.[34]

A brief review of the subgross anatomy of the glomerulus sheds light on the pathophysiology of glomerulonephritis. The renal corpuscle, or glomerulus, is comprised of a tuft of glomerular capillaries surrounded by epithelial cells that line Bowman's capsule. The root that supports the pedicle of the glomerular capillary network is similar to the mesenteric root that supports the intestinal tract, and Bowman's capsule is analogous to the peritoneum (Figure 17.5-1, *A*). On a microscopic level, components of the glomerulus include capillary endothelial cells, mesangium (cells and matrix), glomerular basement membrane (GBM), and visceral epithelial cells. At the vascular pedicle, the latter become contiguous with parietal epithelial cells that line Bowman's space, much as mesothelial cells covering bowel serosa and mesentery become contiguous with the peritoneum at the mesenteric root.[31] Glomerular capillary endothelial cells are unique in that they are fenestrated with pores that represent the initial barrier for passage of blood components into the urinary space (Figure 17.5-1, *B*). The mesangium, which lies between endothelial and 1231
epithelial cells, is the support structure of the glomerular capillaries and is analogous to the mesenteric tissue 1232
supporting bowel. Mesangial cells are a component of the reticuloendothelial system and phagocytize macromolecular substances, among them are fragments of old GBM or larger molecules that pass through endothelial cell pores but cannot pass subsequently through the GBM. In addition, mesangial cells have contractile elements that allow them to participate in regulation of glomerular hemodynamics. Furthermore, these cells proliferate in response to glomerular injury and can release a number of cytokines that modulate the glomerular inflammatory response.[35] The GBM lies between endothelial and epithelial cells and

surrounds glomerular capillaries, except where mesangium is present (Figure 17.5-2, *A*). Returning to the abdominal cavity analogy, the GBM would lie beneath bowel serosa except in the area of mesenteric attachment, which would contain mesangial cells and matrix. The GBM consists of a central electron-dense layer, the lamina densa, and two thinner, more electron-lucent layers, the lamina rara externa and the lamina rara interna (Figure 17.5-2, *B*).[31,36] The main components of the GBM are collagen-like molecules and matrix glycoproteins that are produced principally by visceral epithelial cells. Normal GBM undergoes steady turnover with removal of debris by mesangial cells. The visceral epithelial cells, also called podocytes, cover the uriniferous duct side of the GBM and have many cytoplasmic extensions called foot processes that form extensive interdigitations with foot processes of adjacent epithelial cells. The narrow gap between foot processes—the filtration slit or slit pore—is bridged by a thin membrane, the slit pore diaphragm.[31,36]

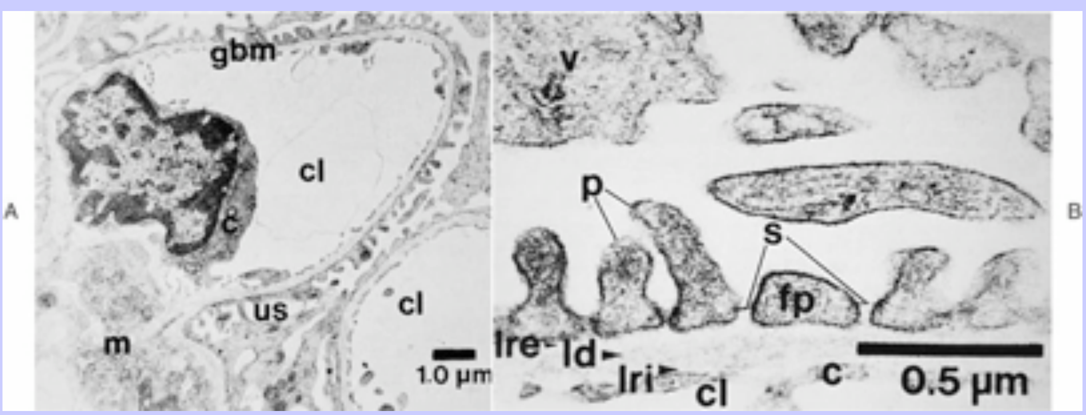
Figure 17.5-1 Subgross anatomy of a renal corpuscle. **A**, A renal corpuscle with a tuft of glomerular capillaries surrounded by Bowman's capsule *(c)* shows visceral *(v)* and parietal *(p)* epithelial cells separated by the urinary space *(u)*.**B**, Cross section of a portion of a glomerulus shows the nucleus *(n)* and fenestrations *(e)* of capillary endothelial cells, the glomerular basement membrane *(b)*, mesangial cells *(m)* separated by mesangial matrix, and the nucleus *(v)* of a visceral epithelial cell. A red blood cell *(r)* is in the lumen *(l)* of one of the glomerular capillaries. (From Osborne CA, Hammer RF, Stevens JB et al: The glomerulus in health and disease: a comparative review of domestic animals and man, *Adv Vet Sci Comp Med* 21:207, 1977.)



The filtration barrier of the glomerulus consists of fenestrated endothelial cells, GBM, and slit pores between epithelial cell foot processes. These structures constitute a size-selective and charge-selective filtration barrier. Although all components of this barrier are anionic (i.e., they repel anionic macromolecules), the GBM is thought to be the principal agent of the permeability characteristics of the filtration barrier. The GBM is rich in glycosaminoglycans, containing heparan sulfate and sialic acid residues. These strongly anionic molecules are responsible for its negative charge barrier, which limits filtration of anionic macromolecules, predominantly albumin.[36,37]

Glomerulonephritis is initiated by deposition of circulating immune complexes along the GBM and in the mesangium, leading to complement activation and leukocyte infiltration and adherence. Release of oxidants and proteinases by neutrophils and macrophages; production of eicosanoids, cytokines, and growth factors by macrophages and mesangial cells; and platelet aggregation and activation of coagulation factors lead to endothelial and epithelial cell swelling (with fusion of foot processes), formation of microthrombi in glomerular capillaries, and mesangial cell proliferation.[31,37,38] Immune complexes can be deposited in a subendothelial, intra-GBM, or subepithelial site, depending on their size and charge properties, but most tend to be found in the subendothelial space. On electron microscopic examination these immune complexes appear as electron-dense granular deposits (Figure 17.5-3, *A*), and staining with anti–immunoglobulin G and anticomplement (C3) antibodies reveals an irregular (granular or "lumpy bumpy") immunofluorescence staining pattern (Figure 17.5-3, *B*).[2,31,37] The GBM proliferates to surround the immune deposits, leading to irregular thickening ofthe filtration barrier. Despite widening of the filtration barrier, the size-selective and charge-selective filtration properties are compromised, and microscopic hematuria and proteinuria result. In rare instances, glomerulonephritis may be attributed to a true autoimmune disorder in which autoantibodies directed against GBM components (e.g., type IV collagen) are produced. Electron microscopic examination
in these cases also reveals GBM thickening with predominantly subepithelial electron-dense deposits (Figure 1232
17.5-4, *A*), and immunofluorescence staining shows a more regular or smooth, linear pattern of 1233
immunofluorescence (Figure 17.5-4, *B*).[31,39,40] Autoimmune glomerulonephritis, accompanied by proteinuria, also has been described as one of the manifestations of systemic lupus erythematosus in horses.[41] Another immune mechanism of glomerulonephritis in horses is production of mixed or monoclonal cryoglobulins and deposition of antibody-antibody immune complexes along the glomerular GBM.[42,43] Cryoglobulinemia is associated with a number of diseases in human beings[42,44] but has been described in only a few horses.[43,45] Deposition of antibody-antibody immune complexes along the GBM may be a more important precipitant of glomerulonephritis than was recognized previously because electron microscopic examination is required to demonstrate characteristic fibrillar or crystalline intracapillary and subendothelial deposits associated with the condition.[42] Regardless of what immune mechanism leads to glomerular injury, the end result is thickening of the filtration barrier, retarded glomerular filtration rate, and development of CRF in severe cases.

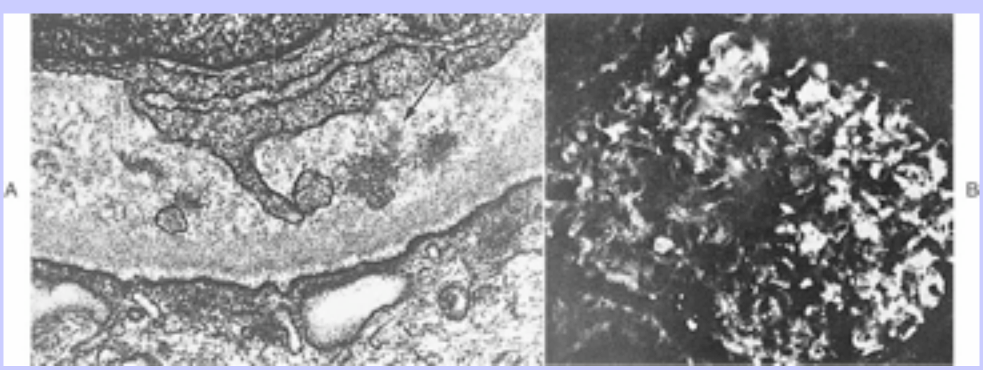
Figure 17.5-2 Electron micrograph of a normal glomerulus. **A**, Low-power magnification illustrates patent capillary lumens *(cl)* separated from the urinary space *(us)* by fenestrated endothelial cell cytoplasm *(c)*, the glomerular basement membrane *(gbm)*, and foot processes of visceral epithelial cells. Mesangial cells and matrix *(m)* are also apparent (bar = 1.0 μm). **B**, Higher-power magnification reveals the ultrastructural features of the filtration barrier including, from bottom to top, the capillary lumen *(cl)* and endothelial cell cytoplasm *(c);* the lamina rara interna *(lri)*, lamina densa *(ld)*, and lamina rara externa *(lre)* of the glomerular basement membrane; and cytoplasm *(v)*, foot processes *(fp)*, and slit diaphragms *(s)* of the visceral epithelial cells. Deposits of glomerular polyanion or glycosaminoglycans *(p)* are visible on the foot processes (bar = 0.5 μm). (From Osborne CA, Hammer RF, Stevens JB et al: The glomerulus in health and disease: a comparative review of domestic animals and man, *Adv Vet Sci Comp Med* 21:207, 1977.)



Although a number of terms are used to describe the specific morphologic changes associated with glomerular injury, glomerulonephritis is categorized most broadly histologically as proliferative or membranous.[31,34,37] Proliferative (or mesangioproliferative) glomerulonephritis describes glomerular injury associated with influx of inflammatory cells and proliferation of mesangial cells. The predominant histologic finding is increased cellularity in glomeruli (Figure 17.5-5, *A* and *B*). This lesion tends to be associated with the more acute stages of glomerulonephritis during which immune complexes are being deposited in a predominantly subendothelial site. *Membranous glomerulonephritis* describes glomerular injury

accompanied by significant thickening of the capillary wall and GBM, and with periodic acid–Schiff staining the predominant histologic finding is increased in the mesangial area and on the GBM (Figure 17.5-5, *C*). Methenamine silver stain further enhances visibility of the thickening of the GBM.[31,34] Membranous glomerulonephritis tends to be associated with more soluble immune complexes or autoantibodies that can pass through the GBM and localize in a predominantly subepithelial site, resulting in less infiltration of inflammatory cells. As would be expected, a spectrum of lesions is visible in naturally occurring glomerulonephritis, leading to varying histologic descriptions of the disease (membranoproliferative 1233
glomerulonephritis). As glomerular injury progresses, proliferation of the parietal epithelium also occurs, 1234
likely in response to filtration of macromolecules and cellular debris. Lesions associated with parietal cell proliferation can include layering of epithelial cells (termed *crescents*) on the inner aspect of Bowman's capsule (Figure 17.5-6, *A*), adhesion formation between the glomerular tuft and Bowman's capsule (Figure 17.5-6, *B*), and tuft collapse. *Glomerulosclerosis* describes the end stage of progressive, irreversible glomerular injury in which replacement of glomerular components with hyaline material is visible on histologic examination (Figure 17.5-6, *C*).[31]

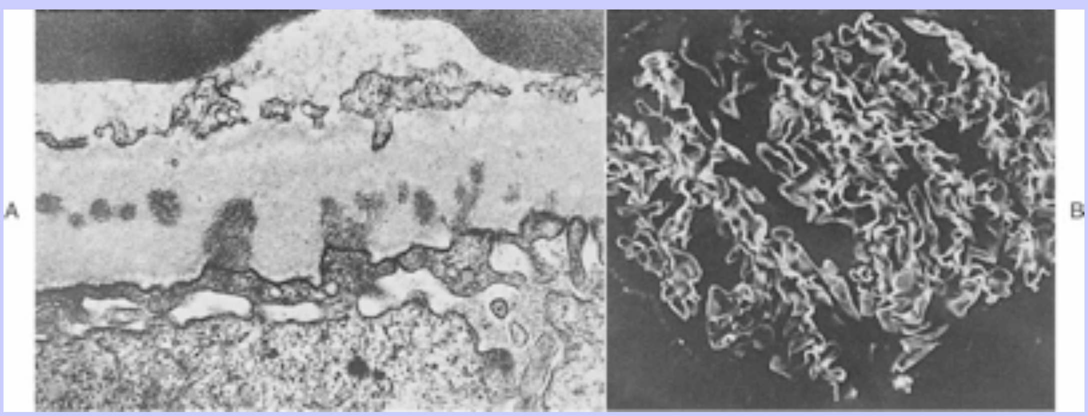
Figure 17.5-3 Immune-mediated glomerulonephritis in a horse 165 days after experimental infection with equine infectious anemia virus. **A**, An electron micrograph (×32,500) shows endothelial cell swelling *(top)*, thickening of the glomerular basement membrane with electron-dense immune deposits in a predominantly subendothelial location *(arrow)*, and fusion of foot processes of the visceral epithelial cells. **B**, Immunofluorescent staining with fluorescein-tagged antiequine immunoglobulin G antibody (×100) demonstrates granular or “lumpy bumpy” deposits of immunoglobulin G along the glomerular basement membrane and in the mesangium. (From Banks KL, Henson JB, McGuire TC: Immunologically mediated glomerulitis of horses. 1. Pathogenesis in persistent infection by equine infectious anemia virus, *Lab Invest* 26:701, 1972.)



Specific histologic categorization of glomerulonephritis provides etiologic and prognostic information for human beings with renal failure attributable to glomerular disease.[35,44] Subcategorization of glomerulopathies also has been done in a prospective study of naturally occurring chronic renal disease in canines. Although classifications—including focal glomerulonephritis, mesangioproliferative glomerulonephritis, endocapillary proliferative glomerulonephritis, crescentic glomerulonephritis, and sclerosing glomerulonephritis—could be made, histologic findings were not prognostically useful.[46] This study also revealed that glomerular disease was responsible for 52% of canine CRF; however, an inciting disease (vegetative endocarditis) could be identified in only one of 31 dogs with glomerulonephritis.

Glomerulonephritis also appears to be an important cause of CRF in horses.[47] Of 60 reported cases of CRF attributable to acquired disease, glomerulonephritis was identified as the inciting cause of CRF in 32 (53%) (Table 17.5-1).[24–26,38,42,43,48–60] Glomerulonephritis also may be the initiating disease process in cases of end-stage kidney disease (ESKD) for which gross and histopathologic changes are so extensive that a primary mechanism of renal injury cannot be identified. A number of systemic inflammatory and infectious disease processes in horses may be accompanied by glomerulonephritis, but progression to CRF appears to be a rare sequela. For example, experimental *Leptospira pomona* infection produced subacute glomerulonephritis characterized by hypercellularity and edema of capillary tufts,[61] but leptospirosis appears to be a rare cause of clinical renal disease in horses.[62–64] Similarly, experimental infection with equine infectious anemia virus produced histologic and immunofluorescent evidence of glomerulonephritis in 75% and 87% of infected horses, respectively.[39] Immunoglobulins with anti–equine infectious anemia activity were eluted from glomeruli collected from experimentally infected horses, but none of the horses showed clinical signs of renal disease. Poststreptococcal glomerulonephritis is a well-recognized cause of renal disease in human beings,[35,65] and Roberts and Kelly speculated that glomerulonephritis in a horse with 1234
chronic pleuritis and purpura hemorrhagica likely resulted from circulating immune complexes involving 1235
streptococcal antigens.[66] Recently, Divers, Timoney, Lewis, et al. provided support for this hypothesis by eluting group-C streptococcal antigens from immune complex deposits in glomeruli collected from a horse with CRF.[60] Finally, an occasional case of equine glomerulonephritis may result from true autoimmune disease, and in one instance, anti-GBM antibody was eluted from glomeruli with linear GBM immunofluorescent staining pattern isolated from a horse.[2] Little information is available about histopathologic subcategories of glomerulonephritis in horses, although several reports have attempted to make comparisons with glomerular lesions that have been better characterizedin other species.[42,58,67] No reports have attempted to correlate histologic changes with the degree of renal failure in horses. Thus assessment of the severity ofrenal disease associated with glomerulonephritis in horses currently is based more on clinical findings (e.g., body condition, magnitude of azotemia) than on histologic changes in a renal biopsy sample.

Figure 17.5-4 Spontaneous immune-mediated glomerulonephritis in a horse. **A**, An electron micrograph (×22,750) shows a red blood cell in the capillary lumen *(top)*, relatively normal fenestrated endothelial cytoplasm, thickening of the glomerular basement membrane with electron-dense immune deposits in a predominantly subepithelial location, and fusion of foot processes of the visceral epithelial cells. **B**, Immunofluorescent staining with fluorescein-tagged antiequine immunoglobulin G antibody (×160) demonstrates smooth, linear deposits of immunoglobulin G. (From Banks KL, Henson JB, McGuire TC: Immunologically mediated glomerulitis of horses. 2. Antiglomerular basement membrane antibody and other mechanisms of spontaneous disease, *Lab Invest* 26:708, 1972.)



17.5.1.2

CHRONIC INTERSTITIAL NEPHRITIS

Tubulointerstitial disease usually results from acute tubular necrosis following ischemia, endotoxemia, sepsis, or exposure to nephrotoxic compounds. Hypovolemia associated with acute blood loss, colic, diarrhea, endotoxemia, or sepsis can lead to renal hypoperfusion and ischemic damage.[68] Severe localized infection (e.g., pleuritis, peritonitis) or septicemia also may be accompanied by tubule damage. Aminoglycoside antibiotics, nonsteroidal antiinflammatory drugs (NSAIDs), vitamin D, vitamin K_3, acorns, and heavy metals such as mercury are potentially nephrotoxic.[69] Intravascular hemolysisor rhabdomyolysis also can lead to acute tubular damage following the nephrotoxic effects of hemoglobin and myoglobin (see Chapter 17.4). In horses tubulointerstitial disease culminating in CRF also can be causedby ascending urinary tract infection resulting in pyelonephritis[24,26,56,70–75] or bilateral obstructive disease caused by ureteroliths or nephroliths.[21,26,76–81] In other cases a cause of the tubule disease may not be identified.[82,83] Finally,

although this has not yet been described in horses, immune mechanisms, including anti–tubular basement membrane disease, can lead to chronic interstitial nephritis (CIN) in human beings.[84]

Chronic interstitial nephritis is defined most strictly by clinical signs of renal disease associated with histologic changes of tubular damage and an interstitial inflammatory cell infiltrate (Figure 17.5-7).
Inflammatory cells include lymphocytes, monocytes, and occasionally plasma cells. Neutrophils are 1235
uncommon; however, eosinophilic infiltrates suggest drug reactions in human patients.[84] Major glomerular 1237
and vascular lesions arenot apparent. The hallmark that distinguishes CINfrom acute tubular and interstitial disease is interstitial fibrosis.

Figure 17.5-5 Histologic changes in equine glomerulonephritis. **A**, Photomicrograph of a normal glomerulus. Bowman's capsule is lined by flattened parietal epithelial cells *(p)*. Visceral epithelial cells *(v)* are adjacent to the glomerular basement membrane, which is of uniform thickness. Mesangial cells *(m)* are surrounded entirely by glomerular capillaries (×100, periodic acid–Schiff stain). **B**, Photomicrograph demonstrates proliferative glomerulonephritis in a horse after experimental infection with equine infectious anemia virus. A combination of neutrophil infiltration *(arrows)* and mesangial cell proliferation is apparent (×160, hematoxylin-eosin stain). **C**, Photomicrograph demonstrates membranous glomerulonephritis in a horse after experimental infection with equine infectious anemia virus. The glomerular basement membranes are thickened *(A)* and mesangial areas contain periodic acid–Schiff–positive material *(B)* (×160, periodic acid–Schiff stain). (**A** from Osborne CA, Hammer RF, Stevens JB et al: The glomerulus in health and disease: a comparative review of domestic animals and man, *Adv Vet Sci Comp Med* 21:207, 1977; **B** and **C** from Banks KL, Henson JB, McGuire TC: Immunologically mediated glomerulitis of horses. 1. Figure 17.5-6 Progressive histologic changes in equine glomerulonephritis. **A**, Photomicrograph of a renal biopsy specimen illustrates membranoproliferative glomerulonephritis (an increase in cell numbers and thickening of the glomerular basement membrane) and parietal epithelial cell proliferation resulting in crescent formation (*arrow*, ×100, periodic acid–Schiff stain). **B**, Photomicrograph demonstrates progressive glomerulonephritis resulting in adhesion formation between the capillary tuft and proliferating parietal epithelial cells. **C**, Photomicrograph of end-stage glomerulosclerosis shows replacement of glomerular components with hyaline material (more complete in glomerulus on the left). (**A** from Osborne CA, Hammer RF, Stevens JB et al: The glomerulus in health and disease: a comparative review of domestic animals and man, *Adv Vet Sci Comp Med* 21:207, 1977; **B** and **C** from Fincher MG, Olafson P: Chronic diffuse glomerulonephritis in a horse, *Cornell Vet* 24:356, 1934.)

Although CIN has a fairly strict histologic definition, a number of disease processes can lead to tubular damage. For all practical purposes, CIN is a catchall term for extraglomerular causes of CRF in horses. As a consequence, gross findings in horses with CIN can vary dramatically. For example, analgesic nephropathy (NSAID toxicity, of which phenylbutazone has the greatest nephrotoxic potential[85]) can produce papillary necrosis[86,87] manifested by hematuria[88] in the early stages of disease, whereas chronic disease may be associated with nephrolithiasis and hydronephrosis. The area of papillary necrosis serves as a nidus for stone formation, and subsequent obstructive disease leads to hydronephrosis.[78,81] Similarly, upper urinary tract infection can lead to minor or major changes in the architecture of the kidneys and to variable histologic changes. 1237

TABLE 17.5-1 Causes of Chronic Renal Failure in 75 Horses (Excluding Reports of Congenital Renal Failure and Experimental Induction of Chronic Renal Failure)

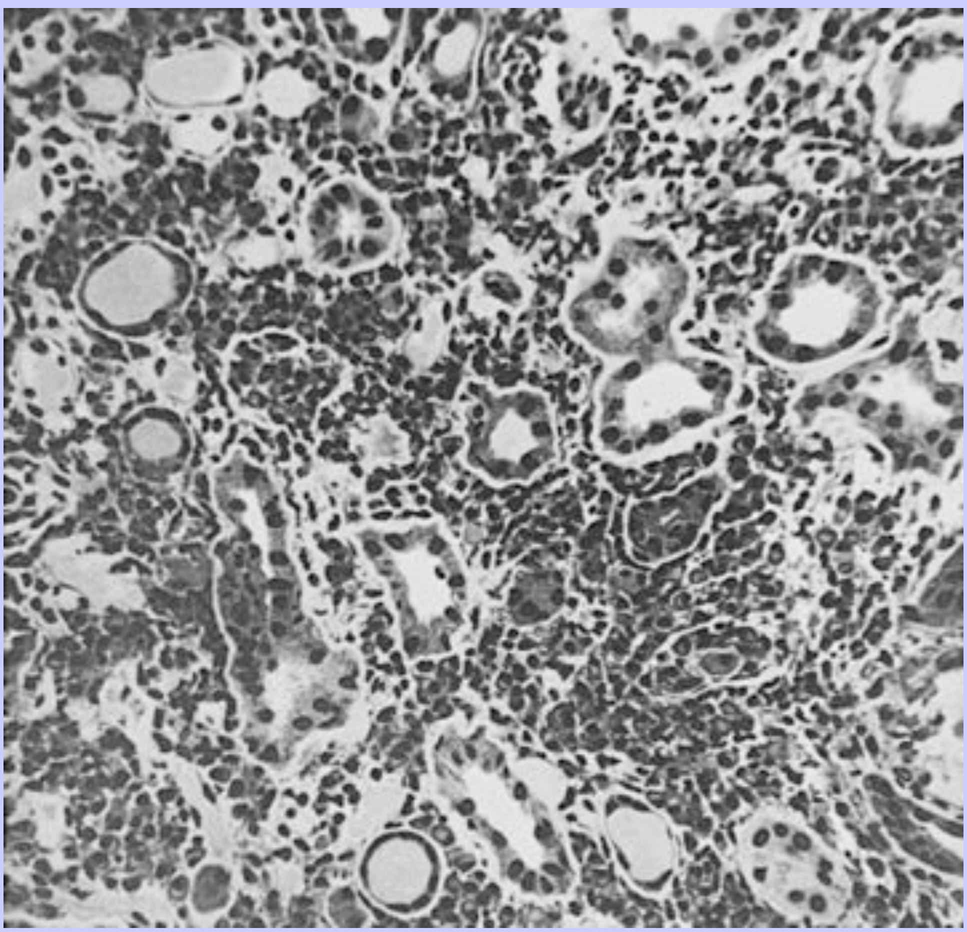
DISORDERS	NUMBER OF CASES	REFERENCES (NUMBER OF CASES)
CONGENITAL DISORDERS (15 OF 75 [20%])		
Renal agenesis/contralateral obstruction and hydronephrosis	1	10 (1)
Renal hypoplasia	4	12 (3); 23 (1)
Renal dysplasia	6	13 (1); 14 (1); 15 (2); 20 (1); 21 (1)
Polycystic kidney disease	4	17 (1); 18 (1); 19 (1); 22 (1)
ACQUIRED DISORDERS (60 OF 75 [80%])[*]		
Glomerulonephritis	32	24 (1); 25 (2); 26 (1); 38 (1); 42 (7); 43 (1); 48 (1); 49 (1); 50 (1); 51 (1); 52 (1); 53 (1); 54 (1); 55 (1); 56 (5); 57 (2); 58 (1); 59 (2); 60 (1)
Chronic interstitial nephritis	2	82 (1); 83 (1)
With obstructive nephrolithiasis and/or ureterolithiasis	11	76 (1); 77 (1); 78 (7); 79 (1); 80 (1)
With pyelonephritis	8	24 (1); 26 (1); 56 (1); 71 (1); 72 (1); 73 (1); 74 (1); 75 (1)
With papillary necrosis	2	26 (1); 86 (1)
End-stage kidney disease[†]	5	83 (1); 89 (1); 90 (1); 91 (1); 92 (1)

* In many reports of acquired renal disease leading to chronic renal failure, histopathologic changes involve glomeruli and interstitium. Categorization in this table is based on author's conclusions in these reports. When severe lesions involved glomeruli and interstitium, a categorization of end-stage kidney disease was made.

† End-stage kidney disease and reports of oxalate nephropathy.

Using CIN as a broad category for nonglomerulonephritis causes of CRF in horses, this group of tubulointerstitial diseases was responsible for 38% (23 of 60) of the previously reported cases of CRF in horses (see Table 17.5-1). Although in theory CIN would be expected to be accompanied by greater evidence of tubular dysfunction (e.g., enzymuria, glucosuria, and increased fractional clearance of sodium), abnormal measures of tubule function have not been detected regularly. Similarly, microscopic hematuria and proteinuria, the hallmarks of glomerular disease, would not be expected.

Figure 17.5-7 Histologic changes in interstitial nephritis. The interstitium contains dense infiltrates of lymphocytes and plasma cells superimposed on moderate interstitial fibrosis and tubular atrophy (×275, hematoxylin-eosin stain). (From Bennett WM, Elzinga LW, Porter GA: Tubulointerstitial disease and toxic nephropathy. In Brenner BM, Rector FC, editors: *The kidney*, ed 4, vol 2, Philadelphia, 1991, WB Saunders.)



17.5.1.3 END-STAGE KIDNEY DISEASE

End-stage kidney disease describes the severe gross and histologic changes in kidneys collected from animals in the final stages of CRF. Grossly, the kidneys typically are pale, shrunken, and firm, and they may have an irregular surface and an adherent capsule. Histologically, severe glomerulosclerosis occurs along with hyalinization and extensive interstitial fibrosis. The end-stage lesions make determining the initiating cause of renal disease virtually impossible. In several cases with a pathologic description consistent with ESKD the underlying cause of renal injury could not be established.[83,89–92]

17.5.1.4 CHRONIC RENAL FAILURE OF OTHER CAUSES

Several early cases of CRF in horses were attributed to oxalate poisoning because oxalate crystals were observed in renal tubules.[82,89] Horses appear to be more resistant than other domestic species to oxalate-induced renal damage,[93] however, and experimental administration of various forms of oxalate (in large doses) produced hypocalcemia and gastrointestinal signs rather than renal failure.[94] In fact, the early reports of oxalate nephropathy in horses failed to demonstrate that the affected horses had been exposed to oxalates. [82,89] Furthermore, long-term ingestion of plants containing oxalate produces fibrous osteodystrophy 1238
(oxalates bind calcium in the intestinal tract, decreasing intestinal calcium absorption), but renal damage in 1239
affected horses has been minimal.[95] Formation of oxalate crystals in diseased equine kidneys now is recognized as a secondary change likely related to stasis of urine in damaged renal tubules.[54]

Amyloidosis is an unusual cause of CRF in horses.[93,96] Amyloid deposits associated with systemic disease typically are composed of aggregates of the amino-terminal fragment of serum amyloid A protein, an acute phase protein.[97–100] Concentrations of serum amyloid A increase with many inflammatory disease processes, and chronic elevations can result in amyloid deposition (AA type) in a variety of tissues, a condition termed *systemic reactive amyloidosis*.[101,102] Incidence and tissue localization of amyloid exhibit considerable species variation. Dogs appears to be affected most often, but the fact that the disease is familial in Abyssinian cats implies a genetic basis for the disease.[102] Amyloid deposits accumulate as stacks of protein in a β-pleated sheet conformation and are identified in tissue samples by their extracellular location and homogeneous, eosinophilic appearance when stained with hematoxylin and eosin. They are birefringent when viewed under polarized light, and staining with alkaline Congo red solution imparts a characteristic green color.[101,102] Amyloid deposition in the kidney is most common in dogs and cattle, and renal amyloidosis is a significant cause of CRF in dogs.[102] In horses, localized amyloidosis of the upper airway or skin is more common than systemic amyloidosis.[101] In the localized form, amyloid deposits are composed of immunoglobulin light chains (AL type). Although reports describe systemic reactive amyloidosis consequent to heavy parasite infestation in horses, renal involvement was minimal or not apparent.[103,104] Systemic amyloidosis has been recognized most often in horses hyperimmunized for antiserum production, and hepatic and splenic involvement may be more common than renal involvement in these horses.[93,96,98]

A final acquired cause of CRF, renal neoplasia, is discussed in greater detail elsewhere in this chapter. Although horses with renal neoplasia may have weight loss, the tumors are usually unilateral and development of CRF is uncommon.

17.5.2 Uremic Toxins and theUremic Syndrome

Regardless of the underlying cause of nephron loss, the ensuing renal insufficiency leads to developmentof azotemia and its clinical manifestation, the uremic syndrome.[97–99,105,107] The uremic syndrome is a multisystemic disorder that develops as a result of the effects of uremic toxins on cell metabolism and function. Although the uremic syndrome originally was attributed to the effects of increased blood urea nitrogen concentration (BUN), a number of nitrogenous compounds now are known to accumulate in CRF and contribute to alterations of cell metabolism and function. In fact, the correlation between the severity of the uremic syndrome and the magnitude of azotemia is poor. For example, urea administered to human beings with normal renal function results simply in fluid shifts, osmotic diuresis, and increased thirst.[106] Urea toxicity also has been studied in nephrectomized dogs and in human patients with CRF sustained by dialysis. Increasing the urea concentrations of the dialysate to maintain BUN at artificially higher values has produced variable results. For example, BUN values up to about 150 mg/dl were associated with few clinical signs, whereas lethargy, weakness, anorexia, vomiting, and a bleeding diathesis (caused by platelet dysfunction) were producedwhen BUN was increased to values exceeding 175 to 200 mg/dl. Excess circulating urea also can degrade spontaneously to ammonia, carbonate, or cyanate. Cyanate can react with the N-terminal amino groups on a number of proteins and by altering tertiary structure can interfere with enzyme activity and structural integrity of cell membranes.[107] Thus accumulation of urea is likely responsible for some of the signs of uremic syndrome.

Creatinine and other guanidino compounds also accumulate in renal failure. These compounds arestrong organic bases that contain an amidino group(N-C=NH).[107] With CRF, urinary excretion of creatinine and other guanidino compounds actually may increase (because of tubular secretion) but not enough to prevent increases in blood concentrations. For example, the author has found that in naturally occurring cases of equine CRF (author's unpublished data), endogenous creatinine clearance, when measured simultaneously with inulin clearance, overestimates glomerular filtration rate (GFR) by 50% to 100%. These data indicate that tubular secretion of creatinine, which Finco and Groves were unable to document in healthy ponies,[108] is initiated by or is quantitatively much greater with CRF. Although metabolic pathways have not been elucidated fully, guanidino compounds appear to be produced predominantly in the liver, and their concentration in blood and tissues increases with decreased renal function or increased dietary protein intake.[106] The relationship between guanidino compounds and the syndrome of uremia is also unclear. For example, administration of methylguanidine to healthy dogs resulted in weight loss, neurologic signs, and anemia, but only when blood concentrations were an order of magnitude greater than those in spontaneous cases of CRF.[107] In contrast, administration of another guanidino compound, guanidinopropionic acid, led to hemolysis by depleting 1239
erythrocyte glutathione concentrations (supporting a role for this uremic toxin in the anemia of CRF). 1240

Products of intestinal bacterial metabolism—including secondary methylamines (from metabolism of choline and lecithin), aromatic amines (from metabolism of tyrosine and phenylalanine), polyamines (from metabolism of lysine and ornithine), and tryptophan breakdown products (indole, skatole, indoleacetic acid, and others)—can contribute to the clinical signs associated with the uremic syndrome. Some of these compounds have been studied thoroughly (e.g., the inhibitory effect of the polyamine spermine on erythropoiesis), whereas others are ill understood but likely contribute to altered neuromuscular and neurologic function.[105–107]

Another group of larger uremic toxins have been termed *middle molecules*.[106,107] These compounds are higher-molecular-weight compounds (500 to 3000 d) that are removed more readily from uremic patients by peritoneal

dialysis than by hemodialysis. These compounds are not well characterized, and their existence is supported more by the difference in clinical response to peritoneal dialysis and hemodialysis in uremic human patients awaiting renal transplantation.

In addition to nitrogenous compounds, abnormal metabolism of hormones and trace minerals also accompanies the decline in renal function associated with acute and chronic renal failure. Secondary hyperparathyroidism (leading to osteodystrophy) and insulin insensitivity are well-recognized endocrine contributions tothe uremic syndrome in human and small animal patients.[106,107,109,110] Endocrine dysfunction can be attributed to several factors: (1) decreased productionof renal hormones (erythropoietin, vitamin D_3); (2) decreased hormone clearance prolonging plasma half-life (parathormone, gastrin); (3) decreased hormone production (testosterone); (4) tissue insensitivity (insulin, parathormone); and (5) hypersecretion to reestablish homeostasis (parathormone).[107] Regarding trace minerals, uremia may be accompanied by aluminum toxicity and zinc deficiency. Aluminum may contribute to some of the neurologic signs associated with azotemia (especially with acute renal failure), whereas zinc has been implicated in testicular atrophy and abnormal taste in uremic human patients.[106,107]

Clearly, as so many potential uremic toxins exert their effects as renal function declines, a single compound or even a few compounds likely will not ever be identified as the primary cause of the uremic syndrome in patients with CRF. Furthermore, these compounds together are more likely to impair basic cell function in a number of tissues, and the signs of uremia are more likely to reflect multisystemic organ dysfunction. Methylation of a number of membrane proteins recently has received considerable attention as one of the common mechanisms of cell dysfunction.[111] What is truly remarkable, however, is the tremendous adaptive capacity of the failing kidneys to maintain sodium and water balance within narrow ranges until GFR declines to 20% of the normal value or less.[112]

17.5.3 Clinical Signs

Horses with CRF present relatively late in the disease course, when their owners note lethargy, anorexia, and weight loss. A history of months to years of polydipsia and polyuria in some cases supports renal disease of long duration. In other animals, preexisting disease (colic, colitis, pleuropneumonia) or prolonged medication (aminoglycoside antibiotics or NSAIDs) may provide important information about the initiation and duration of renal failure. In most cases, however, the onset is insidious and identifying a precipitating event or gauging the duration of renal disease is not possible.

Chronic weight loss is the most common presenting complaint for horses with CRF.[24–30] Partial anorexia, ventral edema, polydipsia and polyuria, rough hair coat, lethargy, and poor athletic performance are other owner concerns. In addition, horses with advanced CRF may have a characteristic odor that likely reflects the combined effects of uremic halitosis and increased urea excretion in sweat. For the horses presented in Table 17.5-1, weight loss, ventral and peripheral edema, and polydipsia and polyuria, respectively, were reported in 53 of 63 (84%), 24 of 56 (43%), and 21 of 48 (44%) of the cases. Lethargy and weight loss can be attributed to several factors. An increase in the concentration of nitrogenous wastes in blood can have a direct central appetite-suppressant effect that can lead to partial or complete anorexia.[106,107] Next, as azotemia develops, excess urea diffuses across gastrointestinal epithelium and is metabolized to ammonia and carbon dioxide by bacterial urease. In the oral cavity, excess ammonia can lead to excessive dental tartar formation (Figure 17.5-8), gingivitis, and oral ulcers. In the gastrointestinal tract, excess urea and ammonia can lead to ulceration and mild to moderate protein-losing enteropathy, and severely uremic animals may produce soft feces.[1,106,107]

The prolonged half-life of gastrin (eliminated through the kidneys) may contribute further to ulcer formation because of increased gastric acid secretion.[107] Finally, as the combined effects of uremic toxins render the affected patient catabolic, body mass declines as body reserves are tapped to meet basal energy requirements.[106,107]

Mild ventral edema with CRF may be attributable to three factors: decreased oncotic pressure, increased vascular permeability, and increased hydrostatic pressure. Because albumin accounts for approximately 75% of plasma colloid oncotic pressure, decreases in albumin concentration (less than about 2.0 g/dl) can decrease 1240
plasma oncotic pressure despite a normal total plasma protein concentration.[113,114] The effects of uremic toxins 1241
on endothelial cell membranes can alter vascular permeability, which contributes to edema.[106,107] Chronic renal insufficiency can lead to renal hypoxia and hypoperfusion, which stimulate renal juxtaglomerular cells to release renin. Activation of the renin-angiotensin system tends to elevate blood (and capillary hydrostatic) pressure and contributes to edema. Activation of the renin-angiotensin system also leads to increased sodium reabsorption in the proximal (direct effect of angiotensin II) and distal (effect of aldosterone) tubules.[114] Sodium retention leads to expansion of circulating volume, which is another factor in edema formation. Alterations in blood pressure in horses with CRF have not been evaluated routinely as they have in small animal and human patients, nor have increased circulating concentrations of angiotensin II or aldosterone been documented. As a result the nephrotic syndrome (characterized by edema, hypoalbuminemia, and heavy proteinuria) is not as well documented in horses as in small animals and human beings with CRF. However, horses with CRF appear less at risk for the significant pleural effusion or ascites that can accompany the nephrotic syndrome in small animals.[1]

Figure 17.5-8 Excessive dental tartar on the canine tooth and lower corner incisor of a horse with chronic renal failure.

Polydipsia and polyuria are variable findings in horses with CRF. The magnitude of polydipsia and polyuria theoretically is related to the degree of tubulointerstitial damage; however, the degree of polyuria does not appear to correlate with the magnitude of azotemia in clinical cases. Typically, polyuria is not as severe with CRF as with diabetes insipidus or psychogenic water drinking and may not be noticed by an owner (see Chapter 17.9). The wide variation in water intake in normal horsesand common use of automatic waterers and large stock tanks also make observation of polydipsia more difficult. The mechanisms of polyuria with CRF can include(1) increased tubular flow rate in surviving nephrons,(2) decreased medullary hypertonicity, and (3) impaired response of collecting ducts to vasopressin (acquired nephrogenic diabetes insipidus). Although these mechanisms may contribute to the polyuria of CRF, which of them may be most important is not known.[1,115]

An early complaint for horses with CRF is poor performance, which may be related to mild anemia (packed cell volume 25% to 30%) and lethargy. Although the anemia of CRF has been attributed to several factors—including blood loss, decreased erythrocyte survival time, nutritional deficiencies, and decreased erythropoeitin activity—the latter clearly has emerged as the principal cause of anemia in human beings and small animals with CRF.[1,116,117] In fact, administration of recombinant human erythropoietin (rhEPO) to patients awaiting kidney transplant has been one of the most significant advances in management of human CRF because it has eliminated the need for blood transfusions, has improved exercise capacity, and has decreased morbidity associated with the uremic syndrome.[116,117] Administration of rhEPO has also benefited anemic dogs and cats with CRF, although both species may neediron supplementation to support erythropoiesis.[1,116] The response often has been only temporary because many small animal patients develop refractory anemia following production of anti-rhEPO antibodies within a few weeks to months after initiation of treatment.[1] Plasma concentrations of erythropoeitin have been determined in normal horses,[118] and rhEPO administration (15 IU/kg intravenously, three doses per week for 3 weeks) has been reported to increase the hematocrit in splenectomized horses[119]; however, no reports describe rhEPO administration to horses with CRF. Furthermore, moderate to severe anemia has been reported anecdotally to develop after repeated rhEPO administration to racehorses,[120,121] suggesting that anti-rhEPO antibodies also would limit the effectiveness of the treatment for CRF in horses.

17.5.4 Diagnosis and Laboratory Evaluation

One establishes a diagnosis of CRF when persistent isosthenuria (specific gravity of 1.008 to 1.014) accompanies azotemia and typical clinical signs.[25–30,122] Rectal palpation of the left kidney may be normal or may reveal a kidney that is small or firm with an irregular surface. Less often, the kidneys and ureters may be enlarged if obstructed by uroliths or if infection or neoplasia is present. The ratio of BUN to serum creatinine
concentration (BUN/Cr ratio) in horses with CRF is typically greater than 10:1 (Table 17.5-2); that for horses 1241
with prerenal azotemia or acute renal failure is often less than 10:1.[26] This difference can be attributed in part to 1242
different volumes of distribution for urea (all body fluids) and creatinine (primarily the extracellular fluid space). As a consequence, with acute reductions in renal blood flow the increase in serum creatinine concentration is usually greater, on a relative or percentage basis, than the increase in BUN. The point deserves emphasis, however, that BUN is influenced by dietary protein intake so that BUN/Cr values do not always distinguish acute renal failure from CRF. In fact, one also can use the BUN/Cr ratio to assess adequacy of dietary protein intake in the management of horses with CRF because a value greater than 15:1 can reflect excessive protein intake.[28]

TABLE 17.5-2 Abnormal Laboratory Values Reported for Horses With Chronic Renal Failure

PARAMETER	NUMBER[*]	PERCENT
BUN/Cr >10	29/34	85
BUN/Cr >15	17/34	50
Anemia (packed cell volume <30%)	12/30	40
Hypoalbuminemia (<2.5 g/dl)	12/14	86
Hypoalbuminemia (<2.0 g/dl)	7/14	50
Hyponatremia (Na^+ <135 mEq/L)	26/40	65
Hyperkalemia (K^+ >5.0 mEq/L)	23/41	56
Hypochloremia (Cl^- <95 mEq/L)	19/41	46
Hypercalcemia (Ca^{2+} >13.5 mg/dl)	26/39	67
Hypophosphatemia (P < 1.5 mg/dl)	17/36	47
Acidosis (pH <7.35)	3/5	60

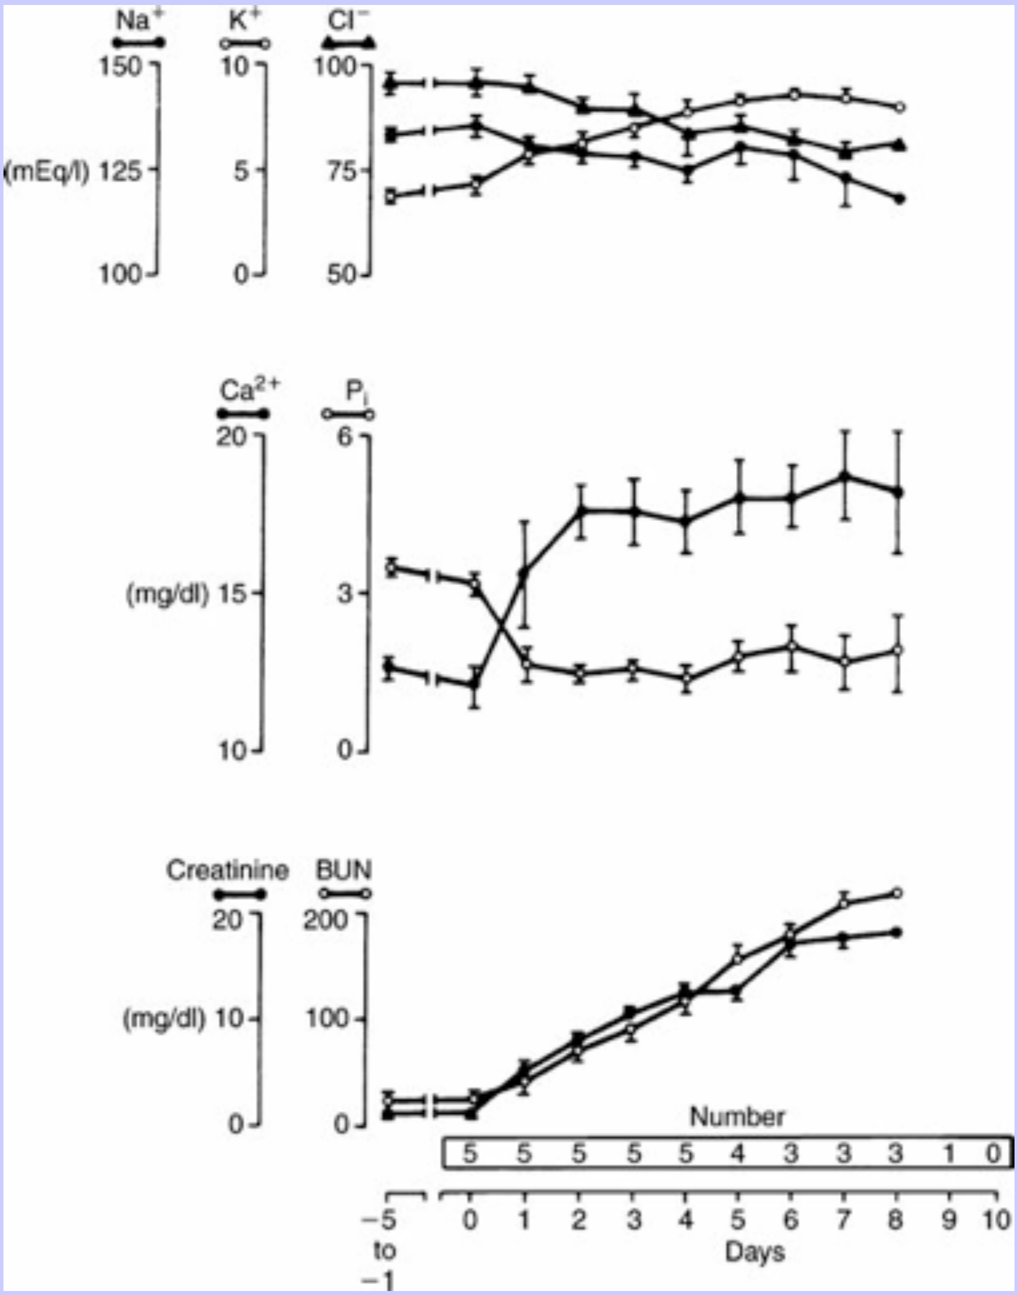
* Number of reports with this laboratory finding/total number of reports in which this laboratory parameter was reported.

In addition to azotemia, further abnormal laboratory data accompanying CRF can include mild anemia, hypoalbuminemia, hyponatremia, hyperkalemia, hypochloremia, hypercalcemia, hypophosphatemia, and metabolic acidosis (see Table 17.5-2). A nonregenerative anemia is related largely to a deficient supply of the renally secreted glycoprotein erythropoietin; however, reduced erythrocyte life span may be another significant contributor to anemia. Normally, equine erythrocytes have a life span of 140 to 155 days.[121] With uremia, erythrocyte life span is shortened because excessive nitrogenous waste products alter the integrity of erythrocyte membranes and the function of ion channels, which regulate erythrocyte volume.[108] These less resilient erythrocytes are more likely to be removed from the circulation by the reticuloendothelial system.

The electrolyte alterations associated with CRF reflect loss of tubule function. Because sodium, chloride, bicarbonate, and phosphate are conserved by renal tubules, excessive urinary loss of these electrolytes accompanies CRF. Although fractional electrolyte clearance values (see Chapter 17.3) may remain within normal ranges or increase only slightly in horses with CRF, significant daily urinary loss of electrolytes still may occur. As an example, if a horse with CRF and serum creatinine and sodium concentrations of 5.0 mg/dl and 130 mEq/L, respectively, is producing 20 L of urine daily with respective creatinine and sodium concentrations of 50 mg/dl and 12.5 mEq/L, the fractional clearance of sodiumis 1.0% and daily urinary sodium loss 250 mEq. An increase in urinary sodium concentration to 25 mEq/L following another decrease in tubular reabsorption would result in an increase in fractional sodium clearance to 2% but would represent an additional 250 mEq of daily sodium loss in the urine. The latter value would approach 1% to 2% of the exchangeable sodium in the body and would require an additional 15 g of salt intake daily to accommodate this loss. Hypercalcemia and hypophosphatemia (Williams-Smith syndrome) are fairly common findings in horses with CRF (see Table 17.5-2), and the degree of hypercalcemia appears to vary with the amount of calcium in the

diet.[24,53,56,123] In human beings with ESKD, hypercalcemia is an occasional finding attributed to hyperparathyroidism, vitamin D supplementation, or use of calcium-containing dialysate solutions. Furthermore, the osteodystrophy of CRF is associated with aluminum deposition in bone, which has been speculated to reduce skeletal buffering capacity for increases in serum calcium concentration and thereby contributes to hypercalcemia.[124] Because the equine kidney is an important route of calcium excretion (via calcium carbonate crystals), impaired tubular function in the face of continued intestinal absorption is the most common explanation for calcium accumulation in blood. This explanation is supported by the rapid development of hypercalcemia after experimental bilateral nephrectomy in ponies fed alfalfa hay (Figure 17.5-9).[9] In addition, parathormone concentrations have been found to be below the lower limit of detection in horses with CRF, indicating that hyperparathyroidism does not play a role in development of hypercalcemia.[22,83] However, parathormone clearance by the kidney also is reduced with CRF and may be associated with a change in the regulatory set-point for serum calcium concentration in uremic human beings.[124] Whether hypercalcemia in horses with CRF leads to exacerbation of renal disease or tissue mineralization remains unknown. Nevertheless, one can demonstrate the effect of dietary calcium by changing the type of hay fed to horses with CRF.Horses with serum calcium concentrations exceeding20 mg/dl on a diet of mostly alfalfa can have theirserum calcium concentrations returned to the normal range within a few of days after changing the diet to grass hay.[19,26] Similarly, nephrectomized ponies fedgrass hay did not become hypercalcemic.[26] The 1242
1243
cause of hypophosphatemia in horses with CRF also remains undocumented, although it has been explained by the law of mass action, which leads to a decrease in serum phosphate concentration in association with hypercalcemia.[123,124] A similar response is not observable in horses that eat *Cestrum diurnum* (leading to a syndrome of hypervitaminosis D): they develop hypercalcemia without hypophosphatemia.[125] Another possibility that has been suggested is that hypophosphatemia may result from long-standing anorexia associated with CRF.[83] Regardless of the cause, clinical problems associated with hypophosphatemia have not yet been recognized in horses with CRF.

Figure 17.5-9 Changes in serum electrolyte concentrations, blood urea nitrogen concentration *(BUN)*, and serum creatinine concentration following bilateral nephrectomy in Shetland ponies. (From Tennant B, Lowe JE, Tasker JB: Hypercalcemia and hypophosphatemia in ponies following bilateral nephrectomy, *Proc Soc Exp Biol Med* 167:365, 1981.)



A degree of metabolic acidosis accompanies CRF in human beings and small animals and is attributed to decreased ability of failing kidneys to excrete hydrogen ions and regenerate bicarbonate.[1,107] Normally, acid-base balance is maintained by reabsorption of filtered bicarbonate and excretion of hydrogen ions along with ammonia and phosphate. As renal function declines in the early stages of renal failure, hydrogen ion excretion via renal ammoniagenesis and ammonium excretion increases. As renal failure progresses, compromised renal ammoniagenesis and decreased medullary recycling of ammonia caused by structural renal damage likely contribute to impaired ammonium excretion. Because hepatic glutamine synthesis is required for renal ammoniagenesis, the earlier increase in ammonium excretion may contribute to protein malnutrition in patients 1243
with CRF.[1] Metabolic acidosis also contributes to a number of the clinical signs of the uremic syndrome and 1244
may exacerbate some of the electrolyte alterations (e.g., hyperkalemia) of CRF. Metabolic acidosis has been reported in a limited number of horses with CRF (see Table 17.5-2); however, in the author's experience and that of others,[25,83] most horses with CRF have normal acid-base status or are alkalotic until the terminal stages of the disease, when metabolic acidosis typically develops. Metabolic alkalosis has been attributed to enhanced bicarbonate reabsorption and production, in association with hypochloremia and increased renal ammoniagenesis, respectively. In some instances, hypochloremic metabolic alkalosis may be accompanied by paradoxical aciduria.[83] The mechanism of paradoxical aciduria is likely similar to that of hypochloremic metabolic alkalosis in ruminants with abomasal outflow obstruction.[126] Briefly, after all chloride has been reabsorbed from the glomerular filtrate, further sodium reabsorption occurs by exchange with (excretion of) potassium or hydrogen ions. Thus paradoxical aciduria is most likely to occur with concomitant hypokalemia or whole-body potassium depletion.

Horses with CRF also can develop hypercholesterolemia and hyperlipidemia (hypertriglyceridemia), and occasionally an animal has grossly lipemic plasma (hyperlipemia).[26,28,122] In fact, Naylor, Kronfeld, and Acland reported a positive correlation between serum triglyceride and creatinine concentrations in a group of azotemic horses.[127] With azotemia, hyperlipidemia can develop as a result of increased synthesis, decreased degradation, or increased mobilization of triglycerides from fat stores.[128] Decreased lipoprotein lipase activity has received the most attention in horses, likely because heparin treatment(40 IU/kg subcutaneously every 8 hours) has been recommended to stimulate lipoprotein lipase in an attempt to clear the serum.[28,129] Hypercholesterolemia and hyperlip-idemia increase the risk of atherosclerotic cardiovascular disease in human beings with CRF.[128] Furthermore, these conditions stimulate mesangial cell proliferation and matrix production in diseased glomeruli and thus accelerate progression to glomerulosclerosis.[130]

The failing kidneys have a tremendous adaptive capacity to maintain tubular function until GFR is low.[112] In the author's experience, tubular dysfunction resulting in significant sodium or phosphorous wasting (manifested by increased fractional clearance values), glucosuria, or enzymuria is more common with acute renal failure than with CRF. When present, however, abnormal tubule function rarely leads to values for fractional sodium clearance in excess of 5%.[79,92,131] In contrast, loss of concentrating ability resulting in isosthenuria is a consistent feature of CRF that usually develops before azotemia. The associated polyuria may or may not be observed by the client, but the horse usually maintains water balance well through polydipsia. Polyuria typically results in urine that is clear and essentially devoid of crystals and mucus. Sediment examination is generally unremarkable, but increased numbers of red or white blood cells may occur with nephrolithiasis or ureterolithiasis or with pyelonephritis, respectively. Gross hematuria further supports lithiasis or neoplasia. One should include a quantitative urine culture in the minimum database of all horses with CRF because bacteriuria may not always be accompanied by pyuria.

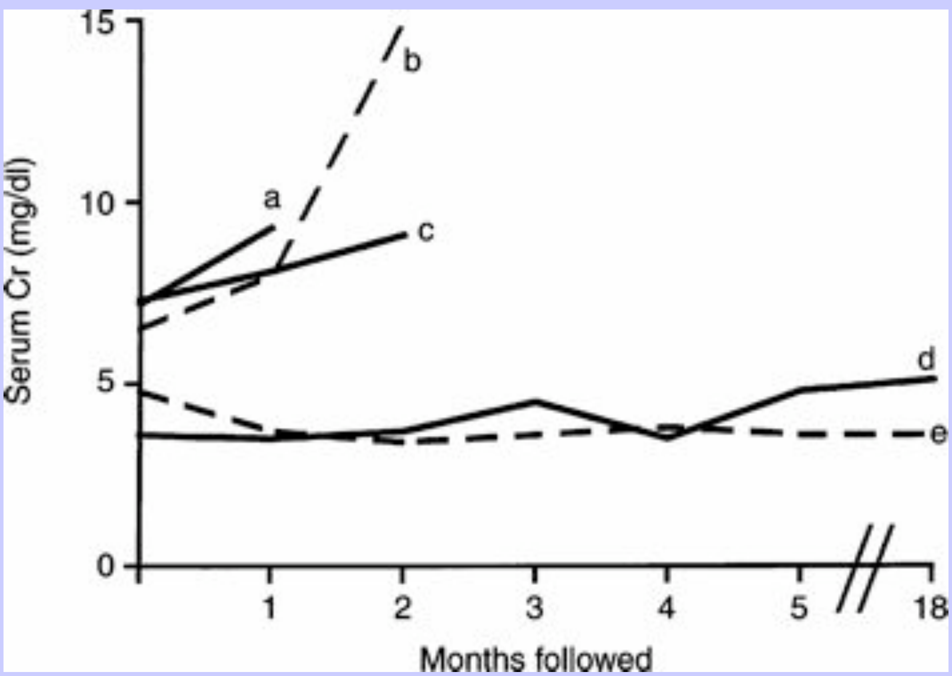
Alterations in the integrity of the highly anionic glomerular filtration barrier also can lead to loss of protein, predominantly albumin, in the urine. Few quantitative data are available on urinary protein loss in horses with CRF because in most previous reports proteinuria was assessed using urine reagent strips. Reagent strip results of +++ or ++++ correlate with protein concentrations of 100 to 300 and 1000 to 2000 mg/dl, respectively, depending on which reagent strip one uses. In a proteinuric horse that is producing 20 L of urine daily, these values would yield a wide range of urinary protein loss: 20 to 400 g daily. The latter value would approach 25% of the total protein content of plasma and so is not realistic. In human beings with CRF, urinary protein loss exceeding 3.5 g per day (50 mg/kg per day for a 70-kg person) is classified as nephrotic-range proteinuria, and some patients with heavy proteinuria may lose in excess of 15 g per day (more than 200 mg/kg per day).[132] The upper limit of acceptable urinary protein excretion in dogs is 20 mg/kg per day.[133] Using these values, estimates for the upper acceptable limits for urinary protein loss and nephrotic-range proteinuria in a 500-kg horse would be 10 g and in excess of 25 g per day, respectively. These values agree well with a mean value of 3.2 mg/kg (1.6 g per day) and a range of 3.6 to 22.3 mg/kg (1.8 to 11.2 g) per day in normal mares reported by the Schott, Hodgson, and Bayly[134] and by Kohn and Strasser,[135] respectively. Another method to document proteinuria is to determine the ratio of urinary protein to urinary creatinine (in milligrams per deciliter). This technique is more practical because it avoids a timed urine collection period. Although a normal range has not yet been reported for horses, values in excess of 1.0:1 and 3.5:1 are considered above normal and indicate nephrotic-range proteinuria in dogs[133] and human beings,[132] respectively. Thus a urine protein/creatinine ratio greater than 2.0:1 likely supports significant proteinuria in a horse with CRF. Finally, a horse with CRF and heavy proteinuria (more than 200 mg/kg per day) could excrete as much as 100 g of protein daily (5% to 7% of total plasma protein). Proteinuria of this magnitude can increase urine specific gravity to 1.020 or greater and certainly would be great enough to lead to a decline in serum albumin (and total protein) concentration, despite 1244
increased hepatic albumin production. In some horses with CRF and a normal total plasma protein 1245
concentration, increased globulin concentration offsets mild hypoalbuminemia, whereas in other cases hyperglobulinemia actually can result in an increase in total plasma protein concentration.

One can use ultrasonography to determine kidney size in horses with CRF and to evaluate for the presence of cysts or nephroliths. Horses with ESKD typically have small kidneys that are more echogenic than normal (becauseof sclerosis and possible tissue mineralization).[136–140] Cystoscopy also can be a useful diagnostic aid to assess urine production qualitatively in each kidney and is particularly useful when ultrasonographic imaging fails to identify a kidney.[138] Renal scintigraphy is another imaging option to detect functional renal tissue that may not be apparent by ultrasonography.[141] One can perform renal biopsy using ultrasonographic guidance to document renal disease. Unfortunately, because most horses are presented for evaluation in the later stages of disease, biopsy results typically reveal glomerular, tubular, and interstitial lesions consistent with ESKD. Rarely do the lesions provide information about the inciting cause of the renal disease unless immunofluorescence testing and electron microscopy are pursued. These require placing samples in special fixatives, in addition to the sample placed in formalin for routine histopathologic examination. In some cases, renal biopsy results supporting pyelonephritis or a congenital anomaly (dysplasia) as the cause of CRF are useful in developing a therapeutic plan or providing a prognosis.

One can assess the severity of CRF in affected horses using available sophisticated techniques. The magnitude of azotemia is the most readily available and practical parameter but is an insensitive one.[132] Azotemia becomes apparent only after 75% or more of renal function is lost. Furthermore, the degree of azotemia can vary with nonrenal factors such as diet, body mass, and hydration. In general, creatinine concentration is a more reliable measure than BUN, and doubling of creatinine roughly correlates to a 50% decline in GFR (see Figure 17.3-1). Serum creatinine concentrations in the range of 5 to 10 mg/dl indicate a significant decline in renal

function, and values exceeding 15 mg/dl are consistent with a grave prognosis. In contrast, horses with a creatinine concentration below 5 mg/dl may exhibit few clinical signs and can be managed for months or years (Figure 17.5-10). Plotting the inverse of serum creatinine concentration (1/Cr) over time also has been used to monitor progression of CRF in human beings[142,143] and in one horse[19] in an attempt to predict the end point of the disease process (Figure 17.5-11). Unfortunately, these plots are subject to considerable variation (because of changes in tubular secretion of creatinine) and have not proved to be of any more value than monitoring creatinine over time.[142,143]

Figure 17.5-10 Serum creatinine concentrations *(Cr)* in five horses with chronic renal failure. The three horses with an initial creatinine concentration greater than 5 mg/dl (*a* to *c*) had rapid progression of renal disease over a 1- to 2-month period, necessitating euthanasia, whereas the two horses with an initial creatinine concentration less than 5 mg/dl (*d* and *e*) were maintained with supportive care for longer than 18 months.



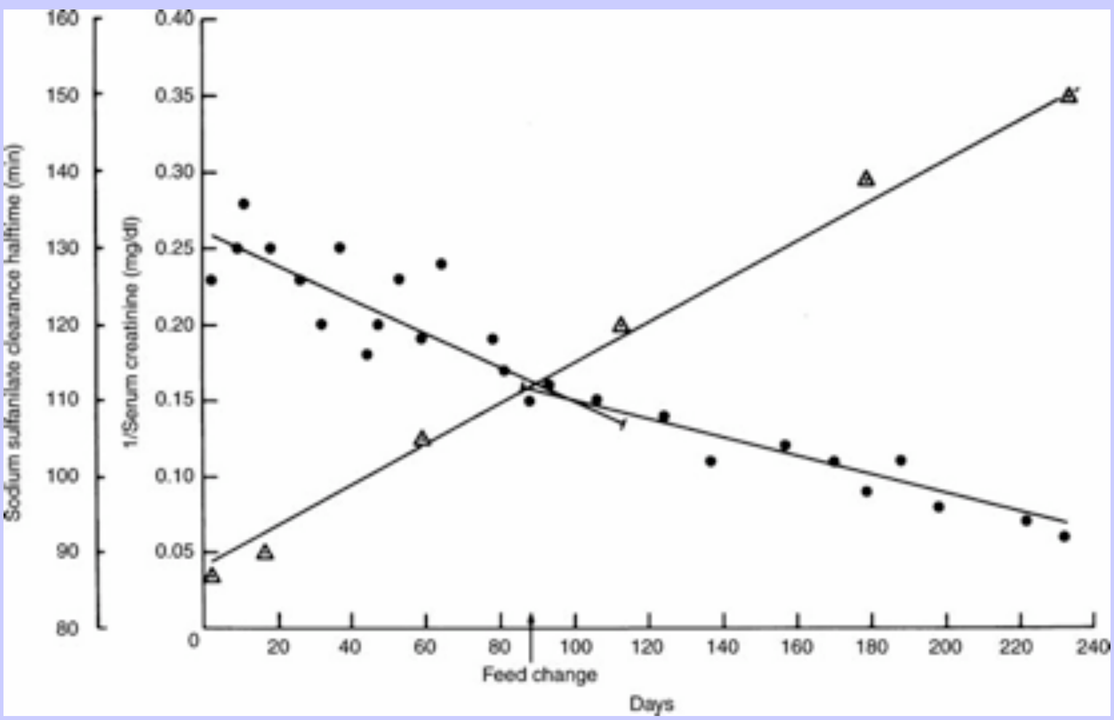
Measurement of GFR provides the most accurate quantitative assessment of renal function but is pursued rarely because it is more time consuming and technically demanding than measurement of serum creatinine concentration. Although a number of methods are available to measure GFR,[144] measurement of endogenous creatinine clearance (Cl_{Cr}) or the plasma disappearance of exogenous creatinine, sulfanilate,[19,145] or 99-metastable technetium tagged to diethylenetriaminepentaacetic acid[146] are the most practical methods in a clinical setting. The former requires timed urine collections, whereas the latter may require special assays or

nuclear medicine capabilities (see Chapter 17.3). Horses in the earlier stages of CRF can develop tubular creatinine secretion, which could lead to overestimation of GFR measured by the Cl_{Cr} technique. As renal disease progresses, however, creatinine excretion decreases faster than GFR declines because of loss of compensatory secretion. Despite these limitations, repeated measurement of Cl_{Cr} in a single animal can be useful for monitoring progression of CRF over time (Figure 17.5-12).

17.5.5 Disease Progression

One of the hallmarks of CRF is the progressive natureof the disease,[147–149] and progression appears to be largely independent of the inciting cause because of the final common pathways of renal injury. The response to a decrease in renal functional mass is a compensatory increase in filtration (termed *single-nephron GFR*) and 1245
tubular function (e.g., creatinine secretion, ammoniagenesis) by remaining nephrons. The increase in single- 1246
nephron GFR results from increased glomerular capillary blood flow and hydrostatic pressure leading to glomerular hyperfiltration. Hyperfiltration is associated with increased permeability of the GBM and proteinuria. Furthermore, increased filtration of macromolecules leads to activation and proliferation of mesangial and epithelial cells and eventually progression to glomerulosclerosis.[113,147–150] In addition to causing proteinuria, increased filtration of protein is accompanied by increased proximal tubular protein reabsorption. The latter leads to upregulation of genes encoding vasoactive and inflammatory mediators by tubular and interstitial cells and contributes substantially to injury of the renal interstitium.[149]

Figure 17.5-11 The inverse of the serum creatinine concentration *(filled circles)* and the whole-blood sodium sulfanilate clearance half-time in a horse with chronic renal failure associated with polycystic kidney disease. The slope of the line describing the reciprocals of serum creatinine concentration from day 1 to day 98 was significantly different (*P* <0.05) from that from day 99 to 235 and the slope change was associated with a change from alfalfa to grass hay. (From Bertone JJ, Traub-Dargatz JL, Fettman MJ et al: Monitoring the progression of renal failure in a horse with polycystic kidney disease: use of the reciprocal of serum creatinine concentration and sodium sulfanilate clearance half-time, *J Am Vet Med Assoc* 191:565, 1987.)

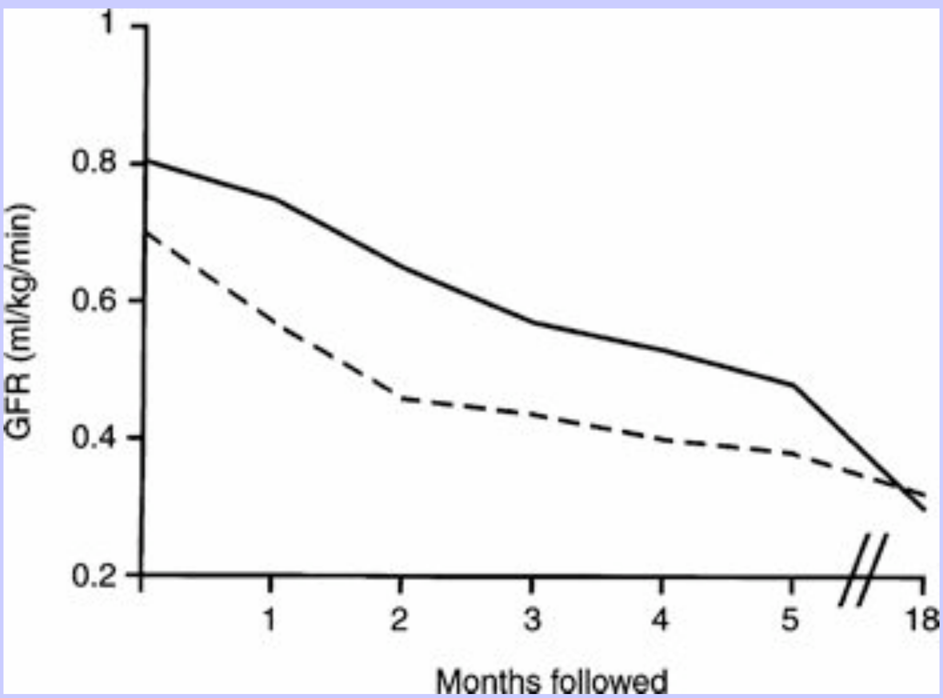


A number of studies investigating the mechanismsof glomerular hypertension have demonstrated that activation of the renin-angiotensin system and angiotensin II production are of considerable importance, for angiotensin II is a potent constrictor of glomerular efferent arterioles.[151–153] Activation of the intrarenal renin-angiotensin system can produce significant glomerular hypertension without producing increases in systemic angiotensin II concentration or blood pressure. In fact, administration of specific angiotensin II receptor antagonists or angiotensin-converting enzyme inhibitors has been demonstrated to decrease glomerular capillary hydrostatic

pressure and the magnitude of proteinuria in experimental studies of renal disease.[151–154] Angiotensin-converting enzyme inhibitors have helped to control hypertension and proteinuria in small animals,[1,155] but no reports describe use of angiotensin-converting enzyme inhibitors in horses with CRF.

The role of dietary protein in the progression of CRF has been the subject of a number of investigations in human beings and small animals with a variety of renal diseases.[156–161] A well-established fact is that one can ameliorate clinical signs of uremia by decreasing dietary protein content; however, whether decreasing dietary 1246
protein slows progression of renal disease remains controversial. Increased dietary protein has been 1247
demonstrated to increase activation of the renin-angiotensin system; therefore decreasing dietary protein could be protective for the reasons discussed in the preceding paragraph. Next, a decrease in protein intake leads to production of smaller amounts of urea and other nitrogenous wastes. In theory, the workload on the kidneys is similarly decreased. Because all work (aerobic adenosine triphosphate production and use) is associated with a degree of free radical production, greater protein intake would generate more free radicals. Free radicals appear to be especially injurious to diseased kidneys because their scavenging mechanisms are compromised. Increased dietary protein also requires increased ammoniagenesis by renal tubules to excrete the associated proton load; however, ammoniagenesis can lead to noninflammatory, nonimmune complement activation in proximal tubule epithelial cells. One can ameliorate this proinflammatory consequence of ammoniagenesis by supplementation with sodium bicarbonate. In summary, excessive dietary protein leads to a greater degree of uremia and has the potential to exacerbate renal damage in CRF by several mechanisms.

Figure 17.5-12 Glomerular filtration rate *(GFR)* as measured by endogenous creatinine clearance *(solid line)* and inulin clearance *(dashed line)* in a mare (see horse *e* in Figure 17.5-10) with chronic renal failure. Glomerular filtration rate declined steadily over the 18-month period despite minimal change in serum creatinine concentration. Compared with inulin clearance, endogenous creatinine clearance overestimated glomerular filtration rate until the terminal stage of the disease process. This difference likely reflects tubule secretion of creatinine in the earlier stages of chronic renal failure, which subsequently diminished during the final weeks of the disease course.



In contrast, protein-calorie malnutrition is associated strongly with increased morbidity and mortality in human CRF patients and can be attributed to increased protein catabolism when dietary protein intake is marginal to low. In human beings a number of serum components, including prealbumin, cholesterol, and insulin-like growth factor; plasma and muscle amino acid profiles; and body composition measurements have been studied as potential indexes of nutritional status; however, serum albumin concentration is the most practical and most extensively studied nutritional index. In addition to heavy proteinuria, hypoalbuminemia also can be attributed to protein-calorie malnutrition. Furthermore, a BUN/Cr ratio less than 10:1 may be another indication of inadequate protein intake. Thus current dietary recommendations call for dietary protein and caloric intake at levels that meet or slightly exceed predicted requirements, which should render nitrogen balance neutral.[162]

Finally, a critically important but often overlooked aspect of nutritional management of CRF patients is provision of a palatable diet.[1,162] Feeding smaller meals more frequently and varying the diet help to increase food intake in CRF patients of all species.

Experimental studies of CRF in horses are limited to the reports by Roberts and Seawright and colleagues that describe the effects of prolonged daily dosing of horses with mercurial compounds.[163–166] In these four reports, each involving a single horse, the subjects were destroyed between 85 and 191 days after mercury administration began. Anorexia, weight loss, and nonpruritic urticaria were the major clinical signs. The renal lesion was CIN, which was accompanied by a decrease in concentrating ability and an increase in water consumption. Additional tubular dysfunction included glucosuria in all four horses and a variable degree of proteinuria. Interestingly, the clinical signs and tubular dysfunction preceded the development of azotemia in all horses, and excretion of sodium or chloride did not increase. The final report focused principally on the effects on renal function, and azotemia did not develop until the final week of life, and GFR (assessed by endogenous Cl_{Cr}) decreased to 35% of the highest measured value onthe day before euthanasia.[166] Aciduria and increased phosphate excretion, in addition to glucosuria and proteinuria, also were detected during the final week of life.

17.5.6 Treatment

At the time of presentation most horses with CRF exhibit obvious weight loss and other clinical signs. Because of the progressive and irreversible nature of the renal disease, the long-term prognosis is grave. Specific corrective treatment for CRF (renal transplantation) is not available for horses, and maintenance by peritoneal dialysis or hemodialysis would only be practical for valuable breeding animals. Pyelonephritis could be considered an exception because antibiotic treatment in theory could lead to resolution of infection and 1247
improved renal function. Unfortunately, significant renal damage usually has occurred by the time the diagnosis 1248
is established in most cases of bilateral pyelonephritis, so that the prognosis for a return to normal renal function is guarded to poor. In contrast, the short-term prognosis may be more favorable. Some horses with CRF may maintain serum creatinine concentration of less than 5 mg/dl for months with minimal deterioration. To predict which patients will deteriorate more rapidly is difficult, but the recent history and initial ability to counteract weight loss with improved management are useful indicators. Laboratory analysis of blood samples at 2- to 4-week intervals to follow the degree of azotemia and serum electrolyte alterations may be useful in monitoring disease progression. In general, animals that are eating well and maintain reasonable body condition carry the best short-term prognosis and may still be able to perform some limited work. Their use as breeding animals may be reduced because azotemia and eventual weight loss would reduce the chance for normal conception and gestation. The goal in each case is provide appropriate supportive care and to monitor the horse closely so as to provide humane euthanasia before the patient develops uremic decompensation.

As previously discussed, once significant renal disease is established, irreversible decline in GFR and progression of renal failure generally ensue.[147–150] Thus management of the equine patient afflicted with CRF involves palliative efforts to minimize further loss of renal function. The goals are to prevent complicating conditions (e.g., by providing plenty of water), to discontinue administration of nephrotoxic agents, and to provide a palatable diet to encourage appetite and minimize further weight loss.[26–30,167] Intravenous fluid therapy to promote diuresis, usually with 0.9% sodium chloride solution, is of much greater benefit in cases of acute, reversible renal failure but also may benefit patients that suffer a sudden exacerbation of CRF. One must administer intravenous fluid therapy cautiously because horses with CRF can develop significant peripheral or pulmonary edema.

Supportive care also can include supplementation of sodium bicarbonate (50 to 150 g per day) when serum bicarbonate concentration is consistently less than20 mEq/L.[167] One may need to add supplemental bicarbonate to a bran mash. If sodium bicarbonate supplementation aggravates ventral edema, one should limit or discontinue supplementation. Edema is not usually a significant problem, and the horse should tolerate mild edema (rather than being treated with diuretics that could be ineffective or lead to further electrolyte wastage) unless the edema interferes with ambulation. In the previous edition of this text, the author also recommended supplementation with sodium chloride to replace potential loss of these electrolytes in urine in horses with CRF. However, a recent study[168] found that supplementation with sodium chloride (used in an attempt to increase water intake) in cats with preexisting renal disease led to progression of renal disease that remained after salt supplementation was discontinued. Thus one should approach salt supplementation in horses with CRF with caution and should consider it only for patients with hyponatremia and hypochloremia.

Substituting high-calcium and high-protein feed sources such as alfalfa hay with good-quality grass hay and carbohydrates (corn and oats) may help control hypercalcemia and the magnitude of azotemia. Ideally, the hay and grain should contain an adequate but not excessive amount of protein (less than 10% crude protein), which should maintain the BUN/Cr ratio in a target range between 10:1 and 15:1.[26] Providing unlimited access to fresh water and encouraging adequate energy intake by feeding a variety of palatable feeds are important. In fact, if appetite for grass hay deteriorates, offering less ideal feeds such as alfalfa hay or increased amounts of concentrate to meet energy requirements and reduce the rate of weight loss is preferable. Often horses continue to graze at pasture when their appetite for hay is diminished. Administration of B vitamins or anabolic steroids for their touted appetite-stimulating effects may benefit some animals. Although dietary fatis calorie dense, one must approach supplementation judiciously in patients with hyperlipidemia and hypercholesterolemia.

Administration of corticosteroids or NSAIDs can limit the intrarenal inflammatory response associated with renal failure and also may attenuate renal injury. For example, administration of meclofenamate limited proteinuria in a group of human patients with severe manifestations of the nephrotic syndrome[169]; however, nonspecific blockade of prostaglandin production by corticosteroids and most available NSAIDs has the adverse effect of decreasing production of important renal vasodilating agents (prostaglandin E_2 and prostacyclin). Production of these prostanoids increases during periods of renal vasoconstriction or ischemia to maintain intrarenal blood flow, particularly to the renal medulla. With excessive or long-term NSAID administration, renal papillary necrosis develops following medullary ischemia.[78,79,86,87] Thus the negative effects of corticosteroids and NSAIDs on renal blood flow outweigh possible benefits, and they are not recommended routinely for the management of CRF in horses.

The progressive renal injury that occurs in CRF is associated with continued damage to glomerular and tubular
membranes mediated by ongoing activation of the inflammatory cascade. In theory, treatment with antioxidant 1248
medications and free radical scavengers could be of benefit, but experimental data in horses do not bear this 1249
out. Similarly, interest in the role of dietary fatty acids as precursors of eicosanoids has been considerable. Specifically, dietary supplementation with sources rich in ω-3 fatty acids (linolenic acid) compared with ω-6 fatty acids (linoleic acid), appear to decrease generation of more damaging fatty acid metabolites during activation of the inflammatory cascade. In horses, dietary supplementation with ω-3 fatty acids (in the form of linseed oil) has been effective at ameliorating the effects of endotoxin in studies in vitro[170–172] and supplementation with fish oil (another rich source of ω-3 fatty acids) slowed the progression of renal failure in laboratory animals.[173,174] Unfortunately, the effects of endotoxin in vivo were not ameliorated by feeding linseed oil in preliminary equine studies,[175] and the possible benefits of feeding ω-3 fatty acids to horses with CRF are not known at this time.

Recently, control of hypertension and reduction of proteinuria have been recognized as the most successful interventions to limit progression of renal disease in human beings with CRF.[149] Thus monitoring the blood pressure and the level of proteinuria (urine protein/urine creatinine ratio) in horses with CRF seems tobe prudent. Treatment with angiotensin-converting enzyme inhibitors could be beneficial in horses with either of these problems but has not yet been pursued because of the expense of the available medications. Attention also has been directed to use of more specific antiinflammatory or immunosuppressant medications to limit renal injury in immune-mediated glomerulonephritis. For example, inhibition of thromboxane synthetase activity (thromboxane A_2 is a potent vasoconstricting agent and platelet activator) was demonstrated to limit renal histologic and functional changes in a canine model of immune-mediated glomerulonephritis.[176] Similarly, cyclosporine was used as an adjunct treatment in a prospective study of naturally occurring canine glomerulonephritis. Unfortunately, renal function declined in cyclosporine-treated dogs, as it did in control dogs. The lack of any beneficial effect, along with the adverse reactions to cyclosporine, led to the conclusion that cyclosporine was of no use for treating CRF.[177] As these studies demonstrate, specific manipulation of the inflammatory or immune response can limit renal injury when one can administer medications before or early in the course of renal disease; however, with long-standing, naturally occurring disease, such treatments are much less likely to retard progression of renal failure significantly. Finally, other investigators are focusing on developing therapeutic strategies that may modulate or limit renal fibrosis. Their studies of the effects of cytokines, lymphokines, and proteoglycans on matrix synthesis and degradation by mesangial cells and on fibroblast activation in damaged glomeruli may lead to novel treatment options in the future.[178,179]

17.6

17.6—Urinary Tract Infections

Harold C. Schott, II

In human beings, bacterial urinary tract infections (UTIs) are among the most common infections.[1] In contrast, bacterial UTIs appear to be uncommon in horses.[2–7] As in other species, ascending UTIs are more common,

although septic nephritis may be an occasional consequence of septicemia, especially in neonatal foals.[8] Mares are at higher risk for UTIs than geldings or stallions because of their shorter urethra.

Development of a UTI requires initial urethral colonization with pathogenic bacteria, entry of pathogens into the bladder, and subsequent multiplication in the bladder.[1,9] Urethral colonization involves adherence to uroepithelial cells, typically by fecal bacteria that possess fimbrial adhesins (pili) that bind to specific glycolipid receptors on uroepithelial cells. Not surprisingly, pathogenic *Escherichia coli* are rich in these specific surface adhesins, whereas nonpathogenic *E. coli* have few specific surface adhesins. Further characterization of human pathogenic *E. coli* strains by their somatic (O), flagellar (H), and capsular (K) antigens has revealed that a small number of *E. coli* strains are responsible for a large percentage of UTIs.[1,10,11] Normal vulvar and preputial flora protect against urethral colonization by pathogenic bacteria, but any anatomic defect leading to turbulent urine flow compromises maintenance of normal flora and may increase the likelihood of colonization by pathogens.[12,13] Although broodmares have not been proved to be at greater risk, intercourse is a well-established risk factor for development of UTIs in women. In addition, human prostatic secretions contain a heat-stable cationic protein that has potent antibacterial activity.[1] Thus stallions may be at lower risk than geldings for UTIs.

Once a pathogen has colonized the distal urethra, rapid proliferation between micturitions allows invasion of the proximal urethra and bladder, which do not have a protective flora. Host defenses in the bladder include immunoglobulins in urine and a mucopolysaccharide layer rich in glycosaminoglycans covering the uroepithelial surface.[10,11] Production of protective glycosaminoglycans is under hormonal control by estrogen and progesterone in rabbits.[14] Thus lack of these hormonal effects has been suggested as an explanation for the increased risk for UTIs in prepubertal and postmenopausal women and in spayed dogs.[9] Furthermore, women with recurrent UTIs have been speculatedto have decreased concentrations of secretory immunoglobulin A in their urine.[15] Although continued urine production dilutes proliferating bacteria, once pathogens have gained access to the bladder, the rate of replication far outweighs any dilution effect and allows the UTI to become established.[1] Although antibiotic therapy is highly effective in eliminating most UTIs, recurrent UTIs can be a challenge to manage. In addition to thorough evaluation to eliminate predisposing factors in these patients, one may consider additional approaches to prevention. For example, fimbrial vaccines have been shown to be effective against experimental UTIs in monkeys.[10]

17.6.1 Urethritis

Bacterial urethritis has been described as a cause of hemospermia in stallions[16,17]; however, with the exception of traumatic, parasitic (habronemiasis), or neoplastic conditions of the penis or urethra that interfere with urine flow, the author is unaware of documented cases of primary bacterial urethritis resulting in dysuria.[18,19] Furthermore, hemospermia likely attributable to urethritis in a number of previous cases probably resulted from 1253
proximal urethral defects, which have become easier to identify with high-resolution videoendoscopy (see 1254
Chapter 17.8).[20] Bacterial infections of accessory sex glands or the prepuce also may cause dysuria. Accessory sex gland infections generally are limited to intact males and are more likely to cause infertility or hemospermia than dysuria.[21,22] Preputial infections can occur following trauma, presence of a foreign body, habronemiasis, or neoplasia, and affected horses typically have a malodorous, swollen sheath. Examination of the sheath and penis, along with biopsy of abnormal tissue, allows diagnosis of the primary problem. Occasionally, an older gelding may develop recurrent sheath swelling or infection that cannot be attributed to a primary disease process. The pathogenesis of this problem is not known, although fat accumulation, poor hygiene, and inactivity may be contributing factors. Treatment involves repeated sheath cleaning, application of topical

antiinflammatory and antibacterial ointments, and when involvement is more severe, systemic antibiotic administration.

17.6.2 Cystitis

Bacterial cystitis is usually a secondary problem that may accompany alterations in urine flow caused by urolithiasis, bladder neoplasia, bladder paralysis, an anatomic defect of the bladder or urethra, or instrumentation of the urinary tract (e.g., catheterization and endoscopy).[2–7,12,13,23–27] Dysuria may be manifested by pollakiuria, stranguria, hematuria, or pyuria. One may observe scalding and accumulation of urine crystals on the perineum of affected mares or on the front of the hindlimbs of affected male horses. One should not confuse these findings with normal estrus activity in the mare. Although nosocomial UTIs are a well-documented problem in hospitalized human[1] and small animal patients,[28] this complication has not been well-recognized in equine patients except for ill neonatal foals. Diagnostic evaluation includes physical and rectal examinations and collection of a urine sample for urinalysis and quantitative bacterial culture. In the absence of uroliths or other bladder masses, transrectal palpation of the bladder is usually within normal limits; however, endoscopic and ultrasonographic examination of the bladder may be helpful in assessing mucosal damage and wall thickening in horses with cystitis.[29,30] Because normal equine urine is rich in mucus and crystals, gross examination may be unrewarding, but sediment examination may reveal increased numbers of white blood cells (more than 10 leukocytes per high-power field) and presence of bacteria in some cases of cystitis. Normal sediment examination results do not rule out UTI. A definitive diagnosis requires quantitative culture results exceeding 10,000 colony-forming units (CFUs) per milliliter in a urine sample collected by midstream catch or urethral catheterization.[5,7,31] For best results, one should evaluate urine sediment within 30 to 60 minutes of collection and should cool samples for culture during transport because bacterial numbers may increase in samples left at room temperature. Organisms that may be recovered on culture include *E. coli, Proteus, Klebsiella, Enterobacter, Streptococcus*, or *Staphylococcus* species, *Pseudomonas aeruginosa*, and rarely *Corynebacterium renale*.[2–7,25] Isolation of more than one organism is common. *Salmonella* spp. occasionally have been isolated from the urine of apparently healthy horses, and *Candida* infections of the lower urinary tract also have been documented in sick neonatal foals receiving broad-spectrum antibiotics.[4,5]

Successful treatment of bacterial cystitis requires correction of predisposing problems such as urolithiasis and administration of systemic antibiotics. Ideally, selection of an antibiotic is based on the results of susceptibility testing of isolated organisms, and the initial recommended course of treatment traditionally has been at least 1 week.[2–7] A trimethoprim-sulfonamide combination, ampicillin, penicillin, and an aminoglycoside, or ceftiofur can be initial choices. In human beings with uncomplicated cystitis, single-dose antimicrobial therapy, which is less costly and is associated with fewer adverse effects, has a success rate comparable with that of longer-term conventional therapy (75% or greater). Furthermore, relapse following single-dose therapy is not accompanied by more severe clinical signs or more extensive urinary tract involvement[1]; however, if clinical signs recur after treatment is discontinued, one should repeat urine culture along with additional diagnostic evaluation to determine a cause for altered urine flow or bacterial persistence.

Treatment of recurrent UTI usually requires long-term medication (4 to 6 weeks) and ease of administration and cost become additional considerations in antibiotic selection. Trimethoprim-sulfonamide combinations and the penicillins are excreted via the kidneys and concentrated in urine. Although results of in vitro susceptibility testing of isolated pathogens may reveal resistance, these drugs may have effective antimicrobial activity against the causative organisms because of the high concentrations achieved in urine.[7] Metabolism of the

antibiotic is another consideration. For example, sulfamethoxazole is metabolized mostly to inactive products before urinary excretion, whereas sulfadiazine is excreted mostly unchanged in urine.[32]

Additional treatments for recurrent UTI can include supplementation with 50 to 75 g of loose salt to the diet[7] or provision of warm water during cold weather in an attempt to increase water intake and urine production.
Administration of the urine-acidifying agent ammonium chloride (20 to 40 mg/kg per day by mouth) also has 1254
been recommended in cases of cystitis and urolithiasis.[23] Use of ammonium chloride at this dose, however, has 1255
not produced a consistent decrease in urine pH. Recently, use of larger oral doses of ammonium chloride (60 to 520 mg/kg per day),[33–35] methionine (1 g/kg every 24 hours), vitamin C (1 to 2 g/kg per day),[36] or ammonium sulfate (175 mg/kg per day)[37] were more successful in reducing urine pH to less than 6.0 in a limited number of horses; however, at these doses medications were usually unpalatable and had to be administered by dose syringe or stomach tube. Adding graninto the diet is another simple way to decrease urine pH, although the decline is modest and urine pH typically remains greater than 7.0.[36] A final treatment aid is bladder lavage. This procedure most benefits horses with accumulations of large amounts of crystalloid material in the bladder, a condition that has been termed *sabulous urolithiasis*.[37] Although one can add a number of antiseptics to the sterile polyionic lavage fluid, the most important consideration is adequate volume to flush the crystalline debris completely from the bladder. Concurrent cystoscopy is a useful tool to assess the efficacy of bladder lavage.

One report of experimental induction of cystitis in equids exists.[38] After chemical irritation of the bladder mucosa, 2.5×10^{13} CFUs of *Proteus mirabilis* were instilled into the bladders of nine female ponies. Three days later all ponies demonstrated stranguria, andculture results yielded 20,000 to 100,000 CFUs/ml of *P. mirabilis*. Sediment examination revealed increased numbers of white blood cells (more than 10 per high-power field) in seven of nine ponies, and bacteria were observed in all samples (although in low numbers of 1to 3 per high-power field). In two untreated ponies, the cystitis resolved spontaneously between 2 and 4 weeks after inoculation; however, resolution was complete within 3 to 6 days in ponies treated with a trimethoprim-sulfadiazine combination.

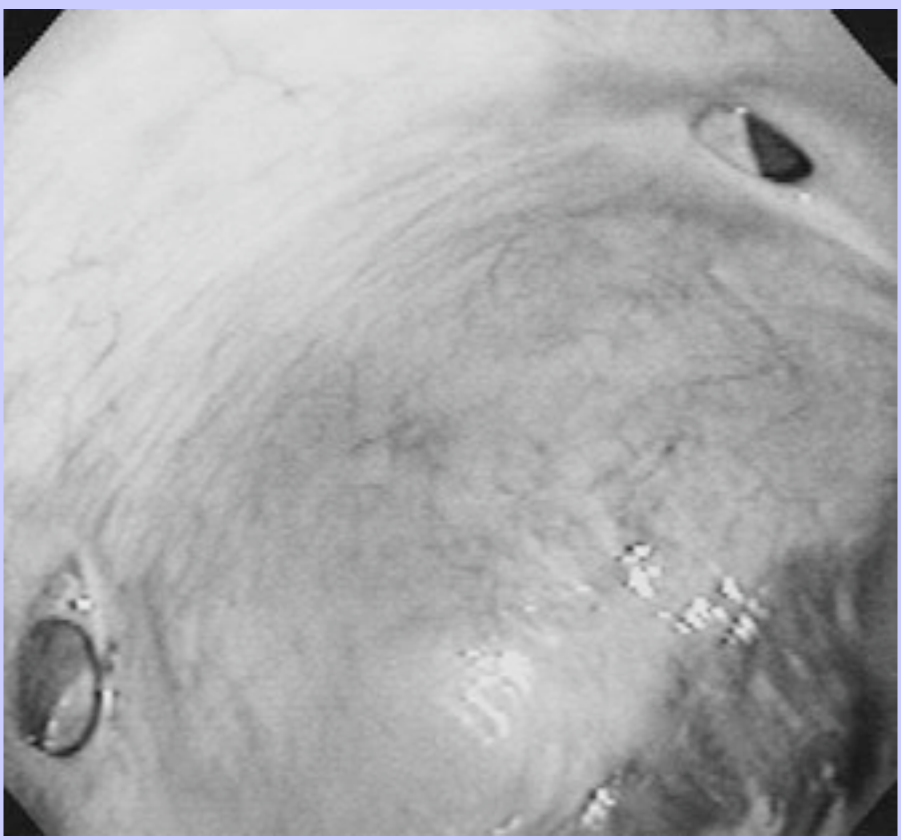
Epizootics of cystitis also have been reported in the southwestern United States[25,39] and in Australia.[40] In the former reports a syndrome of ataxia and urinary incontinence was associated with ingestion of Sudan grass and Johnson grass (hybrids of *Sorghum* species). Both problems were attributed to sublethal intoxication with hydrocyanic acid in the plants, which resulted in demyelination of the lower spinal cord and bladder paralysis. Pyelonephritis was often the cause of death in affected horses.[39] Another outbreak of cystitis, manifested by hematuria more than incontinence, occurred in the Northern Territories and Western Australia in 1963.[40] The kidneys and ureters were not affected, and ataxia was not observed in these horses. The problem, which resulted in loss of more than 200 horses, began shortly after the end of the wet season. Affected horses were on range pasture and, although this was not proved, a fungal toxin was suspected because sporidesmin (a toxin produced by *Pithomyces chartarum*) was known to cause bladder lesions in sheep and cattle. An environmental cause was substantiated further when no additional cases developed in 1964, after a “dry” wet season.

17.6.3 Pyelonephritis

Upper UTIs involving the kidneys and ureters are rarein horses.[3–5,7] The course of the distal segment of the ureters in the dorsal bladder wall creates a physical barrier or valve to prevent vesicoureteral reflux (VUR), a prerequisite for ascending pyelonephritis. Vesicoureteral reflux is more common in children because the

intramural portion of the distal ureter lengthens with growth. Furthermore, congenital VUR often occurs in families, which suggests a genetic tendency for the problem, which has been associated with developmental anomalies of the intramural insertion of one or both ureters.[1] More obvious problems that interfere with this barrier and increase the risk for VUR and associated upper UTIs include ectopic ureter or bladder distention, which may occur with bladder paralysis or urethral obstruction. Over time, VUR leads to progressive ureteral dilation and renal scarring (Figure 17.6-1). This effect explains the common finding of ureteral dilation in young horses with ectopic ureters and provides further support for unilateral nephrectomy, rather than 1255
reimplantation of the ureter, as the treatment of choice for ectopic ureter.[41,42] In addition to VUR, intrarenal 1256
reflux also is required to initiate renal damage predisposing the parenchyma to ascending infection. The renal papillae contain collections of papillary duct openings. These are typically conical structures that protrude into the renal pelvis. Similar to the protective nature of the intramural ureteral segment against VUR, this morphology protects against intrarenal reflux; however, in human infants and young pigs a second type of large, concave, "refluxing" papillae also have been described in the areas of the renal pelvis most often affected with renal scarring.[1] Thus VUR and intrarenal reflux are important in development of pyelonephritis.

Figure 17.6-1 Endoscopic image of the bladder of a pony mare with recurrent cystitis and pyelonephritis. The ureteral openings were distended easily by insufflation of the bladder with air. Ureteral dilation resulted from long-term vesiculoureteral reflux.



The role of recurrent lower UTI in the development of pyelonephritis is less clear. For example, pyelonephritic scarring (without infection) can develop following high-pressure urinary tract obstruction (urethrolithiasis) and can predispose to future upper UTI. In contrast, many cases of recurrent cystitis never proceed to involve the upper urinary tract.[1] Because the kidneys are densely vascular organs, septic nephritis may develop in association with septicemia in neonatal or adult horses.[8] Unless renal involvement is extensive, the upper UTI may go undetected but could lead to development of nephrolithiasis or chronic renal failure months to years later. As in the bladder, defense mechanisms within the normal kidney act to minimize bacterial colonization and proliferation. Efficacy of renal clearance varies with the species of bacteria entering the kidney. In addition, obstruction to urine flow (unilateral ureterolithiasis or nephrolithiasis) increases, rather than decreases, the risk of bacterial proliferation in the obstructed kidney.

Pyelonephritis in horses has been described in association with urolithiasis, recurrent cystitis, and bladder paralysis.[3–5,7,24,39] Other causes have included accidental amputation of the penis during castration,[43] foreign bodies in the bladder,[44] and lower urinary tract neoplasia.[26,45] With pyelonephritis, dysuria is manifested by hematuria or pyuria rather than stranguria and pollakiuria (as for cystitis). In addition, horses with upper UTIs generally have other clinical signs, including fever, weight loss, anorexia, or depression.[3–5,7,44–52] Upper UTIs also can be accompanied by nephrolithiasis or ureterolithiasis or both.[52] In such cases, whether lithiasis or infection develops first or whether both are consequences of VUR, intrarenal reflux, and renal parenchymal damageis unclear. In an occasional case, small uroliths may travel down the ureter and lead to recurrent urethral obstruction with renal colic as the presenting complaint.

As for cystitis, diagnostic evaluation includes physical and rectal examinations, urinalysis, and a quantitative urine culture. Careful palpation may allow detection of an enlarged ureter or kidney, although the kidney also may become shrunken in long-standing cases. In addition to the organisms causing cystitis, one also can isolate *Actinobacillus equuli, Streptococcus equi, Rhodococcus equi,* or *Salmonella* spp. from horses with hematogenous septic nephritis.[5,8] In horses with upper UTIs, one should perform a complete blood count and serum biochemistry profile to assess the systemic inflammatory response and renal function. Finally, cystoscopy (including watching for urine flow from each ureteral opening) and ultrasonographic imaging of the bladder, ureters, and kidneys are helpful adjunct diagnostic procedures.[29,30] Ureteral catheterization (by passing polyethylene tubing via the biopsy channel of the endoscope or by using a No. 8 to 10 French polypropylene catheter, which can be passed blind in mares) may allow collection of urine samples from each ureter to distinguish unilateral from bilateral disease.[53]

Treatment for upper UTIs includes a prolonged course of appropriate systemic antibiotics (selected based on susceptibility testing results on isolated pathogens). In select cases with unilateral disease, one may consider surgical removal of the affected kidney and ureter.[47,54,55] Prerequisites for a nephrectomy include documentation of unilateral disease by normal laboratory results for renal function (absence of azotemia), recovery of insignificant numbers of bacteria (fewer than 10,000 CFUs/ml) from urine collected from the ureter leading to the nonaffected kidney, and ultrasonographic evidence of abnormal structure (e.g., fluid-filled structures and nephrolithiasis) in the affected kidney. Alternatively, poor response to several weeks of appropriate antimicrobial therapy or recurrence of clinical signs of pyelonephritis are additional indications for nephrectomy. Unfortunately, successful treatment of bilateral pyelonephritisis rare, but the poor prognosis likely is related to failure to establish the diagnosis until late in the diseasecourse.

17.6.4 Parasitic Infections

One occasionally finds parasitic lesions associated with the nematodes *Strongylus vulgaris, Halicephalobus* (previously *Micronema*) *deletrix*, and *Dioctophyme renale* in equine kidneys.[56] Although larval migration of *S. vulgaris* in the renal artery and parenchyma is considered aberrant,[57] larval migration was found in more than 20% of horses in one abattoir survey. Passage through renal tissue may result in infarction or subcapsular or pelvic hemorrhage when parasites localize in these sites.[58] Although rare, *H. deletrix* infection is often life threatening because of central nervous system involvement leading to a variety of neurologic deficits that generally require euthanasia.[59–63] *Halicephalobus deletrix* has been suggested to be the most important cause 1256
of verminous meningoencephalomyelitis in horses.[64] Only the female parasite has been identified in equine 1257
tissues, typicallyin highly vascular organs. One usually finds large, granulomatous lesions that are full of the rhabditiform nematodes in the kidneys. The life cycle of *H. deletrix* is unknown, but the apparent saprophyte appears to have worldwide distribution. The finding of gingival lesions and oral granulomata in some horses suggests that ingestion is the likely route of infection. Attempts to find nematode larvae or eggs in urine have been unsuccessful, and whether the horse is an accidental host or is important for the life cycle of the parasite is unclear.[59] The free-living form is found in decaying organic debris (e.g., tree stumps) and also has been described to affect human beings.[63] Antemortem diagnosis has not been made, and cerebrospinal fluid cytologic changes in affected horses cannot differentiate between nematodiasis and protozoal encephalomyelitis.[62] Renal involvement is typically inapparent, although one affected horse demonstrated a 2-week course of stranguria and polyuria before onset of neurologic deficits.[60] *D. renale* is a large, bright red nematode, and the female may reach 100 cm in length. The typical hosts are carnivorous species, but the parasite occasionally affects horses that ingest the intermediate host (annelid worm) while grazing or drinking from natural water sources.[65] Once localized in the kidney, the parasite may live 1 to 3 years; eggs are shed in the urine. The parasite completely destroys the renal parenchyma, and death of the parasite leads to shrinking of the host kidney into a fibrous mass. Occasionally, hydronephrosis or renal hemorrhage may be a serious complication of parasitic infection.[66,67]

In contrast to the nematodes, infection with the coccidian parasite *Klossiella equi* appears common, yet no reports describe clinical disease associated with this coccidial infection.[68–73] Although disorders accompanied by immunosuppression have been suggested to increase its likelihood, *K. equi* infection is still considered an incidental finding in affected horses. The life cycle has not been elucidated fully, but one proposal is that ingested sporocysts (or sporozoites) enter the bloodstream and undergo schizogony in endothelial cells of the glomeruli. Merozoites are released into the urinary space and undergo one or more additional rounds of schizogony in tubular epithelial cells. Eventually, a population of merozoites develops into microgametes and macrogametes. Little evidence of an inflammatory response to parasite replication in renal tissues is apparent. Sporogony follows with the subsequent release of sporocysts into the urine.[69,73] Although *K. equi* has not been associated with clinical disease, it warrants mention that the organism has been found worldwide in horses, ponies, donkeys, burros, and zebras and a recent postmortem survey of47 horses in Australia revealed that 6 (12.8%) were infected.[73]

17.7 17.7—Obstructive Diseaseof the Urinary Tract

Harold C. Schott, II

Most cases of obstructive urinary tract disease in horses are caused by urolithiasis. Urinary tract displacement, trauma, and neoplasia are other causes.[1–4] Urinary tract obstruction can result in a variety of clinical signs depending on the site and degree of obstruction. Incomplete obstruction can result in dysuria, incontinence, and mild abdominal pain, whereas complete obstruction usually results in moderate to severe pain termed *renal colic*. Another complication of complete obstruction is rupture of the bladder or urethra. Signs of pain subside after rupture but are replaced by depression and inappetance, which accompany postrenal acute renal failure. In some cases of disruption of the urinary tract, one also may observe progressive abdominal distention and enlargement of the penis and prepuce.

17.7.1 Epidemiology of Urolithiasis

The epidemiology of urolithiasis varies with species.[5–8] Lower urinary tract stones predominate in veterinary species, whereas upper urinary tract stones are more common in human beings. Historically, lower urinary tract stones were a more substantial problem in human beings as well, and they remain the more common form of urolithiasis in underdeveloped countries. The shift in prevalence from lower to upper urinary tract stones appears to have accompanied industrialization, but the reasons for the shift are not entirely clear.[8]

From 1970 to 1989, urolithiasis was responsible for 0.11% of equine admissions to 22 veterinary teaching hospitals and accounted for 7.8% of the diagnoses of urinary tract disease.[5] Male horses, especially geldings, are predisposed to urolithiasis (75% of all cases), but a breed predisposition has not been described. This sex predilection has been attributed to the shorter, distensible urethra of the mare, which likely permits voiding of small calculi.[6] Urolithiasis is typically an adult disease and the mean age of affected horses is about 10 years.[5] Nevertheless, young horses can be affected, and the author has seen bilateral nephrolithiasis in a weaning foal (likely a consequence of neonatal septicemia) and dysuria in a3-month-old colt caused by multiple cystoliths that formed on sutures used for repair of a ruptured bladder as a neonate. Uroliths are most common in the urinary bladder (60%), although they also may develop in the kidneys (12%), ureters (4%), and urethra (24%).[5] Interestingly, as many as 10% of affected horses have had uroliths in multiple locations.[5] Uroliths can vary greatly in size. In one mare a cystolith weighing more than 6 kg was detected as an apparently incidental finding in a horse destroyed for a limb fracture.[9]

17.7.2 Pathophysiology of Urolithiasis

In general, two steps are required for calculus formation: (1) nucleation and (2) crystal growth.[10–13] Factors that contribute to precipitation of urinary crystals and nucleation include supersaturation of urine; prolonged urine retention; genetic tendencies to excrete larger amounts of calcium (hypercalciuria), uric acid (hyperuricosuria), or oxalates (hyperoxaluria); and inhibitors and promoters of crystal growth. For two or more ions in a solution to precipitate into a crystal, the product of their individual ion activities must exceed the equilibrium solubility product (K_{sp}). A supersaturated solution is one in which the ion activity product exceeds the K_{sp}. A mildly supersaturated solution is termed *metastable*, for crystals tend to precipitate and dissolve at similar rates, so that crystal growth does not occur and the solution remains clear. Once the ion activity product exceeds a critical value (formation product ratio), however, precipitation outpaces dissolution and rapid crystal growth occurs and the solution becomes cloudy.[10–13] Normal human urine typically is supersaturated with one or more ion activity products; however, the formation product ratios are considerably higher in urine (10 times greater than K_{sp}) than they are in an aqueous solution because of the presence of inhibitors of crystal growth.[10] This activity explains why observation of crystals in urine sediment examination is common, yet calculus formation is uncommon. Furthermore, although K_{sp} values are constant for each type of crystal, they vary with temperature and pH. Typically, cooling promotes crystal formation (as when samples are refrigerated), whereas effects of pH vary with the type of calculus (acidification leads to dissolution of calcium crystals but promotes crystallization of urate crystals).[11] Next, any problem resulting in urine retention or incomplete bladder emptying increases the chance of crystal growth. Although not described for horses, genetic variations in ion excretion rates are well-documented risk factors for human and canine urolithiasis. For example, hypercalciuria is inherited as an autosomal dominant trait in human beings and is responsible for 30% to 40% of nephroliths.[10] Similarly, dogs with cystine urolithiasis have an inherited defect in renal tubular transport of cystine, whereas Dalmatians are afflicted with urate stones because of a defect in uric acid metabolism in the breed.[7]

Normal urine is rich in a number of inhibitors of crystal growth including pyrophosphate, citrate, magnesium 1259
ions, glycosaminoglycans, and several glycoproteins including nephrocalcin.[10,11,13] The degree of inhibitory 1260
activity varies with crystal type; for example, pyrophosphate is responsible for 50% of the inhibitory activity against calcium phosphate stone formation in human urine but has a much less inhibiting effect on calcium oxalate stone formation.[10] Although poorly documented, inhibitors of crystal growth in equine urine, including its high mucous content, likely play an important protective role against calculus formation, which would seem

especially true in light of the substantial urinary excretion of calcium carbonate crystals by normal horses. Similar to the risk associated with increased ion excretion, one should not be surprised that defects in inhibitor activity also have been documented in syndromes of human urolithiasis.[10,11] Other urine components may act as promoters of crystal growth. These components principally include organic matrix components of calculi: matrix substance A, uromucoid, and a number of serum proteins.[11,12] Finally, some urine components may have inhibitor and promoter activity. For example, Tamm-Horsfall glycoprotein, a protein secreted in the ascending limb of the loop of Henle that forms the backbone of urine casts, has been shown to promote struvite crystal formation in feline urine.[14] In contrast, the glycoprotein also inhibits calcium oxalate crystal aggregation, and a group of human patients with calcium oxalate urolithiasis recently were demonstrated to have an abnormality in Tamm-Horsfall mucoprotein.[15]

Because normal urine of most species typically is supersaturated and is in balance between crystal precipitation and dissolution, spontaneous nucleation rarely initiates calculus growth. Rather nucleation generally requires stasis of urine flow, increasing the chance of contact between crystalloid material and uroepithelium (as occurs in areas of the renal pelvis) or a damaged uroepithelial surface.[11–14] The latter results in local activation of inflammatory and clotting pathways, producing a nidus for local crystal adherence.[16] In addition, desquamated epithelial cells, leukocytes, or necrotic debris may provide a nidus for crystal growth at more distal sites in the urinary tract. Tissue damage from a variety of causes is likely the most important factor for the development of uroliths in horses. For example, after urinary tract instrumentation (e.g., catheterization and endoscopy), areas of traumatized uroepithelium are covered rapidly with a fine layer of crystalline material. This material usually resolves spontaneously unless infection develops. Similarly, nephroliths may form in the renal medulla or pelvis following papillary necrosis accompanying phenylbutazone toxicity. Once crystal growth begins around a nidus, equine urine has the disadvantage of being highly alkaline, favoring crystallization of most urolith components, especially calcium carbonate.

Horses develop two basic forms of uroliths, and both are composed primarily of calcium carbonate.[6,17] More than 90% are yellow-green, spiculated stones that easily fragment (Figure 17.7-1, *A*). Less commonly, uroliths are gray-white, smooth stones that are more resistant to fragmentation (Figure 17.7-1, *B*). The latter stones often contain phosphate in addition to calcium carbonate. The crystalline composition of normal equine urine sediment (calcium carbonate crystals predominate, although calcium oxalate and phosphate crystals also occur) and uroliths is similar: calcium carbonate in the form of calcite (a hexagonal crystal form of $CaCO_3$) is most common, followed by vaterite (a metastable, hexagonal crystal form in which $CaCO_3$ is replaced partially by magnesium or to a lesser extent by manganese, strontium, and sulfur). Other less common components include aragonite (an orthorhombic crystal form of $CaCO_3$), weddellite (calcium oxalate dihydrate), struvite (magnesium ammonium phosphate hexahydrate), hydroxyapatite, and uric acid (Table 17.7-1).[17–22] Neumann, Ruby, Ling, et al.[17] recently examined the cut surface of a number of equine uroliths by scanning electron microscopy and described a pattern of irregular, concentric bands around the core (Figure 17.7-2, *A*) that were separated by small spherules of crystalline material (Figure 17.7-2, *B*). This pattern suggested that calculus growth occurs by accretion of preexisting microscopic spherules (the crystals already present in normal equine urine) on the surface of the growing urolith rather than by de novo crystal formation at the surface of the urolith. Furthermore, banding was speculated to represent growth through incorporation of organic matrix on the surface of the urolith at times when fewer spherules were present in urine. The gaps between adjacent spherules result in porosity to the urolith. Because precipitation and dissolution occur simultaneously during growth of urinary calculi, porosity allows exposure of inner aspects of the urolith to urine, which can lead to dissolution as urine composition changes. Neumann, Ruby, Ling, et al. described two types of porosity observed by electron microscopy: primary porosity, consisting of the original pores or gaps between spherules,

and secondary porosity, which developed following dissolution of inner areas of the uroliths. Greater dissolution or secondary porosity developed preferentially in areas of the urolith with higher magnesium content (vaterite). More extensive developmentof secondary porosity theoretically leads to increased urolith fragility, which has the therapeutic benefit of increasing the chance that the urolith can be crushed or fragmented before removal.

The role of urinary tract infection (UTI) in the development of urolithiasis appears to vary with species.[7,10,12] 1260
Struvite urolithiasis in human beings and dogs appears to be almost exclusively a consequence of UTI, whereas 1261
most struvite uroliths in cats and sheep are not associated with infection.[12] In addition to contributing to uroepithelial injury and nidus formation, UTI with urease-positive bacteria (*Proteus* species and coagulase-positive staphylococci are most common) allows splitting of urea into two ammonia molecules, which are hydrolyzed rapidly to ammonium ions (a component of struvite crystals).[10,12,13] In a review of 68 horses with urolithiasis, Laverty, Pascoe, Ling, et al. reported positive urine culture results in only 2 of 19 horses in which urine culture was performed[5]; however, culture of material from the centers of 30 calculi yielded positive results from 19 (63%), and a variety of different bacterial species were isolated. Only 1 of 28 calculi examined 1261
in this study contained struvite. The significance of finding bacteria in the center of equine calcium carbonate 1262
uroliths is not known, especially for isolates other than coagulase-positive staphylococci and *Proteus* species, and culture of an appropriately collected sample of urine always is preferred over culture of a calculus.[5,23] Nephroliths and ureteroliths also are found in some cases of pyelonephritis.[24–27] Laing, Raisis, Rawlinson, et al. described a 2-year-old colt with bilateral nephrolithiasis and chronic renal failure. They recovered a *Proteus* species from urine, and the nephroliths were composed principally of calcium carbonate but also contained lesser amounts of struvite.[27] In contrast, Ehnen, Divers, Gillette, et al. found evidence of infection in only one of eight horses with nephrolithiasis or ureterolithiasis or both and chronic renal failure.[28] In the author's experience, the presence of stones in the upper urinary tract or presence of multiple uroliths warrants concurrent evaluation for UTI, for the author has seen two horses with recurrent urinary tract obstruction with urethroliths that were determined ultimately to be sequelae of unilateral pyelonephritis. Holt and Pearson described a similar case in which a renal calculus and abscess were found 5 months after removal of a cystic calculus.[29]

Figure 17.7-1 Equine cystic calculi. **A**, The more common flattened, spherical type of bladder calculus usually is spiculated. **B**, The less common form of gray, smooth-surfaced calculus may be more irregular in shape. (**B** from DeBowes RM: Surgical management of urolithiasis, *Vet Clin North Am Equine Pract* 4:461, 1988.)

17.7.3 Nephrolithiasis and Ureterolithiasis

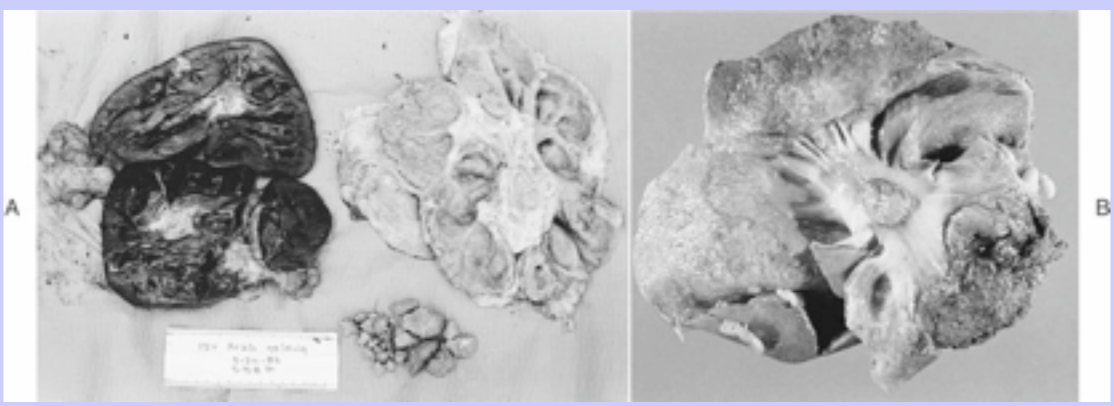
Renal or ureteral calculi rarely were described as a cause of equine urolithiasis before the last decade[30]; however, a number of recent reports[5,26–28,31–35] have described nephrolithiasis and ureterolithiasis in horses. In a review of 68 horses with urolithiasis by Laverty, Pascoe, Ling, et al., 16% had uroliths in the kidneys and ureters and a few horses with cystic calculi also had calculi in the upper urinary tract.[5] Interestingly, 9 of 15 horses with nephroliths in this review were stallions; 3 were geldings, and 3 were mares. Whether a true increase in prevalence of nephrolithiasis and ureterolithiasis has occurred or whether these conditions have become easier to document with the simultaneous development of ultrasonographic imaging as a diagnostic tool for equine medicine is not clear. An undocumented speculation is that young racehorses may be at greater risk of developing renal calculi because of the common use of nonsteroidal antiinflammatory drugs (and risk for development of papillary necrosis) in these athletes.[28] The important point is that one should not overlook upper urinary tract lithiasis in horses.

Nephroliths may develop around a nidus associated with a variety of renal diseases, including polycystic kidney disease (see Figure 17.1-6), pyelonephritis (Figure 17.7-3, *A*), papillary necrosis (Figure 17.7-3, *B*), or neoplasia. At present, data on upper urinary tract stones in horses are insufficient to know whether they develop spontaneously (in the absence of tissue damage) as in human beings or whether they differ significantlyin mineral composition from cystic calculi. Although nephrolithiasis and ureterolithiasis are painful conditions in human beings, horses with nephroliths or ureteroliths often remain asymptomatic until bilateral obstructive

disease leads to development of acute or chronic renal failure. Upper urinary tract stones also may be an incidental finding at necropsy.[30] When clinical signs are present, nonspecific presenting complaints consistent with uremia (poor performance, lethargy, inappetance, and weight loss) are more common than signs of obstructive disease (colic, stranguria, hematuria). Occasionally in the horse, a stone or nidus may pass down the ureter and lead to urethral obstruction and signs of acute obstructive disease. Rectal palpation may reveal an enlarged kidney or ureter (or bladder with urethral obstruction), and ureteral calculi may be palpable in an enlarged ureter. Because normal ureters are not palpable on rectal examination, one should palpate the entire course of the ureters (retroperitoneally along the dorsal abdominal wall to the dorsolateral aspects of the pelvic canal to their insertion at the dorsal bladder neck) because an enlarged ureter is easy to overlook.

One usually diagnoses renal and ureteral calculi during rectal or ultrasonographic examination (Figure 17.7-4). Although ultrasonographic imaging may provide information on the presence, number, and location of calculi, one can miss stones smaller than 1 cm in diameter despite complete examination. Other ultrasonographic findings to support upper tract lithiasis include dilation of the renal pelvis or proximal ureter and, in long-
standing cases, hydronephrosis.[36,37] Although azotemia generally accompanies bilateral disease, horses with 1262
unilateral disease often maintain normal renal function. For reasons detailed previously, one should perform a 1263
quantitative urine culture in all horses with nephrolithiasis or ureterolithiasis to assess possible intercurrent UTI.

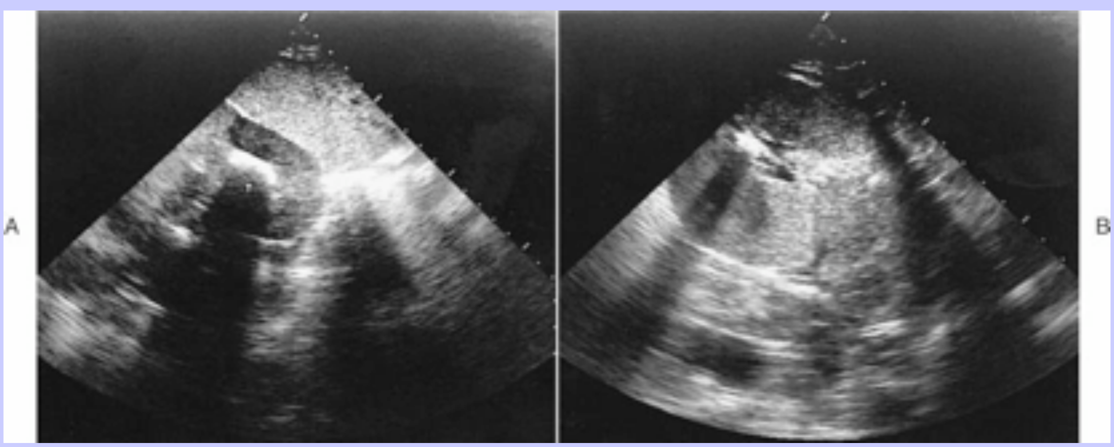
Figure 17.7-3 **A**, Multiple nephroliths developed in association with unilateral pyelonephritis in a gelding that was presented for repeated urethral obstruction. **B**, A small nephrolith lodged in the renal pelvis resulted in ureteral obstruction and development of hydronephrosis in a Standardbred gelding that had a 4-year history of phenylbutazone therapy.



Because most horses with nephrolithiasis or ureterolithiasis are in chronic renal failure by the time the diagnosis is established,[28,38,39] few cases are amenable to treatment. Thus reports of successful managementof horses with renal and ureteral calculi are few. Removal of the calculus, limited to horses with unilateral disease or mild azotemia, has been the only effective means of treatment.[31,33,35] In the absence of azotemia, nephrectomy is the preferred technique for management of unilateral renal calculi.[33] Furthermore, removal of the affected kidney and ureter should eliminate any associated upper urinary tract infection or chance of recurrence. The approach

involves a dorsal flank incision, rib resection, and blunt retroperitoneal dissection to expose the kidney.[40–42] In one horse with mild azotemia, nephrotomy (via an approach similar to nephrectomy) was performed successfully to remove obstructing calculi in the renal pelvis and proximal ureter. Unfortunately, little 1263
improvement in azotemia occurred, and the horse was destroyed a few weeks later.[28] Ureteral calculi also have 1264
been removed by ureterolithectomy via ventral celiotomy and paralumbar approaches.[31,34] A basket stone dislodger (Dormia Stone Dislodger, V Mueller Co., McGow Park, Illinois) introduced through a vestibulourethral approach and guided by rectal palpation also has been used for removal of distal ureteral calculi in the mare.[31] Medical management (antibiotics, grass hay, and salt to promote diuresis) of bilateral ureterolithiasis was attempted in a 3-year-old Thoroughbred filly with incomplete ureteral obstruction and mild azotemia.[34] After 4 weeks, deterioration of clinical signs and more severe azotemia prompted ureterolithectomy to remove stones from the left ureter. Percutaneous nephrostomy was used successfully for placement of a catheter in the right renal pelvis (to establish percutaneous urine flow) for short-term management of azotemia in the postoperative period. Unfortunately, the filly was destroyed after developing cecal impaction 6 days later, and necropsy examination revealed a shrunken, nonfunctional left kidney and a previously undetected nephrolith in the right kidney. This case demonstrated the feasibility and potential benefits of accessing the renal pelvis of the horse via percutaneous nephrostomy.[43,44]

Figure 17.7-4 Ultrasonographic images of the left **(A)** and right **(B)** kidneys of a 10-month-old Arabian filly that developed bilateral nephrolithiasis and chronic renal failure as sequelae of neonatal septicemia. The nephroliths are highly echogenic and cast acoustic shadows in both kidneys.



Rodger, Carlson, Moran, et al. recently described the successful use of electrohydraulic lithotripsy through a ureteroscope to disintegrate a single, unilateral ureterolith in a horse with evidence of bilateral renal disease.[35] Electrohydraulic lithotripsy is a means of converting electric energy into mechanical energy that can be directed to fragment the urolith.[35,45,46] Basically, the device produces an electric discharge arc (a spark) between two electrodes at the tip of the instrument. The heat associated with the discharge causes a small amount of the liquid medium (urine) to burst into gas bubbles, and the associated shock wave fractures the urolith. One must keep the end of the instrument adjacent to the urolith yet away from the mucosa, which could be disrupted by

the same shock waves that destroy the calculus. Although the technique has not been highly successful for treatment of canine uroliths,[47] equine uroliths may be more amenable to its use because they are commonly porous (and fragile). Although electrohydraulic lithotripsy has been effective in treating selected equine cystoliths[45,46] and one ureterolith,[35] the expense of the equipment and availability of other surgical options likely will limit its use to selected cases that are not amenable to routine surgical treatments. A more recent development in upper tract stone removal for human beings and dogs is extracorporeal shock wave lithotripsy.[44] This noninvasive technology uses a reflector to focus the energy from a shock wave generated outside the body on a nephrolith in situ and has proved efficacious in treating human nephrolithiasis. Although extracorporeal shock wave lithotripsy and laser technology have not yet been attempted in horses, they provide future treatment options for equine nephrolithiasis and ureterolithiasis.

17.7.4 Cystic Calculi

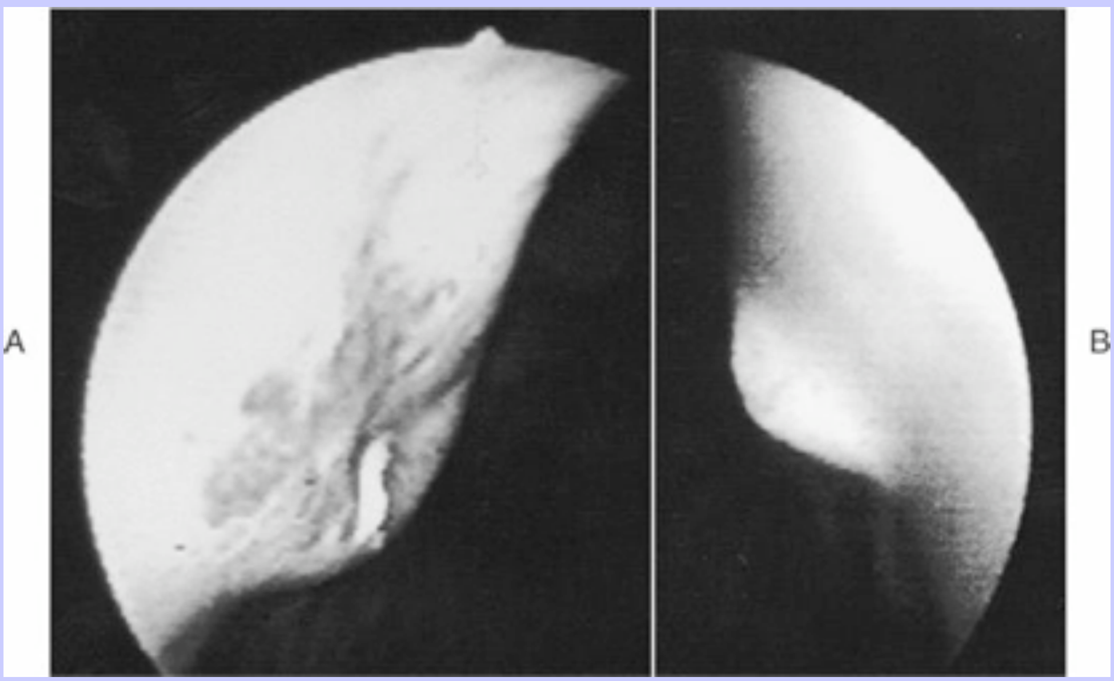
Cystic calculi are the most commonly recognized form of equine uroliths.[1–6,29] Cystoliths typically are flattened, spherical stones with a spiculated or smooth surface. Dysuria resulting from cystoliths may include hematuria, stranguria, pollakiuria, pyuria, or incontinence. Hematuria may be more apparent after exercise. An affected male horse may demonstrate stranguria by repeatedly dropping its penis and posturing to urinate but voiding little or no urine. An affected mare also may posture repeatedly to urinate and demonstrate winking, and these signs could be confused with estrus activity. Less common signs include an irritable attitude, recurrent colic, and loss of condition; one burro was presented for recurrent rectal prolapse.[48]

One usually diagnoses cystic calculi by palpation of the bladder per rectum. Bladder uroliths are usuallylarge enough to be detected easily; however, if the bladder is distended, one may need to empty it by passing a catheter to facilitate palpation of the stone. Bladder catheterization also allows assessment of urethral patency and collection of samples for urinalysis and quantitative culture. One should perform a complete blood count and serum biochemical profile to document whether anemia, inflammation, or azotemia has developed. Cystoscopic examination is helpful in assessing the severity of damage to the bladder mucosa and any asymmetry in appearance or function of the ureteral openings (Figure 17.7-5).[49,50] Because one may find caluculi in multiple sites in the urinary tract, thorough evaluation of the upper urinary tract is warranted for all cases of cystic urolithiasis.

In contrast to upper urinary tract lithiasis, many reports[45,46,48,51–66] and several reviews[*] detail the clinical signs and surgical options for management of cystic calculi. The size of the calculus, gender of the horse, and surgeon's preference play a role in treatment selection. The preferred technique in males, especially for larger stones, is laparocystotomy through a ventral midline or paramedian incision with the horse in dorsal recumbency under general anesthesia. For removal of smaller cystoliths, one can perform a perineal urethrotomy in the standing male horse with the use of local or epidural anesthesia. One catheterizes the urethra to facilitate identification of the urethra and makes an incision at the level of the ischial arch. After incising the 1264
urethra, one uses forceps to grasp and remove the calculus and lavages the bladder to remove remaining debris. 1265
One may attempt removal of larger calculi via this approach by using a lithotrite to crush the urolith into smaller fragments. One can close the urethral incision, but it usually is allowed to heal by second intention. Although one can perform this approach at less expense and avoid the risks of general anesthesia, the risk of complications is greater. Complications include urethral trauma and stricture formation,[29,69,70] urethrolith formation at the surgical site,[5,71] development of a urethral diverticulum,[71] and persistent urine passage through a fistula at the surgical site.[70,72] The distensible urethra of the mare allows retrieval of cystic calculi via this route in many cases. Using sedation and epidural anesthesia, one can remove the stone intact with forceps or by

direct grasping if the surgeon has small hands. One may crush a spiculated urolith with a lithotrite to ease removal. One can manipulate spiculated stones or urolith fragments further into a sterile plastic bag or palpation sleeve to minimize trauma to the urethral mucosa during removal. If necessary, one also can enlarge the urethral lumen by performing sphincterotomy in the dorsal aspect of the urethra.[73] A pararectal (Gökels) approach for a dorsal cystotomy[40,66] and electrohydraulic lithotripsy,[45,46] as described for ureterolithiasis, also have been used in male and female horses to treat cystic calculi.

Figure 17.7-5 View of the abnormal left **(A)** and normal right **(B)** ureteral openings of a horse with unilateral pyelonephritis and recurrent cystic calculi. The diagnosis was confirmed by culture of urine samples collected from each ureter.

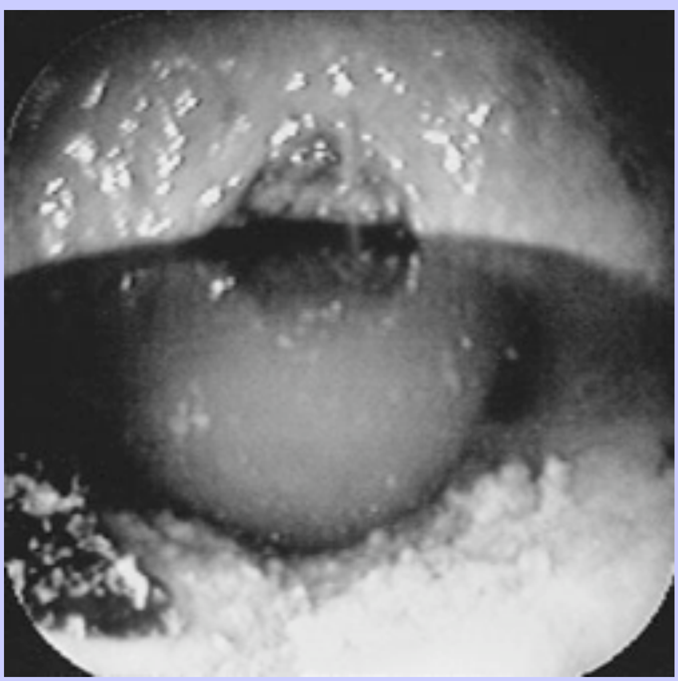


Following surgical removal of cystoliths, one administers systemic antibiotics and an antiinflammatory agent for a minimum of 1 week. As for cystitis, one shouldbase antibiotic selection on susceptibility testing of recovered isolates. If culture results are negative, a sulfonamide-trimethoprim combination is an appropriate selection. An early report by Lowe described excellent long-term results—and no recurrence—after removal of cystic calculi by laparocystotomy in four horses.[71] Similar low rates of recurrence have been echoed in several reviews of equine urolithiasis.[6,29,40,67] In contrast to these favorable reports (most of which do not provide supporting data), Laverty, Pascoe, Ling, et al.[5] reported that clinical signs of urolithiasis recurred in 12 of 29 horses (41%) for which follow-up data were available. The interval between episodes of recurrence was 1 to 32 months (mean 13 months). As initially described in 1965 by Lowe,[71] Laverty, Pascoe, Ling, et al.[5] also found greater recurrence of cystic calculi after treatment by perineal urethrotomy (7 of 15 horses) compared with laparocystotomy. Other complications of cystic calculi unrelated to the surgical approach have included vesicoureteral reflux and renal failure[74] and concurrent urolithiasis at other sites.[5] Although a more common

complication of urethral obstruction,[69] bladder rupture also may occur following cystic urolithiasis. The author also has seen a case of squamous cell carcinoma of the bladder that was associated with a large cystic calculus and development of uroperitoneum following bladder rupture (Figure 17.7-6).

Postoperative recommendations that may help prevent recurrence include control of UTI and use of urinary acidifiers, although the benefits of the latter are not well-documented (see Cystitis in Chapter 17.6).[6,64,67,68,75] Other considerations for decreasing recurrence include dietary modifications to decrease calcium excretionand 1265
to promote diuresis. Changing the diet from a high-calcium hay such as alfalfa to grass or oat hay would 1266
decrease dietary calcium and thus should decrease urinary calcium excretion because fecal calcium excretion is relatively constant in horses.[76] This dietary change should decrease total calcium excretion and may decrease urinary nitrogen excretion and daily urine volume.[77] The latter changes could enhance supersaturation of urine. In theory, the addition of 50 to 75 g of loose salt daily to the concentrate portion of the diet should promote diuresis; however, in a study of ponies fed sodium chloride as 1%, 3%, or 5% of the total dry matter of the diet (1% approximates 75 g of sodium chloride for a 500-kg horse), no differences in water intake, urine production, or calcium excretion were observed.[78] Another factor that affects urine pH and urine calcium excretion is dietary cation-anion balance (DCAB = [Na + K] – [Cl + S]). A lower DCAB has been associated with a decrease in urine pH and an increase in urinary calcium excretion.[79–81] Increasing the amount of grain in the diet, changingto lower-quality hay, or adding one or more minerals to the diet (e.g., ammonium chloride, calcium chloride, or ammonium sulfate) usually lowers DCAB. Not surprisingly, supplements that decrease DCAB are familiar as urinary acidifying agents. Because a diet low in calcium and DCAB could result in a negative calcium balance, a possible long-term effect could be decreased skeletal calcium content.

Figure 17.7-6 A large urolith is present in the bladder below the surface of the pool of urine. The cystolith was accompanied by bacterial cystitis and squamous cell carcinoma of the bladder.



Despite the success of dietary management (low-protein, phosphorous, and magnesium) for medical dissolution of canine[82] and feline[83] uroliths, dietary management is unlikely to replace surgical treatment of cystic urolithiasis in horses. This problem can be attributed to the fact that dietary management for small animals has been directed at struvite urolithiasis and that such stones are not common in horses. Nevertheless, one should not overlook dietary management as one of the postoperative recommendations for urolithiasis, for it could decrease the risk of recurrence. At the least, legume hays and dietary supplements containing calcium should be avoided, and the diet could be supplemented with 50 to 75 g of loose salt daily. Remillard, Modranksy, Welker, et al. successfully used these dietary manipulations effectively, along with administration of ammonium sulfate as a urine-acidifying agent, to manage one recurrent case of equine urolithiasis.[84]

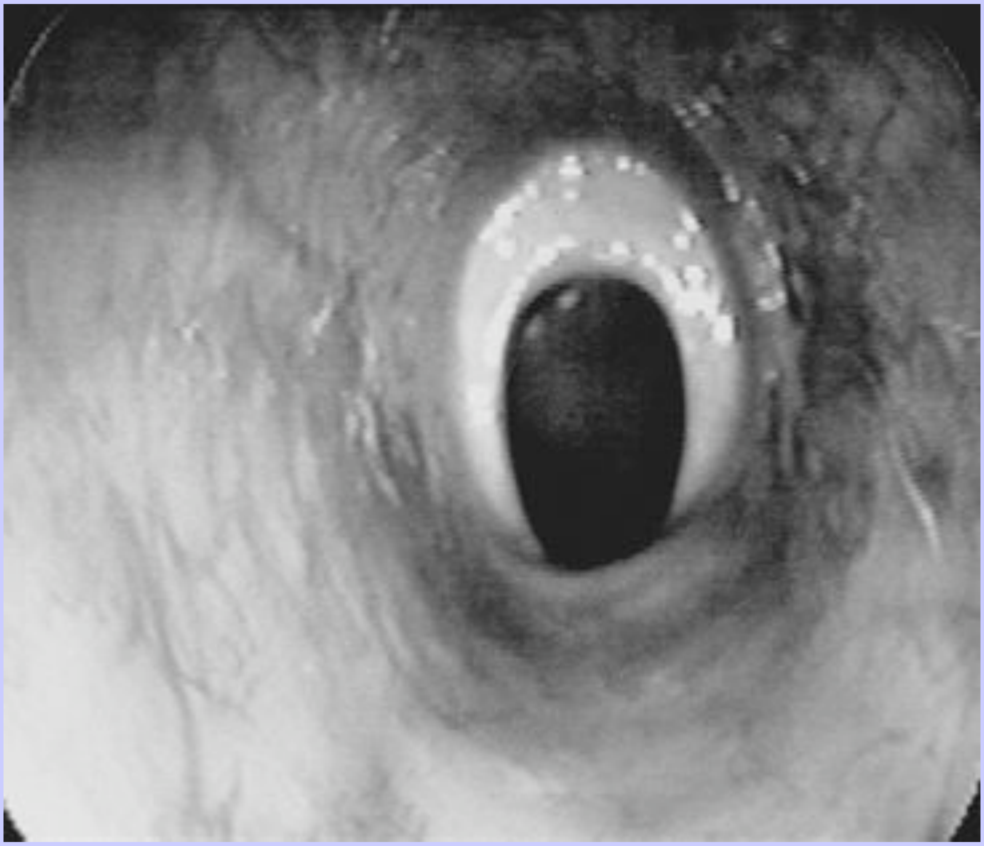
17.7.5 Urethral Calculi

Urethral calculi are primarily a problem of malehorses,[1–6,69,71,85,86] although they have been detected ina few mares.[5] In the absence of predisposing urethral damage or stricture formation, urethroliths are usually small cystoliths passed into the urethra. Thus most urethroliths initially lodge where the urethra narrows as it passes over the ischial arch. They may pass slowly farther down the urethra, until complete obstruction produces signs of renal colic. One should consider an obstructing urethral calculus when male horses show colic signs and frequently posture to urinate. Occasionally, one may see blood on the end of the urethra. Palpation of the penis may reveal repeated urethral contractions or a firm mass in the urethra. Rectal palpation reveals a distended bladder that is turgid, unlike the flaccid bladder distention of bladder paralysis. If the bladder ruptures, colic signs are supplanted by progressive depression and anorexia following the development of postrenal acute renal failure.[5,69,85,86] One confirms the diagnosis by passage of a urinary catheter that is then obstructed by the urolith or by endoscopic examination of the urethra. One can confirm suspected bladder rupture by measuring a twofold or greater increase in peritoneal fluid creatinine concentration compared with serum creatinine concentration.

One can remove calculi lodged at the ischial arch through a perineal urethrotomy. Passage of a catheter into the bladder, if that is not achieved before surgery, is necessary to ensure a patent urinary tract after stone removal. The urethrotomy is allowed to heal by second intention, and temporary use of an indwelling bladder catheter usually is not necessary. One often can remove calculi lodged in the distal urethra from a sedated horse by gentle transurethral crushing of the urolith with a hand or forceps. For a calculus lodged distal to the ischial 1266
arch and unpalpable in the distal portion of the penis, general anesthesia and positioning the horse in dorsal 1267
recumbency are generally necessary for surgical removal of the stone. One may close the urethra or allow it to heal by second intention. Follow-up endoscopic examination of the urethra allows assessment of urethral healing and possible stricture formation (Figure 17.7-7). Further treatment includes administration of antibiotics and antiinflammatory agents until dysuria resolves. Although initial treatment of urinary tract obstruction caused by a urethrolith is straightforward, the prognosis for affected horses should remain guarded because a number of potential complications of perineal urethrotomy (described previously) may occur. Furthermore, a substantial number of horses have had poor outcomes because of associated bladder rupture and peritonitis[5,69,85] or upper urinary tract lithiasis or pyelonephritis.[5,29]

Figure 17.7-7 Stricture formation in the urethra at the level of the ischial arch formed as a complication of a perineal urethrotomy.



17.7.6
Sabulous Urolithiasis

Another form of equine urolithiasis termed *sabulous urolithiasis* also has been described in a limited number of horses.[29,87] Sabulous (Greek for *sand*) urolithiasis refers to the accumulation of large amounts of crystalloid urine sediment in the ventral aspect of the bladder. This condition is a secondary problem resulting from bladder paralysis or other physical or neurologic disorders interfering with complete bladder emptying.[88–90] Affected horses usually are presented for evaluation of urinary incontinence or hindlimb weakness and ataxia, and one may detect accumulation of urine sediment in a distended bladder during rectal palpation. Symptomatic treatment includes repeated bladder lavage, medications that promote bladder emptying, and broad-spectrum antibiotics, but the condition carries a poor prognosis unless the primary problem resulting in bladder paralysis can be resolved (see Chapter 17.12).

17.7.7
Bladder Displacement

Displacement of the urinary bladder is a rare cause of obstruction and dysuria.[91–95] In mares, two types of bladder displacement can occur: (1) extrusion through a tear in the floor of the vagina or (2) true prolapse with

eversion of the bladder.[96] Urethral obstruction also may occur with vaginal or uterine prolapse. In male horses, scrotal herniation of the bladder has been described, but this type of bladder displacement is rare.[97] Bladder displacements typically result from repeated abdominal contractions or straining. Thus they most often are associated with parturition and to a lesser extent with colic. Perineal lacerations following trauma or foaling may lead to extrusion, whereas excessive straining without laceration leads to prolapse/eversion. Because the bladder turns inside out with the latter problem, one establishes the diagnosis by recognizing the appearance of the bladder mucosa and ureteral openings. Eversion does not always result in obstruction.

With urethral obstruction, one should pass a catheter into the bladder before correction of the displacement. In the absence of obstruction, one corrects extrusions during repair of the perineal or vaginal laceration. One should institute a course of broad-spectrum antibiotics and an antiinflammatory agent because pelvic abscess and peritonitis are potential complications. Manual reduction of bladder eversions may be successful in some cases, but more often than not one may need to perform urethral sphincterotomy to replace the bladder.[95] In some cases, reduction via laparotomy may be necessary because the everted bladder may be filled with the pelvic flexure, complicating manual reduction.[94] A purse-string suture placed in the area of the external urethral sphincter may be of benefit to prevent recurrence of the prolapse, and medical treatment should include broad-spectrum antibiotics and an antiinflammatory agent because UTI is a potential complication.

17.7.8 Penile Trauma

Urinary tract obstruction is an occasional complication of penile trauma or paraphimosis, and one should consider the patency of the urethra in all cases of penile injury. Causes may include blunt trauma, breeding injuries, use of stallion rings, sedation with phenothiazine tranquilizers, or laceration during castration.[98–101] In 1267
addition to preputial swelling, injury may result in a penile hematoma or possible paraphimosis.[102,103] In one 1268
report, hematoma formation in the corpus spongiosum penis of a Quarter Horse stallion resulted in complete obstruction and bladder rupture.[104] In addition to ensuring patency of the urinary tract, treatment includes administration of antibiotics and antiinflammatory agents until most of the swelling resolves. One may close lacerations of the urethra or leave them to heal by second intention depending on location and condition ofthe wound. Because stricture formation is a possible complication, some wounds may be treated better by phallectomy than by urethral repair.[100]

17.8 17.8—Hematuria

Harold C. Schott, II

Hematuria can be a presenting complaint for a variety of disorders of the urinary tract, including vascular malformation, urinary tract infection, urolithiasis, and neoplasia. In addition to these problems, which are discussed elsewhere in this chapter, several other specific causes of hematuria occur. These causes range from microscopic hematuria accompanying exercise to more severe conditions that can result in life-threatening urinary tract hemorrhage. In addition, normal equine urine may contain pyrocatechine, an oxidizing agent that can cause urine to turn red to brown after exposure to air, snow, or bedding (especially wood shavings).[1]

Although values have not been determined in horses, normal human urine contains about 5000 (range 2000 to 10,000) red blood cells per milliliter.[2] This range of red blood cell excretion should yield negative results on reagent strip analysis and a report of not more than 5 red blood cells per high-power field on sediment examination. Increases in red blood cell excretion may lead to microscopic or macroscopic hematuria. Microscopic hematuria, which implies an increase in red blood cell excretion that is not visible grossly, usually is associated with increases in the range of 10,000 to 2.5 million red blood cells per milliliter of urine. On sediment examination at least 10 red blood cells per high-power field should be apparent. Reagent strip analysis results can range from trace to +++. One must realize that reagent strip results, which use the peroxidase-like activity of hemoglobin and myoglobin to oxidize a chromogen in the test pad, do not differentiate between hemoglobin and myoglobin.[3] Thus positive results are not specificfor hematuria and may be more appropriately termed *pigmenturia*. Despite this limitation, one can use reagent strips to differentiate hematuria from hemoglobinuria or myoglobinuria when the color change is limited to scattered spots on the test pad. This pattern implies that intact red blood cells were adsorbed onto the pad, underwent lysis, and produced a localized color change caused by hemoglobin activity on the chromogenic substrates. Ability to differentiate hematuria from excretion of the heme pigments is limited to a threshold of 250,000 to 300,000 red blood cells per milliliter of urine, unless urine samples are diluted with normal saline. Other limitations of reagent strip analysis include false-positive reactions when urine samples are contaminated with oxidizing agents (e.g., disinfectants) or false-negative reactions when urine samples contain vitamin C or have been preserved with formalin.[3]

Macroscopic or gross hematuria indicates red blood cell excretion in excess of 2.5 million to 5 million red blood cells per milliliter of urine (or about 0.5 ml of blood per liter of urine).[2–5] One can differentiate macroscopic hematuria from other causes of pigmenturia by centrifuging a sample of urine to produce a red cell pellet and yellow supernatant urine. Quantification of erythrocyte numbers in macroscopic hematuria is of little clinical value. In contrast, urinary red blood cell numbers may provide diagnostic and prognostic information in cases of

microscopic hematuria in human beings.[2] However, variations in urine concentration complicate accurate counts. In concentrated urine (specific gravity greater than 1.020), red blood cells tend to become crenated because of the osmotic shift of water out of the cells. In urine with a specific gravity less than 1.010, osmotic swelling and dilution of hemoglobin lead to "ghost cell" formation.[2,6] Furthermore, many red blood cells lyse in dilute urine (especially alkaline urine) so that red blood cell excretion is vastly underestimated. Reagent strip analysis can be useful in dilute urine samples to detect hemoglobin released from lysed erythrocytes.[5]

Microscopic examination of urine sediment in cases of hematuria is helpful in distinguishing glomerular from nonglomerular bleeding. The hallmark of glomerular bleeding is a substantial variation in red blood cell size, shape, and hemoglobin content (termed *dysmorphism*), whereas bleeding from other sites produces a more uniform population of urinary erythrocytes.[2,5,7] Dysmorphism is attributed to membrane deformation, which occurs as erythrocytes traverse the glomerular filtration barrier.[7] Urinary red blood cells in normal persons are 1270
typically dysmorphic, indicating glomerular origin, but the excretion rate is low.[2] Thus one must interpret urinary 1271
red blood cell morphologic characteristics along with urinary red blood cell numbers to determine significance.[7,8] The volume of dysmorphic cells tends to be lower than that of erythrocytes of nonglomerular origin, so that measurement of mean corpuscular volume also has been used to separate glomerular from nonglomerular bleeding.[9] The presence of red blood cells or hemoglobin casts is also pathognomonic for glomerular bleeding.[2,5,7] These casts form as urinary red blood cells and hemoglobin from the proximal portion of the nephron (glomerulus) combine with Tamm-Horsfall mucoprotein secreted in the ascending limb of the loop of Henle. Because urinary red blood cells and casts deteriorate rapidly in urine samples, other methods of detecting glomerular hematuria such as immunocytochemical staining for Tamm-Horsfall glycoprotein have been developed but have not gained widespread use.[10]

Noting the timing of hematuria is usually a more practical means of initially localizing the site of urinary tract hemorrhage.[6] Hematuria throughout urination is consistent with hemorrhage from the kidneys, ureters, or bladder, whereas hematuria at the beginning of urination often is associated with lesions in the distal urethra. Hematuria at the end of urination usually results from hemorrhage from the proximal urethra or bladder neck. A thorough diagnostic evaluation, including physical examination, rectal palpation, analyses of blood and urine, endoscopy of the lower tract, and ultrasonography, usually is rewarding in establishing the source and cause of urinary tract hemorrhage.[1]

Urinary tract infection, although uncommon in horses, may result in hematuria. With infection of the upper urinary tract, partial anorexia, weight loss, and fever may be additional presenting complaints, whereas horses with cystitis generally manifest stranguria and pollakiuria; however, hematuria has been the presenting complaint in several reports of cystitis and pyelonephritis.[11–15] The presence of uroliths at any level of the urinary tract may cause mucosal irritation and hemorrhage, resulting in hematuria.[16–18] Typically, affected horses also show signs of renal colic or painful urination (stranguria or pollakiuria), especially with uroliths in the bladderor urethra. Finally, neoplasia of the kidneys, ureters, bladder, or urethra also may result in hematuria as the presenting complaint.[19–22] These conditions are discussed in detail in other sections in this chapter.

17.8.1 Drug Toxicity

Nephrotoxicity, particularly following administrationof nonsteroidal antiinflammatory drugs (especially phenylbutazone), may result in microscopic or gross hematuria.[23–27] Historical or current use of nephrotoxic

medications supports this diagnosis, and discontinuation of the nephrotoxic agent and supportive care are the appropriate treatments.

17.8.2 Urethral Defects

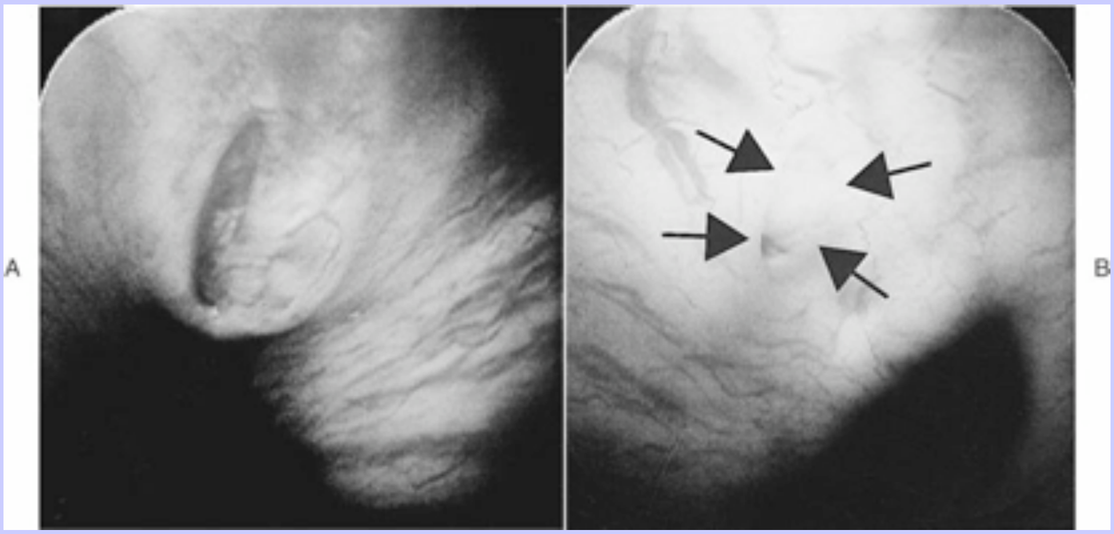
Although a recognized cause of hemospermia in stallions, rents or tears of the proximal urethra at the level of the ischial arch are a more recently described cause of hematuria in geldings.[1,28,29] Because the defects are difficult to detect without high-resolution videoendoscopic equipment, the lesions likely may have been missed in previous reports of urethral bleeding.[30,31] Consequently, hematuria has been attributed to urethritis or hemorrhage from "varicosities" of the urethral vasculature.[28,31] Because the vasculature underlying the urethral mucosa becomes prominent when the urethra is distended with air during endoscopic examination, especially in the proximal urethra (to the point that one can see blood flowing in the submucosal vasculature), one easily would suspect that hemorrhage could arise from apparent urethritis or urethral varicosity.

Urethral rents or tears typically result in hematuriaat the end of urination in association with urethral contraction.[1,28,29] Affected horses generally void a normal volume of urine that is not discolored. At the end of urination, a series of urethral contractions results in squirts of bright red blood. Occasionally, the horse may pass a smaller amount of darker blood at the start of urination. In most instances the condition does not appear painful or result in pollakiuria. Interestingly, most affected stallions with hemospermia and geldings with hematuria have been Quarter Horses or Quarter Horse crosses that have been free of other complaints.[29,31] Treatment with antibiotics for suspected cystitis or urethritis routinely has been unsuccessful, although hematuria has resolved spontaneously in approximately half of the cases seen by the author.

Examination of affected horses is often unremarkable. In comparison, horses with hematuria caused by neoplasms involving the distal urethra or penis usually are presented with additional complaints such as pollakiuria, a foul odor to the sheath, or presence of a mass in the sheath or on the penis.[32] With urethral rents, laboratory analysis of blood reveals normal renal function, although mild anemia can be an occasional finding. Urine samples collected midstream or by bladder catheterization appear grossly normal. Urinalysis may have normal results or the number of red blood cells may be increased on sediment examination, a finding that also would result in a positive reagent strip result for blood. Bacterial culture of urine yields negative results.

One makes the diagnosis via endoscopic examination of the urethra, during which one typically sees a lesion 1271
along the dorsocaudal aspect of the urethra at the level of the ischial arch (Figure 17.8-1, *A*). With hematuria of 1272
several weeks' duration, the lesion appears as a fistula communicating with the vasculature of the corpus spongiosum penis (Figure 17.8-1, *B*). External palpation of the urethra in this area is usually unremarkable but can help localize the lesion because external digital palpation is visible via the endoscope as movements of the urethra.

Figure 17.8-1 Endoscopic images of urethral defects or tears at the level of the ischial arch. **A**, A more acute lesion (hematuria of 2 weeks' duration) is surrounded by a raised rim of tissue. **B**, A chronic lesion (hematuria of 6 months' duration) is flat to recessed *(between arrows)*. Evidence of inflammation around both lesions is minimal.



Although the pathophysiology of this condition remains unclear, the defect has been speculated to result from a "blowout" of the corpus spongiosum penis (cavernous vascular tissue surrounding the urethra) into the urethral lumen (Figure 17.8-2).[29] Contraction ofthe bulbospongiosus muscle during ejaculation causes a dramatic increase in pressure in the corpus spongiosum penis, which is essentially a closed vascular space during ejaculation. The bulbospongiosus muscle also undergoes a series of contractions to empty the urethra of urine at the end of urination; thus the defect into the urethra may develop by a similar mechanism in geldings. Once created, the lesion is maintained by bleeding at the end of each urination, and the surrounding mucosa heals by formation of a fistula into the overlying vascular tissue. An explanation for the consistent location along the dorsocaudal aspect of the urethra at the level of the ischial arch has not been documented but may be related to the anatomy of the musculature supporting the base of the penis and an enlargement of the corpus spongiosum penis in this area. Furthermore, a narrowing of the lumen of the urethra at the distal extent of the ampullar portion of the urethra occurs that also may contribute to the location of the defects. An anatomic predisposition in Quarter Horses has not been documented but could be speculated to be based on an apparently increased risk in this breed. In addition, some of the affected horses have asymmetry to the musculature under the tail in this area, supporting a possible developmental defect (Figure 17.8-3).

Because hematuria may resolve spontaneously, no treatment may be required initially. If hematuria persists longer than a month or if significant anemia develops, a temporary subischial urethrotomy has been successful in a number of affected geldings. With sedation and epidural or local anesthesia, one makes a vertical incision down to a catheter placed in the urethra. The surgical wound requires several weeks to heal, and moderate hemorrhage from the corpus spongiosum penis is apparent for the first few days after surgery. Additional

treatment consists of local wound care and prophylactic antibiotic treatment (typically a trimethoprim-sulfonamide combination) for7 to 10 days. Hematuria should resolve within a week following this procedure. Limiting the incision to entry of the corpus spongiosum penis but not into the urethral lumen also has been a successful treatment and is now the preferred surgical treatment.[29] This treatment option provides support for the blowout cause and lessens the risk of urethral stricture formation. Furthermore, the treatment decreases the chance of a permanent fistula forming at the site, a surgical complication that has occurred in two geldings.

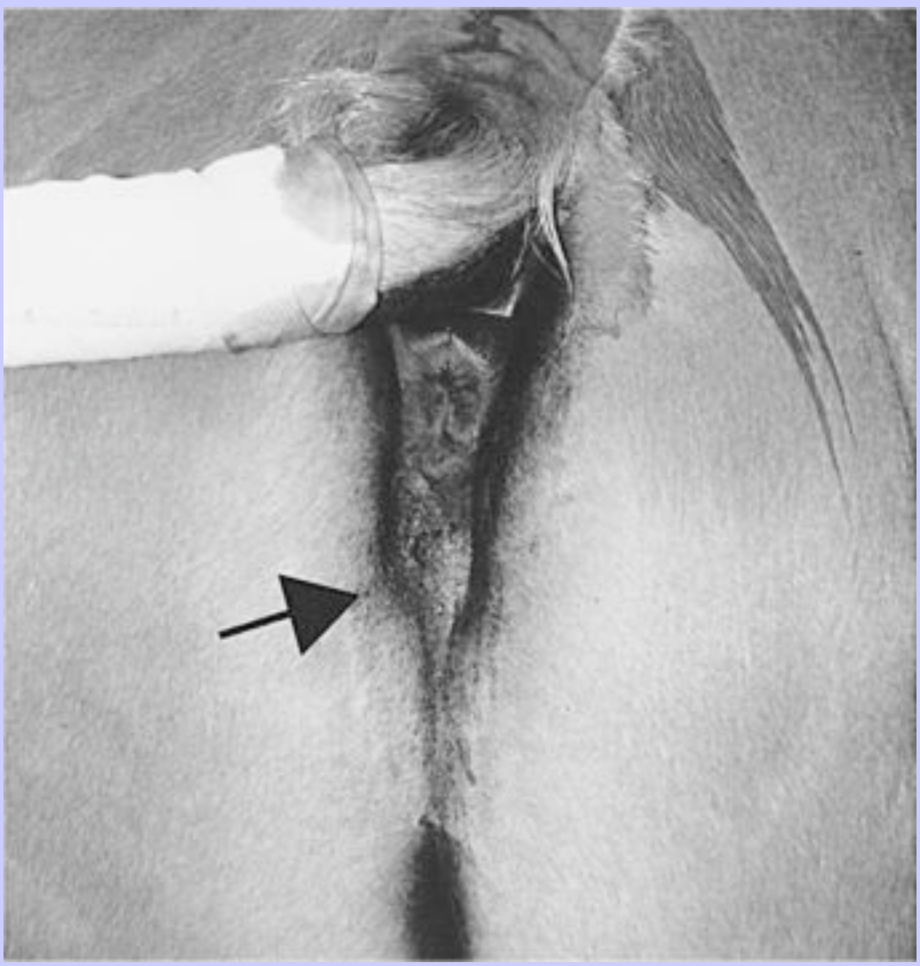
Figure 17.8-2 Cross-sectional diagram of the equine penis at the level of the ischial arch shows a defect between the corpus spongiosum penis (csp) and the urethral lumen *(U)*. The corpus spongiosum penis is a cavernous tissue surrounding the urethra that is distinct from the corpus cavernosum penis (CCP); the corpus spongiosum penis is also adjacent to the bulbospongiosus muscle (BS) caudally. (From Schumacher J, Varner DD, Schmitz DG et al: Urethral defects in geldings with hematuria and stallions with hemospermia, *Vet Surg* 24:250, 1995.)

1272

17.8.3 Idiopathic Renal Hematuria

Idiopathic renal hematuria is syndrome characterizedby sudden onset of gross, often life-threatening hematuria.[33,34] Hemorrhage arises from one or both kidneys and is manifested by passage of blood clots in urine. Endoscopic examination of the urethra and bladder usually reveals no abnormalities of these structures, but one may see blood clots exiting one or both ureteral orifices. Although one may establish a definitive cause of renal hemorrhage in some horses (e.g., renal adenocarcinoma and arteriovenous or arterioureteral fistula),[35,36] the disorder is termed *idiopathic* when one cannot find a primary disease process. Both sexes, a wide age range, and several breeds of horses (including a mammoth donkey and a mule) have been affected. However, more than 50% of animals with idiopathic renal hematuria have been Arabians.

Figure 17.8-3 Perineum of Paint gelding with hematuria associated with a proximal urethral defect; the asymmetry of the perineal musculature is visible at the level of the ischial arch. (Arrow shows where asymmetry is more prominent on left side.)



Use of the term *idiopathic renal hematuria* to describe this syndrome of horses was adopted from its use in human patients and dogs with severe renal hemorrhage.[37–44] *Benign essential hematuria* and *benign primary hematuria* are other terms that describe less severe hematuria that is not associated with trauma or other obvious causes of hematuria. In the latter species, hematuria is more commonly a unilateral than a bilateral problem, similar to what has been observed in the few affected horses. The pathophysiology remains poorly understood, but macroscopic hematuria has been associated with immune-mediated glomerular damage (e.g., acute postinfectious glomerulonephritis, membranoproliferative glomerulonephritis, and immunoglobulinA nephropathy or Berger's disease), thin basement membrane nephropathy, and the loin pain–hematuria syndrome in human patients.

Although hematuria and pigmenturia can accompany a number of systemic diseases in horses,[45–47] patients affected with idiopathic renal hematuria appear to have spontaneous, severe hematuria in the absence of other signs of disease. Although one report suggested that severe renal hemorrhage resulted from pyelonephritis,[15] supportive data were lacking. In cases managed by the author, neither urinary tract infection nor lithiasis has 1273
been detected and the magnitude of hematuria often resulted in need for repeated blood transfusions. As with 1274
hemorrhage associated with guttural pouch mycosis, the syndrome may produce episodic hemorrhage. Initially, one notes hemorrhage by finding a large amount of clotted blood in stall bedding or in the pasture. However, other client complaints (e.g., depression, anorexia, and weight loss) are typically absent. Examination may reveal dried blood at the end of the penis or in the sheath of males or on the vulvar lips and between the hindlimbs of mares. In both sexes neoplasia of the external genitaliaor urinary tract is an important differential diagnosis, whereas in mares one also must consider varicositiesin the area of the vestibulovaginal sphincter, especially in multiparous mares. When one does not detect bloodin the sheath or vulvar areas, further evaluation may be unrewarding because the renal bleeding may cease spontaneously. Bleeding has been attributed anecdotally to cystitis and pyelonephritis in the absence of positive urine culture results because hemorrhage stops during a course of antimicrobial therapy. More likely, spontaneous resolution has occurred. Furthermore, the magnitude of hematuria is considerably greater with idiopathic renal hematuria than with most urinary tract infections, pyuria is absent, and urine culture results are negative. In the author's experience, one or two initial episodesof hemorrhage are followed by a more severe hemorrhagic crisis within months to several years after observation of the initial bleeding episode. Interestingly, renal colic has been notably absent in the history of affected horses.

One diagnoses idiopathic renal hematuria by exclusion of systemic disease, other causes of hematuria, and alterations in hemostasis. Physical examination may reveal tachycardia, tachypnea, and pale membranes consistent with acute blood loss. Rectal palpation may reveal an enlarged, irregular bladder because of the presence of blood clots. Azotemia is inconsistent. Endoscopic examination is important to document that hematuria is originating from the upper urinary tract and to determine whether hemorrhage is unilateral or bilateral (Figure 17.8-4). Repeated examinations may be required to answer the latter question. Ultrasonographic imaging is necessary to rule out nephrolithiasis or ureterolithiasis and occasionally may reveal a distended vascular space or renal vascular anomaly as the cause of hematuria. Renal scintigraphy can be a useful technique in affected horses because it may provide semiquantitative information about renal function when a nephrectomy is being considered. Renal biopsy and immunofluorescent staining may assist in documenting immune-mediated glomerular injury, but the significance of such results is not well understood at this time.

Treatment for idiopathic renal hematuria consists of supportive care for acute blood loss, including blood transfusions. Medications intended to promote hemostasis (e.g., α-amino-caproic acid and formalin) also have been administered, but their efficacy has not been validated. In addition, treatment with corticosteroids may be

useful in cases with potential immune-mediated mechanisms as the cause of bleeding. Because the condition may be self-limiting in some patients, supportive care is warranted. With severe and recurrent hematuria of unilateral renal origin, a nephrectomy may be indicated, but one should warn owners of the risk of hematuria developing in the contralateral kidney. In the author's experience, risk of contralateral renal bleeding appears to be greater in the Arabian breed.

Figure 17.8-4 Endoscopic image of a large blood clot exiting the right ureteral opening of a gelding with idiopathic renal hematuria.

17.8.4

Exercise-Associated Hematuria

Exercise is accompanied by increased filtration of red blood cells and protein across the glomerular barrier in a large percentage of human and equine athletes.[4,48] Typically the hematuria is microscopic, but occasionally one may observe gross discoloration of urine. Gross hematuria more often may result from bladder erosions, which may be induced traumatically by the abdominal contents pounding the bladder against the pelvis during exercise.[49] Detection of focal bladder erosions or ulcers with a contrecoup distribution and a history of emptying the bladder immediately before the exercise bout would be characteristic for this problem. A 1274

diagnosis of exercise-associated hematuria should be one of exclusion after diagnostic evaluation has ruled out other causes of hematuria such as presence of a cystolith.

17.8.5 Pigmenturia Associated WithSystemic Disease

With any systemic disease that may lead to hemolysis, thrombocytopenia, coagulopathy, or alterations in vascular permeability, hematuria or hemoglobinuria may develop. Discolored urine has the potential to be accompanied by a degree of nephrotoxicity because of interaction of iron ions of the heme molecules with surface molecules on proximal tubular epithelial cells. With transient pigmenturia (as with exercise-associated hematuria), changes in renal function may not be apparent, but with more severe disease processes, acute renal failure may develop. In human beings, a syndrome of hemolytic anemia and thrombocytopenia leading to development of acute renal failure has been termed the *hemolytic-uremic syndrome*.[50] The syndrome is recognized more commonly in children than in adults and is the most common cause of acute renal failure in children. Similar syndromes have been described in a limited number of horses.[45–47] Furthermore, hemolysis and hemoglobinuria may be recognized with liver disease, medications, or intoxications (e.g., ingestion of red maple leaves). Finally, conditions accompanied by extensive rhabdomyolyis also may result in pigmenturia and acute renal failure.[51] Assessment of muscle enzyme activity in these cases usually is rewarding in establishing myoglobin as the most likely cause of pigmenturia. In addition, one can use the Blondheim test (ammonium sulfate precipitation) to differentiate myoglobinuria from hemoglobinuria.[52]

17.9

17.9—Polyuria and Polydipsia

Harold C. Schott, II

For small animals, polyuria and polydipsia have been defined as urine output exceeding 50 ml/kg/day and fluid intake of more than 100 ml/kg/day.[1,2] These values would equate to 25 L of urine production and50 L of water

consumption for a 500-kg horse. Compared with normal values for daily urine production and water consumption of 5 to 15 L and 20 to 30 L, respectively,[3–10] these definitions of polyuria and polydipsia appear applicable to horses as well. One must remember that urine production and water consumption vary with age, diet, workload, environmental temperature, and gastrointestinal water absorption. For example, urine production increases by 50% to 100% when the diet is changed from a grass to a legume hay.[11] Although this increase in urine production has been associated with higher dietary protein intake and urinary nitrogen excretion,[12] increases in calcium intake and urinary calcium excretion maybe another contributing factor. Similarly, horses that are exercised heavily, are stabled in hot climates, or have chronic diarrhea may have a water intake exceeding100 L per day yet produce normal volumes of urine.[13]

A brief review of water turnover by the equine kidneys provides insight into how a small change in renal water reabsorption can lead to a dramatic increase in urine production (polyuria). In normal horses, glomerular filtration rate exceeds 1000 L per day, a volume that is 10 times greater than the total extracellular fluid volume; however, approximately 99% of this water is reabsorbed in the renal tubules and collecting ducts, resulting in production of between 5 and 15 L of urine daily. The result is urine that is 3 to 4 times more concentrated than plasma (urine osmolality of 900 to 1200 mOsm/kg and a specific gravity of 1.025 to 1.050). Futhermore, urea (in urine) has replaced sodium (in plasma) as the most important solute. If only 98% of water is reabsorbed, urine volume would double and the additional water would result in more dilute urine (urine osmolality of 450 to 600 mOsm/kg and a specific gravity of 1.015 to 1.025). If water reabsorption decreased to 96% of filtered water, the horse would produce approximately 40 L of urine with a urine osmolality of 225 to300 mOsm/kg and a specific gravity of 1.005 to 1.010 (Table 17.9-1). In the latter case, urine is more dilute than plasma (hyposthenuria) and the kidneys are excreting or losing water actively. Under certain conditions, active water excretion by the kidneys is important for maintenance of plasma osmolality in the normal range. The best example is a neonatal foal that may ingest a volume of milk exceeding 20% of its body weight daily.[14] This ingestion equates to a fluid intake approaching250 ml/kg/day, and failure to produce a large volumeof hyposthenuric urine could result in water retention, decreased plasma osmolality, and clinical hyponatremia (manifested by neurologic signs).

Determining that a horse is producing more urine than normal is often difficult, especially in horses kept at 1276
pasture. Owners may report that a horse is polyuric when in fact the frequency of urination has increased 1277
(pollakiuria) rather than the volume. Pollakiuria occurs with conditions such as cystitis and urolithiasis or during estrus in the mare. Horses housed in stalls bedded with straw are difficult to evaluate because excessive urine may not be obvious to the casual observer. For those bedded on shavings or sawdust, excessively wet bedding may be easier to recognize, but this is a subjective impression. Occasionally in a horse the polyuria may be so severe that urine may flow from the stall into the barn aisle. When doubt exists as to whether a horse has polyuria and polydipsia, documentation of water consumption over one or more 24-hour periods may be necessary.[6] Futhermore, one can quantify urine production by collecting urine over a 12- or 24-hour period. For geldings and stallions, one can construct a collection device by cutting off the bottom of a large plastic bottle, padding it, and fitted it over the prepuce. One covers the opening of the bottle with a rubber tube and clip to allow removal of urine every few hours. In mares, one can place an indwelling Foley catheter in the bladder or apply a urine collection harness.[15–19] During the collection period, horses usually are tied to minimize interference with the collection device.

TABLE 17.9-1 Relationship of the Percentage of Water Filtered That Is Reabsorbed to Daily Urine Output and Renal Water Absorption

GLOMERULAR FILTRATION RATE (L/DAY)	FILTERED WATER REABSORBED (%)	URINE PRODUCTION (L/DAY)	URINARY OSMOLE EXCRETION (mOsm)	URINE OSMOLALITY (mOsm/kg)	RENAL WATER REABSORPTION* (L/DAY)
1000	99	10	10,000	1000	23.3
1000	98	20	10,000	500	13.3
1000	96	40	10,000	250	−6.7

* Renal water reabsorption (the inverse of free water clearance) is a calculated volume of water that is retained or lost by the kidney. Renal water reabsorption is calculated from actual urine volume and the calculated volume of urine required to excrete all osmoles in urine that is isosmotic with plasma. In this table a urine osmolality value of 300 mOsm/kg is assumed to be isosmotic to plasma, 1 kg of water is assumed to equal 1 L of water, and a total of 10,000 Osm is assumed to be excreted daily. Thus when 98% of filtered water is reabsorbed, the 20 L of urine produced (if isosmotic) would contain 6000 mOsm. Because an additional 13.3 L of water would be needed to excrete the remaining 4000 mOsm (as isosmotic urine), the kidneys are considered to be actively reabsorbing 13.3 L of water.

The major causes of polyuria in horses include renal failure, pituitary adenoma (Cushing's disease), and primary or psychogenic polydipsia.[15,20] Less common causes include excessive salt consumption, central and nephrogenic diabetes insipidus, diabetes mellitus, sepsis and endotoxemia, and iatrogenic causes (sedation with α_2-agonists, corticosteroid therapy, or diuretic use).

17.9.1 Renal Failure

Horses with acute renal failure usually have a transient period of anuria or oliguria. If horses survive the acute phase of renal disease, tubule damage results in a subsequent period during which impaired concentrating ability results in polyuria.[15,21] Urine is frequently hyposthenuric during this period of tubular repair. Owners should provide horses recovering from acute renal failure with adequate water, salt, and a low-nitrogen (protein) and low-calcium diet. Such a diet consists of good-quality grass hay or nonlegume pasture. Repair of tubules and return of concentrating ability may take several weeks. Although these animals appear to have normal renal function after this recovery period, a permanent reduction in total renal function likely persists because most animals can maintain apparently normal health with only about 30% to 50% of functioning nephrons.

Chronic renal failure may develop following damage from nephrotoxins. In addition, immune-mediated mechanisms, chronic infection, and nephrolithiasis also may give rise to chronic renal failure.[21–23] Horses that do not recover from the ischemic renal damage occurring with hypovolemic or endotoxic shock also may progress to chronic renal failure. Signs vary and include polyuria and polydipsia in some cases. When present, polyuria and polydipsia are usually moderate compared with the dramatic increases in urine production observed with primary polydipsia or diabetes insipidus. Most horses with chronic renal failure also exhibit other signs, including poor performance, weight loss, and ventral edema. A variable degree of azotemia is present,

and urinalysis reveals isosthenuria (urine is isosmotic with plasma[260 to 300 mOsm/kg] with a specific gravity of1.008 to 1.014).

The mechanisms of polyuria following acute and chronic renal failure are not entirely clear.[24] Increased tubular flow rate in surviving nephrons is one possible mechanism that would result in less time for water removal from tubular fluid. Next, medullary hypertonicity may decrease because of diminished transport of sodium and chloride out of tubular fluid passing through the ascending limb of Henle's loop (diluting segmentof the 1277
nephron) along with increased blood flow through the remaining medullary tissue. A third possibility is 1278
impaired response of collecting ducts to vasopressin (acquired nephrogenic diabetes insipidus). Although all these mechanisms may contribute to the polyuria of renal failure, which one may be most important is not known. Futhermore, because the horse can produce hyposthenuric urine during the recovery phase of acute renal failure, the mechanisms of polyuria differ somewhat for acute and chronic renal failure.

17.9.2 Pituitary Adenoma

Pituitary adenomata are common in older horses and result in a syndrome of hyperadrenocorticism (Cushing's disease).[25–33] Although the most consistent clinical sign is hirsutism, hyperadrenocorticism often is accompanied by polydipsia and polyuria. In addition, affected horses may show weight loss, lethargy, laminitis, and recurrent infections. A horse occasionally may have neurologic signs, including blindness and seizures. Diagnosis is based on presence of excessive hair growth, one or more of the other clinical signs, and supportive laboratory data. In addition to hyperglycemia, neutrophilia, lymphopenia, and mild anemia often are present. Serum activity of hepatic enzymes also may be elevated. One may confirm the diagnosis by several endocrinologic tests, including measurement of elevated plasma adrenocorticotropin concentration,[34] a failure of plasma cortisol concentration to decrease (suppress) after dexamethasone administration,[25,26,35] or an exaggerated cortisol response to administration of thyrotropin-releasing hormone.[36] Treatment with serotonin antagonists (cyproheptadine) or dopamine agonists (bromocriptine or pergolide) may modify the clinical signs but does not achieve a cure because the pituitary lesion continues to grow slowly.[25,26,37]

In one review of 17 horses with Cushing's disease caused by pituitary adenoma, polyuria and polydipsia were found in 13 (76%)[33]; however, in another series of 21 cases of pituitary adenoma, polyuria and polydipsia were not a historical complaint in any of the affected horses.[32] Thus the polyuria and polydipsia associated with Cushing's disease are generally less severe than that observed with primary polydipsia or diabetes insipidus. Pituitary adenomata may lead to polyuria by several mechanisms. First, polyuria may result from actions of hormones derived from proopiomelanocortin, most specifically adrenocorticotropin. Hyperadrenocorticism resulting from excessive adrenocorticotropin activity on the adrenal cortex can lead to hyperglycemia, which may exceed the renal tubular threshold for reabsorption. The renal threshold for glucose in horses appears to be lower than in small animals (about 150 mg/dl).[38] When plasma glucose concentrations exceed this threshold value, the resultant glucosuria can lead to an osmotic diuresis. Although commonly implicated as the cause of polyuria in horses with pituitary adenomata, glucosuria was found in only one of five affected horses in a recent clinical report.[32] Futhermore, horses with hyperglycemia and glucosuria still may be able to concentrate their urine in response to water deprivation.[29] A second mechanism implicated in the development of polyuria is cortisol antagonism of the action of vasopressin on the collecting ducts. Although frequently cited as the mechanism of polyuria in canine hyperadrenocorticism, experimental evidence to support this mechanism is lackingin dogs and horses. Futhermore, considerable species heterogeneity exists in the effects of corticoids on vasopressin activity, and in some species a primary dipsogenic effect may be more important. Next, growth of the adenoma may lead to impingement on the posterior pituitary and hypothalamic nuclei (located immediately

dorsal to the pituitary gland), the sites of vasopressin storage and production, respectively. Decreased vasopressin production and release would result in a partial central diabetes insipidus as a third mechanism for polyuria.[26] Central diabetes insipidus, however, is not the cause of polyuria in all cases because some affected horses can concentrate their urine when deprived of water.[29] Consequently, polyuria and polydipsia seenin many horses with pituitary adenomas is likely the combined result of several mechanisms.

17.9.3

Primary Polydipsia

Although rare, primary or psychogenic polydipsia is probably the most common cause of polyuria and polydipsia in adult horses for which clients have a primary complaint of excessive water consumption and urination.[15,20] Primary polydipsia can be attributed to the fact that horses that exhibit this problem are generally in good body condition and are not azotemic. Futhermore, the magnitude of polyuria typically is much greater than that observed with renal failure or a pituitary adenoma. Owners may report that horses with primary polydipsia drink 2 to 3 times more water than their stablemates and their stalls often are flooded with urine. In some instances, primary polydipsia appears to be a stable vice that reflects boredom in affected horses, whereas in other cases it may develop following a change in environmental conditions, stabling, diet, or medication administration. Anecdotally, primary polydipsia is reported to be more common in southern states during periods of high temperature and humidity. In human beings, primary polydipsia can be a compulsive behavior associated with mental illness or may be caused by a primary abnormality in the osmoregulation of thirst, in which case it is referred to as *dipsogenic diabetes insipidus*.[39] The latter may be idiopathic or may follow 1278

1279 neurologic disease involving the hypothalamic osmoreceptors regulating thirst. Excessive water consumption causes expansion and dilution of body fluids, leading to a decrease in plasma osmolality and suppression of vasopressin release. With low plasma vasopressin concentrations, collecting ducts become impermeable to water and hyposthenuria is induced to allow rate of water excretion to balance intake. In human beings, the magnitude of polydipsia and resultant polyuria vary considerably between affected persons, and similar variation, although undocumented, likely occurs in affected horses as well.

One diagnoses primary polydipsia by exclusion of renal failure and hyperadrenocorticism. In addition, one must exclude other factors such as salt supplementation and medication administration. One excludes diabetes insipidus and confirms the diagnosis by demonstrating urine-concentrating ability after water deprivation.[7,9] Specific gravity should exceed 1.025 after water deprivation of sufficient duration (12 to 24 hours) to produce a 5% loss in body weight. In cases of long-standing polyuria, the osmotic gradient between the lumen of the collecting tubule and the medullary interstitium may be diminished (medullary washout). In these cases vasopressin activity may not lead to an increase in urine specific gravity to values greater than 1.020. Consequently, in horses with primary polydipsia of several weeks in duration that fail to concentrate their urine after24 hours of water deprivation, one may try a modified water deprivation test. One performs the test by restricting water intake to approximately 40 ml/kg/day for 3to 4 days. By the end of this time, urine specific gravity should exceed 1.025 in a horse that has had medullary washout. If the urine specific gravity remains in the isosthenuric range (1.008 to 1.014), one should evaluate the polyuric horse further for early chronic renal failure, in which urine-concentrating ability may be compromised before the onset of significant azotemia. In theory, chronic renal failure could occur when between two thirds and three fourths of functional nephrons have been lost. Subtle signs of decreased performance and mild weight loss also would support early renal failure. Finally, horses with primary polydipsia typically produce hyposthenuric urine. Although such dilute urine would be an unlikely finding in the early stages of chronic renal failure, it could be found in the polyuric recovery phase following acute renal failure. In the latter instance a thorough history should reveal whether any event that may have been complicated by acute renal failure may have affected the horse recently.

Management of horses with primary polydipsia is empiric. Because the diagnosis is one of exclusion, once one establishes that the horse is not suffering from a significant renal disease, one may safely consider restricting water intake to meet maintenance, work, and environmental requirements of the horse. In addition, one should take steps to improve the attitude of the horse by reducing boredom. Increasing the amount of exercise or turning the horse out to pasture are possible options, as is providing a companion or toys in the stall. Increasing the frequency of feedings or the amount of roughage in the diet also may increase the time spent eating and thus reduce the habitual drinking.

17.9.4 Excessive Salt Consumption

In an occasional case of apparent primary polydipsia, polyuria and polydipsia may be attributed to excessive salt consumption and are manifested by increased fractional sodium clearance. Such psychogenic salt eaters appear to be less common than psychogenic water drinkers, for the former would have to consume a substantial amount of salt to develop polyuria. In fact, the authors are aware of only one well-documented report of psychogenic salt eating in which a yearling Paint filly drank in excess of 500 ml/kg/day and had excessive urination when provided free access to salt.[40] The fractional clearances of sodium (3.4%) and chloride (2.6%) were increased and supported excessive intake. Although salt intake was not quantified for this filly, it may have exceeded 10% of the dry matter intake and appeared to be associated causally with muscle fasciculations and a stilted gait. Such a high intake is suggested because no increases in water consumption or urine volume were detected in one study in which ponies were fed diets containing 1%, 3%, and 5% of sodium chloride.[41] The 5% sodium chloride diet contained 5 to 10 times the daily requirement of sodium chloride and was similar to feeding about 350 g sodium chloride daily to a 500-kg horse. Similar to cases of primary polydipsia, the filly described in this report was able to concentrate urine in response to water deprivation, and the problem was managed successfully by limiting water intake to 50 ml/kg/day and preventing access to salt.

17.9.5 Diabetes Insipidus

Diabetes insipidus results in polyuria and polydipsia because of vasopressin deficiency or insensitivity of the renal collecting duct epithelial cells to vasopressin. In human beings, vasopressin deficiency, or neurogenic diabetes insipidus, is the more common form, with hereditary and acquired forms being described. The hereditary form appears to result from decreased numbers of neurosecretory neurons in the supraoptic nuclei of the hypothalamus and is inherited in an autosomal dominant fashion. However, polyuria and polydipsia do not develop until after the first few years of life in affected persons, suggesting progressive loss of neurosecretory 1279
tissue. The acquired form of neurogenic diabetes insipidus results from degeneration of neurons in the 1280
supraoptic nuclei following trauma, vascular abnormalities, infection, or a variety of tumors.[39,42,43] As with the hereditary form, polyuria and polydipsia usually are not manifested until 80% to 90% of the neurosecretory neurons are destroyed.

In equids, two well-documented cases of neurogenic diabetes insipidus have been described.[44,45] Neither animal could concentrate urine in response to water deprivation, but administration of exogenous vasopressin resulted in an increase in urine concentration and a decrease in urine volume. In a Welsh pony in which the condition was considered idiopathic, the absence of an increase in plasma vasopressin concentration after water deprivation (compared with control ponies) further supported a diagnosis of neurogenic diabetes insipidus.[44] Acquired neurogenic diabetes insipidus following encephalitis was confirmed histologically in the other horse.[45] Two other reports of diabetes insipidus in horses more likely described cases of primary polydipsia because

both animals demonstrated an ability to concentrate urine during water deprivation or had random urine specific gravities greater than 1.020.[46,47]

Nephrogenic diabetes insipidus results from resistance of the cortical and medullary collecting ducts to the antidiuretic action of vasopressin.[39,42,43] In the absence of systemic disease, nephrogenic diabetes insipidus is most commonly a familial disorder in human beings with an X-linked semirecessive mode of inheritance. As such, the disorder is carried by females and expressed in male offspring.[48] Schott, Bayly, Reed, et al. previously described nephrogenic diabetes insipidus in sibling Thoroughbred colts, suggesting that an inherited form of nephrogenic diabetes insipidus also may occur in horses.[49] These colts could not increase urine concentration in response to water deprivation, although they did show appropriate increases in plasma vasopressin concentration. Futhermore, minimal response to exogenous vasopressin administration confirmed resistance of the cortical and medullary collecting ducts to the antidiuretic action of vasopressin. Nephrogenic diabetes insipidus also maybe acquired following drug therapy or a variety of metabolic, infectious, or mechanical (postobstruction) disorders. Anomalous or neoplastic disorders resultingin structural deformation of the kidneys are another potential cause of nephrogenic diabetes insipidus.[39,42,43]

As far as pathophysiology the neurogenic and nephrogenic forms of diabetes insipidus are similar to each other. Polyuria because of a lack of vasopressin activity results in net water loss and an increase in plasma osmolality. As plasma osmolality increases, stimulation of thirst results in a compensatory increase in water consumption. In normal individuals and those with nephrogenic diabetes insipidus, the osmoreceptors in the hypothalamus sense the increase in plasma osmolality and subsequently signal for vasopressin release. As little as a 1% increase in plasma osmolality (about 3 mOsm/kg) results in a1 pg/ml increase in plasma vasopressin concentration. In normal individuals, this small change is substantial enough to increase urine osmolality and decrease urine flow. With greater increases in plasma osmolality, more vasopressin is secreted. In human beings, urine osmolality approaches a maximum after an increase in vasopressin concentration to about 5 pg/ml (from a resting value of about 1.0 pg/ml).[39,43]

Limited studies in ponies and horses suggest that a similar degree of vasopressin release occurs in response to minor increases in plasma osmolality[50–52]; however, vasopressin also appears to be a “stress hormone” in horses because substantially greater concentrations (tenfold higher than those induced by water deprivation) have been measured after application of a nose twitch, nasogastric intubation, or exercise.[53] Thus increases in plasma vasopressin concentration following water deprivation would be expected to vary in horses, and separating osmotic effects from stress effects in an individual horse may be difficult. A word of caution also is warranted about subjecting horses suspected of having diabetes insipidus to water deprivation. Because urine-concentrating ability may show minimal improvement with either form of diabetes insipidus, affected horses may continue to excrete excess water in the face of water deprivation. As a result, they may become substantially dehydrated (10% to 15%) within the first 12 hours of water deprivation. Thus one carefully should monitor horses suspected of having diabetes insipidus during the period of water deprivation to decrease the risk of inducing serious hypertonic dehydration. In addition to assessing the effects of water deprivation on urine-concentrating ability and plasma vasopressin concentrations, the final diagnostic manipulation is often administration of exogenous vasopressin. A suggested regimen for an adult horse is administration of 60 IU of exogenous vasopressin (Pitressin synthetic, Parke-Davis, Morris Plains, N.J.) in oil every6 hours combined with monitoring urine specific gravity.

The medullary interstitial osmotic gradient develops as a result of countercurrent exchange, and the magnitude of the gradient is related inversely to tubular flow. Medullary washout may occur with the high tubular flow rates that can accompany renal disease. Although partial medullary washout may contribute to the

concentrating defect in diabetes insipidus, the rapid response to exogenous vasopressin administration in cases of neurogenic diabetes insipidus (increase in urine osmolality to900 mOsm/kg or greater) indicates that the medullary concentration gradient is not severely compromised.[39,54] This response further explains why in some 1280
cases of diabetes insipidus urine osmolality can be greater than plasma osmolality after water deprivation. The 1281
mechanism for this response is thought to be a decrease in tubule flow rate that allows more time for passive water extraction from the hypoosmotic tubular fluid. With nephrogenic diabetes insipidus, one also may observe mild improvement in urine-concentrating ability (an increase in urine osmolality up to 500 mOsm/kg) in response to exogenous vasopressin administration. This response has been attributed to partial sensitivity of the collecting ducts to vasopressin and to vasopressin activity at other portions of the renal tubule.[39,42]

Treatment of diabetes insipidus should aim to manage polydipsia and polyuria. With neurogenic diabetes insipidus, recovery of vasopressin secretion is rare once the secretory neurons have degenerated to the degree that polyuria and polydipsia become apparent. Consequently, treatment consists of hormone replacement. In the past, intramuscular injection of Pitressin tannate in oil every 2 to 3 days was successful in limiting polyuria; however, development of resistance or allergic reactions was an occasional problem. With the development of potent vasopressin analogs (desmopressin), effective treatment by nasal insufflation is now available.[39] The use of desmopressin for diagnosis and treatment of neurogenic diabetes insipidus in small animals has been described.[54,55] Largely by chance, other oral medications, including chlorpropamide and clofibrate, have been found efficacious in treating neurogenic diabetes insipidus. The mechanism of action of these drugs is uncertain, but they are thought to potentiate the effect of vasopressin on the collecting ducts.[39,54]

With nephrogenic diabetes insipidus, replacement hormone therapy is ineffective, and the only practical form of treatment for many years has been to restrict sodium and water intake or to administer thiazide diuretics. The latter treatment may reduce polyuria by 50% in many cases.[39] Thiazide diuretics inhibit sodium reabsorption in the distal tubule (diluting segment of the nephron) and increase solute delivery to the collecting duct. The mechanism by which such therapy paradoxically benefits patients with nephrogenic diabetes insipidus is ill understood. Explanations include enhanced proximal tubular fluid reabsorption (via glomerulotubularbalance) and decreased glomerular filtration and tubular flow (via a greater osmotic stimulus to the macula densaand subsequent tubuloglomerular feedback).[39,43] Recently, treatment with prostaglandin inhibitors or amiloridehas decreased polyuria in patients with nephrogenic diabetes insipidus. The former agents probably work by decreasing renal blood flow and glomerular filtration, whereas the latter drug, a sodium channel blocker, is thought to act in a manner similar to the thiazide diuretics.[39]

17.9.6 Diabetes Mellitus

Diabetes mellitus is a state of chronic hyperglycemia usually accompanied by glucosuria.[56,57] The resultant osmotic diuresis is an occasional cause of polyuria and polydipsia in horses that has been described to result in a water intake exceeding 80 L per day.[58] Type I (insulin-dependent) diabetes mellitus results from a lack of insulin that in human beings is usually attributable to viral or autoimmune disease. Persons with type II (non–insulin-dependent) diabetes mellitus have normal to high insulin concentrations but their tissues are insulin insensitive. Thus the response to an oral carbohydrate load or an intravenous glucose challenge is impaired, resulting in prolonged hyperglycemia.[56] The mechanism of insulin resistance is not well documented for horses but may result from decreased numbers of insulin receptors or lack of insulin receptor activationin response to insulin binding. The most common cause of equine non–insulin-dependent diabetes mellitus is pituitary

adenoma.[27–31] With Cushing's disease, elevated plasma cortisol concentrations appear to antagonize the effect of insulin, leading to hyperglycemia and glucosuria.

Although uncommon, a few reports describe insulin-dependent and non–insulin-dependent diabetes mellitus that were not caused by a pituitary adenoma andthat resulted in polyuria and polydipsia as one of the presenting complaints.[58–62] Diagnostic evaluation reveals consistent hyperglycemia but negative dexamethasone suppression test results (a normal decrease of plasma cortisol to low concentrations). Treatment in most instances is supportive, although replacement insulin therapy may be helpful in cases in which measured serum insulin concentrations are low (insulin-dependent diabetes mellitus). Insulin therapy may be of some benefit in horses with elevated serum insulin concentrations because pharmacologic doses in part may overcome the insulin insensitivity. In such cases, synthetic insulin products may be preferable over protamine zinc insulin, for one horse with a pituitary adenoma and secondary diabetes mellitus developed antiinsulin antibodies and had a relapse in clinical signs after 7 weeks of insulin therapy.[31]

17.9.7 Sepsis and Endotoxemia

Polyuria and polydipsia also have been reported as clinical signs in horses with sepsis or endotoxemia, although other clinical signs such as fever, abdominal pain, and weight loss predominate.[63] The mechanism is unclear but may result from endotoxin-induced prostaglandin production. Prostaglandin E_2 is a potent renal vasodilating agent in laboratory animals, and it antagonizes the effects of antidiuretic hormone on the collecting 1281
ducts.[64] Some horses with chronic gram-negative bacterial infections (such as peritonitis or pleuritis) may have 1282
low-grade or intermittent endotoxemia as a mechanism for polyuria, similar to the polyuria observed with canine pyometra.[65]

17.9.8 Iatrogenic Polyuria

Finally, polyuria can be iatrogenic, following a number of management practices or medical treatments. The most obvious iatrogenic cause is fluid therapy, for which polyuria is a desired response. Polyuria also has been observed with exogenous corticoid administration, although as for pituitary adenomata the mechanism remains unclear. Human beings and dogs appear to experience a potent thirst response to exogenous corticoids; thus polydipsia may be an important cause of the polyuria observed. In horses receiving long-term dexamethasone treatment for immune-mediated disorders, one may observe profound glucosuria (2 to 3 g/dl) that leads to osmotic diuresis in these patients. Finally, transient diuresis or polyuria accompanies sedation with the α_2-agonists xylazine and detomidine.[66,67] Although these agents cause hyperglycemia, and occasionally glucosuria, a more likely mechanism for the transient polyuria is the existence of α_2-adrenoreceptors on collecting duct epithelial cells. Activation of these receptors is another mechanism of vasopressin antagonism.[68]

17.10—Renal Tubular Acidosis

Warwick M. Bayly

The veterinary profession recognizes well that horses with acute or chronic renal failure are frequently acidotic. These animals are almost invariably azotemic, hypochloremic, and normo- or hyperkalemic and frequently have significant abnormalities on urinalysis. A less frequent renal disease associated with acidosis is renal tubular acidosis (RTA). Renal tubular acidosis is a clinical syndrome of impaired renal acidification characterized by a hypokalemic, hyperchloremic acidosis without azotemia. Affected horses frequently have normal urinalysis. The condition has been well-described in human beings,[1–3] and several case reports documenting its existence in horses have appeared since the mid-1980s.[4–7]

The causes and pathogenic mechanisms responsible for the development of RTA are ill understood. In human beings RTA may be primary (genetic or idiopathic) or secondary, following a variety of conditions, including hyperglobulinemia, various autoimmune disorders, kidney disease such as polynephritis and obstructive uropathy, cirrhosis, drug- or toxin-induced nephropathies (including amphotericin B toxicity), metabolic disorders involving nephrocalcinosis, and a number of genetically transmitted diseases. All reported equine cases apparently have been idiopathic because no signs of primary renal, hepatic, or autoimmune disease or disturbance of calcium metabolism have been evident, and the horses have had no history of access to toxins. In some cases, however, low-grade renal tubular disease has been suspected because of mild proteinuria.

General agreement is that three types of RTA exist.[8] Type 1, which is also known as *distal* or *classic RTA*, arises from the inability of the cells of the distal tubule to establish a steep hydrogen ion gradient between the blood and the urine. This inability results from failure of normal H^+ excretion from the distal tubules. In many cases, this gradient may be less than 10:1. Whether this low ratio is caused by an insufficient number of proton-secreting pumps in the distal nephron or by H^+ diffusing back across the lumenal membrane after being secreted is not clear. Accelerated K^+ secretion occurs because of the existing electrochemical driving forces in the distal nephron and the lack of protons to offset them. In addition to having high urinary K^+ clearances, patients may be hypercalciuric and hyperphosphaturic, although in horses this may be difficult to assess. Equine urinary concentrations of K^+ and Ca^{2+} in particular are high. In human beings, about 70% of adults with distal RTA 1283
develop some form of urolithiasis.[9] This condition has not been recognized in the few reported equine cases and 1284
may not be, given the significant differences between the two species.

Type 2, or proximal, RTA is caused by a failure of HCO_3^- resorption in the proximal tubule. This part of the nephron usually reabsorbs the bulk of the filtered HCO_3^- via Na^+ and H^+ exchange and the subsequent breakdown of carbonic acid to carbon dioxide and water under the influence of carbonic anhydrase. Disruption of normal Na^+ and H^+ exchange or carbonic anhydrase activity therefore results in excess flow of HCO_3^- to the distal tubule where the ability to resorb the anion is poor. This bicarbonaturia also results in accelerated K^+ secretion and hypokalemia. In human beings with this form of the disease, the suggestion is that a reduction occurs in the threshold concentration at which HCO_3^- is reabsorbed from the proximal nephron. As a result, reabsorption resumes once serum HCO_3^- concentration drops below this threshold, and a new steady state is said to develop. More likely, because of the urinary HCO_3^- loss, plasma HCO_3^- concentration decreases, as does glomerular filtration of HCO_3^-. Eventually the distal tubule reaches a point at which it can handle the amount of

HCO_3^- presented. Urine pH may start to decrease because of the lower amount of HCO_3^- being excreted. A new steady plasma HCO_3^- concentration is established, albeit considerably below the normal range, and acid-base homeostasis may return gradually. Consequently, the type 2 condition often appears to be self-limiting in human beings.[10] This form of the disease occurs rarely by itself in human beings and almost always is associated with other signs of proximal tubule dysfunction such as defective resorption of glucose, amino acids, and phosphate (Fanconi's syndrome). Type 2 RTA has been reported in two horses.[4]

Type 4 RTA is characterized by hyperkalemic, hyperchloremic acidosis and is common in human beings, but it has not been reported in horses. Type 4 RTA apparently is associated with hypoaldosteronism or resistance of the distal nephron cells to the effects of aldosterone. As a result the renal clearance of K^+ and H^+ is reduced. The associated natriuresis ultimately may lead to a reduced ability to concentrate urine because of “washout” of the medullary concentrating gradient, if the condition becomes chronic. Another form of RTA (type 3), which formerly had been described as having characteristics of type 1 and type 2 RTA, now is considered to be a variation of type 1.[8]

TABLE 17.10-1 Features Used to Differentiate Type 1 and Type 2 Renal Tubular Acidosis

VARIABLE	TYPE 1	TYPE 2
Acidosis	Severe	Less severe, self-limiting
Hypokalemia	Severe	Mild to moderate
Glycosuria, proteinuria	Absent	Often present
Urine pH during		
Mild/moderate acidosis	Inappropriately high	Inappropriately high
Severe acidosis	Inappropriately high	Normal
Effect of alkali administration	Decreases or worsens hypokalemia, depending on stage of disease	Worsens hypokalemia
Amount of HCO_3^- needed to correct acidosis	Low	High
Ammonium chloride challenge	Failure to excrete acid (urine does not acidify)	Urine pH decreases
Bicarbonate loading	Filtered bicarbonate is reabsorbed	Bicarbonate is lost in the urine

Differentiating between the distal (H^+ retention) and proximal (HCO_3^--wasting) forms of RTA is theoretically important if the approach to the human form of the disease is any guide because in human beings the two types differ respecting clinical severity, treatment, and prognosis.[11] The ability to differentiate between the forms of the disease in horses appears to be less critical, for treatment does not seem to differ much according to the suspected type of RTA. Table 17.10-1 summarizes some differential characteristics of the two types of the disease. In human beings with type 2 RTA, plasma HCO_3^- concentrations tend to be higher than those associated with the distal

form of the disease; but this does not appear to be the case in horses, for all the horses the author has seen, plus those that have been described in the literature, have been severely acidotic (HCO_3^- concentrations of 10 mmol/L or less). In horses, differentiation between the distal and proximal types of the condition has been based on measurement of the urine pH. Evaluation of urine ammonium excretion, urine net charge or anion gap, and urinary P_{CO_2} have not been reported in horses, although they are regarded as critical to the specific differentiation of RTA in human beings.[12–14] Because of the alkalinity of normal equine urine, measurement of urine P_{CO_2} is probably of little benefit. With type 1 RTA, urine pH tends to stay high (i.e., in the normal to alkaline range). In 1284
type 2, urine pH is generally neutral or slightly acidic. A suggested way of making this differentiation is to assess 1285
the urinary response to the administration of the urine-acidifying agent ammonium chloride (0.1 g/kg). Typically, one gives this solution orally and it should lower the urine pH to less than 7.0, which it supposedly does in normal horses and those with type 2 RTA. In cases of distal (type 1) RTA, the urine pH remains high in the face of the increased acid load. Because the administration of such acidifying agents potentially could worsen the degree of acidosis in cases of type 2 RTA because of reduced buffering capacity, performance of this test is not recommended until one has attempted at least partial replacement of the HCO_3^- deficit. In the author's experience, the ammonium chloride challenge test has proved unreliable, having failed to acidify the urine of normal healthy horses even when given intravenously in a 4-L solution. The dose and rate of administration may need to be increased before the test can be considered worthwhile. A more suitable alternative may be to infuse sodium sulfate as is done sometimes in human beings.[1] The author could find no reports of the use of this test in horses.

Another diagnostic option that may be worthy of investigation in horses is calculation of the urine net charge. As in any body fluid, the sum of urinary cations must equal the sum of its anions. Therefore in urine,

$$Na^+ + K^+ + Ca^{2+} + Mg^{2+} + NH_4^+ = Cl^- + HPO^- + SO^- + \text{other urine buffers} + \text{organic anions}$$

In human beings, Ca^{2+} and Mg^{2+} tend to be present in urine in small, constant quantities. Excretion of HPO^-, SO^-, titratable buffers, and organic anions is also constant and exceeds the Ca^{2+} and Mg^{2+} by an amount that is referred to as the urine anion gap (AG_u). Thus

$$Na^+ + K^+ - Cl^- = AG_u - NH_4^+$$

The expression ($Na^+ + K^+ - Cl^-$) is referred to as the *urine net charge* and reflects the excretion of NH_4^+.[13] Given the aforementioned plasma electrolyte and acid-base abnormalities, type 2 RTA has been shown likely to exist when the urine net charge is negative (i.e., $Cl^- > [Na^+ + K^+]$) because NH_4^+ is greater than AG_u. In other words, H^+ continues to be secreted normally from the distal tubule, and plenty of NH_4^+ is being produced. When ($Na^+ + K^+$) is greater than Cl^-, the net charge is positive, indicating that NH_4^+ excretion is low because of failure to excrete H^+ (i.e., type 1 or distal RTA exists).

Horses with RTA usually have a history of severe, progressive weakness, depression, and anorexia. Various other signs such as chronic weight loss, ataxia, dysphagia, and periodic collapse also have been noted. The latter three signs may be manifestations of severe weakness, which probably is caused by the severe hypokalemia. The reduced K^+ concentration also may be associated with bradycardia.

On clinical examination, affected horses are usually afebrile. Mild icterus is common, presumably because of the anorexia, although significant indirect hyperbilirubinemia and increases in serum concentrations of γ-

glutamyltransferase and alkaline phosphatase have been observed. Although cirrhosis of the liver has been associated with the development of RTA in human beings, the equine cases of which the author is aware have demonstrated no clinicopathologic changes compatible with severe liver disease. Sulfobromophthalein clearance half-time was normal in the one case in which it was measured.[5]

One should suspect RTA whenever a horse has a severe hyperchloremic metabolic acidosis in the absence of any obvious cause of extrarenal hypovolemia such as diarrhea or small intestinal ileus. In such cases the plasma anion gap usually is widened, whereas with RTA it remains normal. (However, hypoalbuminemia may mask widening of the anion gap because albumin is normally responsible for much of the normal anion gap.[15] Therefore the anion gap value should be smaller in hypoalbuminemic horses.) Azotemia has not been recognized in cases of equine RTA, although signs of tubular dysfunction such as mild proteinuria and increases in fractional K^+ clearance and urine γ-glutamyltransferase activity have been observed. The results from renal biopsy and ultrasonic examination of the kidneys are normal.

Definitive diagnosis of RTA is based on the demonstration of severe hypokalemia (2.3 mmol/L or less) and a urine pH that is generally neutral or alkaline in the face of a severe acidosis (venous blood pH less than 7.15), although theoretically one could observe a slight aciduria with type 2 RTA. Hypokalemia in the face of severe acidosis is uncommon. Classically, the reverse is expected because of intracellular buffering of H^+ and the reciprocal role of H^+ and K^+ in maintaining the electric neutrality of the extracellular fluid. Occasionally, serum chloride concentrations are in the high normal range rather than being increased. Blood gas measurement usually reveals some degree of compensatory respiratory alkalosis (P_{CO_2} equals 25 to 35 torr).

The differential diagnosis of RTA includes those of any animal that has sudden weakness, depression, and possible collapse: cardiovascular failure, neurologic disease (including rabies), hypoglycemia, and peracute toxemia or endotoxemia. One usually can rule out allof these based on a thorough physical examination that finds nothing to support their possible existence. These findings, plus demonstration of the aforementioned electrolyte
and acid-base abnormalities, suggest RTA. Conditions such as hypokalemic periodic paralysis, Addison's disease, 1285
adenoma of the pars intermedia of the pituitary, and chronic corticosteroid or diuretic abuse could cause some of 1286
these clinicopathologic disturbances, but not the combination of hyperchloremia, acidosis, hypokalemia, and a normal plasma anion gap.

Prompt recognition of the disease and quick institution of therapy are important because the untreated condition is potentially fatal. All reported equine cases of RTA have responded satisfactorily to treatment, as have the cases the author has seen. Although the ability to differentiate between type 1 and type 2 RTA may be important in human beings from a therapeutic perspective, the distinction has not seemed to be essential in horses. Regardless of the suspected type of the disease, treatment of the condition in horses is associated with HCO_3^- and K^+ replacement therapy. Although the administration of $KHCO_3$ would seem to be ideal, the lack of ready availability of this substance and the need for prompt therapy means that treatment usually involves a combination of orally administered KCl and intravenously administered $NaHCO_3$ and KCl. That one should not give $NaHCO_3$ without some form of potassium supplementation deserves emphasis, to ensure that the hypokalemia does not get worse. Generally, a steady improvement in the condition of the patient occurs after 12 to 24 hours of treatment. All fluids usually are given 4 to 6 times per day for the first 48 hours, whereas intravenous fluids frequently are given at a slow but steady rate. Inclusion of glucose or dextrose in the latter helps to promote uptake of K^+ by the cells. The serum chloride concentration usually decreases as HCO_3^- concentration increases. In the author's experience, a steady improvement occurs in HCO_3^- values, and these tend to improve more rapidly than the K^+ concentrations. Serum concentrations of the latter appear to be slower to return to normal, possibly because intracellular stores are

replaced first. Estimating the total potassium deficit before the onset of treatment is impossible because of the huge intracellular deficit these animals suffer. In the author's experience, total deficits of this cation frequently exceed 4000 mmol.

With the correction of the acid-base and electrolyte disturbances, muscle strength and appetite generally return within 48 hours of the onset of treatment. At this point, one usually can reduce potassium supplementation and subsequently discontinue it once the forage intake of the horse has returned to normal. Obviously, giving the horse a diet that includes ample amountsof good-quality hay is important because of the high potassium content of this feedstuff. Bicarbonate therapy generally continues longer, although one usually discontinues intravenous assistance in the horse with return of the appetite. Periodic rechecking of the animal is advised until it becomes clear that its condition is stable. Long-term follow-up of cases the author has seen and those that have been reported in the literature suggest that the prognosis is favorable.

17.11—Neoplasia of the Urinary Tract

Harold C. Schott, II

Although neoplasia of the urinary tract is uncommon in horses,[1–6] reports exist of tumors involving the upper and lower urinary tract in this species. Renal neoplasms, which represent fewer than 1% of all equine tumors, include adenomata, renal cell carcinomata, and nephroblastomata.[7] Renal adenomata are small, well-circumscribed lesions in the renal cortex, that are usually incidental necropsy findings.[8] The best-described renal tumor in the horse is renal cell carcinoma or adenocarcinoma.[9–16] These lesions arise from epithelium of the proximal convoluted tubules in most cases. In human beings, renal cell carcinomata are known as the "internist's tumor" because of their diverse and often obscure presenting signs. Although a classic triad of symptoms including flank pain, gross hematuria, and palpable renal mass has been described, these symptoms occur in fewer than 10% of affected human beings at presentation.[17] Similarly, affected horses usually have nonspecific presenting complaints, including poor performance, depression, weight loss, and recurrent colic (Table 17.11-1). Signs that increase suspicion of a primary urinary tract problem include hematuria (7 of 12 cases in Table 17.11-1) and detection of a palpable mass on rectal examination (8 of 12 cases in Table 17.11-1). Renal cell carcinomata are typically unilateral, and the contralateral kidney maintains normal renal function. Although nephrectomy is the treatment of choice in human beings, tumors are typically large and adherent to surrounding organs by the time they are detected in horses. Thus surgical removal usually is not possible. Furthermore, frequent metastases (8 of 12 cases in Table 17.11-1) are another indication that renal adenocarcinoma is usually not a treatable disease. The poor prognosis can be attributed to the fact that clinical signs of intraabdominal neoplasia in horses often are not apparent until the disease is advanced.[18] In one report of renal carcinoma, clinical signs of the tumor were absent until the horse was anesthetized for laryngeal surgery. After an uncomplicated surgery, the horse was repositioned for recovery but died shortly thereafter. Compression of the caudal vena cava by a large renal carcinoma was suspected to have led to a decrease in venous return as the cause of sudden death.[19] Other neoplastic diseases that may affect the kidneys include nephroblastoma,[20–22] transitional cell carcinoma,[18,23] and squamous cell carcinoma.[24] Nephroblastoma (Wilms' tumor) is an embryonal tumor that arises in primitive nephrogenic tissue or in foci of dysplastic renal tissue, whereas the latter tumor types arise from the uroepithelium of the renal pelvis or ureter.[8] Neoplastic involvement of the upper urinary tract also may occur with dissemination of lymphosarcoma, hemangiosarcoma, melanoma, or adenocarcinoma arising from other tissues in the abdomen.[2,7,8,18,25] Finally, although they are not truly cancerous disease processes, mucinous hyperplasia of the renal pelvic and proximal ureteral uroepithelium or ureteropelvic polyp formation also can lead to development of a tissue mass in either kidney, ureteral obstruction, and hydronephrosis.[26,27]

In addition to rectal palpation for a mass in the area of either kidney and examination of urine for red blood cells (hematuria), ultrasonographic evidence of a tissue mass destroying the normal architecture of the kidney would support renal neoplasia. Unfortunately, attempts to establish a definitive antemortem diagnosis were successful in only two previous reports. In the first case, neoplastic cells were detected on analysis of a sample of peritoneal fluid,[12] whereas percutaneous biopsy of the tissue mass in a second horse demonstrated neoplastic tissue. Thus these procedures are warranted in all horses with a mass consistent with a renal neoplasm. In addition to analyzing urine for hematuria, cytologic examination of urine for neoplastic cells is also warranted.[28]

The most common presenting complaint for bladder neoplasia is hematuria.[28–30] Unlike dogs, in which transitional cell carcinoma is the most commonly described bladder neoplasm, squamous cell carcinoma has been

reported most frequently in horses.[28,29] Other types of bladder neoplasms affecting horses include transitional cell carcinoma, lymphosarcoma, leiomyosarcoma, and fibromatous polyps. In contrast to cattle, which develop bladder neoplasia in association with chronic ingestion of bracken fern and other plants (enzootic hematuria), dietary factors have not been incriminated in development of bladder cancer in horses.[8] One can establish diagnosis of bladder neoplasms by palpation or ultrasonographic imaging of a bladder mass, endoscopic examination and biopsy (Figure 17.11-1), and urine cytologic examination. Treatment has included partial bladder resection or intravesicular instillation of 5-fluorouracil, but successfuloutcomes have not been reported.[28] Again, a poor prognosis likely is related to the extensive bladder involvement by the time clinical signs are apparent.

Tumors of the urethra and external genitalia are the most common urinary tract neoplasms of horses. Although reports describe a paraurethral lipoma[31] and fibrosarcomata[32] resulting in frequent urination or dribbling and urinary tract infection, respectively, tumors of the external genitalia are more common than urethral tumors.[33–35] 1287
Tumors affecting the external genitalia include squamous cell carcinoma, sarcoid, melanoma, mastocytoma, 1289
hemangioma, and papillomata or warts. Habronemiasis used to be a significant cause of genital lesions before the use of ivermectin, and the disease should remain on the differential list because it can be distinguished from squamous cell carcinoma or sarcoid only by examination of a biopsy sample. Breeds with nonpigmented genitalia (Appaloosas and Paints) appear to be predisposed to squamous cell carcinoma. Similarly, a predilection for geldings and stallions has been associated with a carcinogenic potential of smegma.[36] Affected horses may have a malodorous sheath or hematuria if the distal urethra is involved. Urinary tract obstruction is uncommon unless the tumors are large. Diagnosis is by visual examination and collection of a biopsy sample. Collection of the latter often is by complete excision of the lesion. In addition to surgical excision, a rather high rate of recurrence has led to use of a number of adjunct therapies, including immunotherapy, cryotherapy, hyperthermia, and radiation therapy. Because all treatment combinations have had variable success, some authors recommend aggressive surgical treatment early in the course of the disease.[37] Most recently, local injection of cisplatin, a cytotoxic antineoplastic agent, has been used with a high success rate to treat equine sarcoid and squamous cell carcinoma.[38,39]

TABLE 17.11-1 Clinical Features of 12 Horses With Renal Cell Carcinoma

BREED	AGE (YEARS)	SEX	UNILATERAL OR BILATERAL	PRESENTING COMPLAINT	WEIGHT LOSS	PAIN/COLIC	HEMATURIA	PALPABLE MASS ON RECTAL EXAMINATION?	AZOTEMIA	POSTMORTEM FINDINGS	REFERENCE
American Saddlebred	15	G	Bilateral	Recurrent colic	Yes	Yes	No	Yes	No	25-cm diameter renal calculus, metastases to liver and other kidney	9
Albino	10	F	Unilateral, left	Abortion and ascites	No	No	No	Yes	Mild	75-cm diameter, 31-kg mass, metastases to peritoneum	10
Standardbred	16	F	Unilateral, right	Weight loss, hematuria	Yes	No	Yes	Yes	No	30-cm diameter, 8-kg mass, adhesions to liver and bowel, no metastases	10
Thoroughbred	16	F	Unilateral, left	Weight loss	Yes	No	Yes	Yes	Mild	35-cm diameter, 20-kg mass, hemoperitoneum, no metastases	11
Thoroughbred	16	F	Unilateral, right	Weight loss, soft feces	Yes	No	No	No	Mild	Metastases to liver and lungs	12
Pony	15	G	Unilateral, left	Weight loss, hematuria	Yes	No	Yes	Yes	No	6.6-kg mass, metastases to liver and lungs	13
Pony	10	G	Unilateral, right	Weight loss, back pain, colic, polyuria/polydipsia	Yes	Yes	Yes	No	No	6-cm diameter mass hemoperitoneum, no metastases	13
Thoroughbred	4	G	Unilateral, left	Respiratory noise	No	No	NR	NR	No	30-cm diameter mass, local invasion of sublumbar muscles	13
Grade	7	G	Unilateral, right	Hematuria, follwed by weight loss and colic	Yes	Yes	Yes	No	Mild	40-cm diameter, 23-kg mass, hemothorax and hemoperitoneum, metastases to liver and lungs	13
Thoroughbred	9	F	Unilateral, right	Recurrent colic, weight loss	Yes	Yes	No	Yes	No	30-cm diameter mass, metastases to omentum and muscle	14
Shire	4	F	Unilateral, right	Hematuria, followed by weight loss	Yes	Yes	Yes	Yes	No	65-cm diameter, 47.7-kg mass, adhesions to liver and bowel, no metastases	15
Grade	14	F	Unilateral, left	Pyrexia, hematuria, diarrhea	Yes	No	Yes	Yes	No	5-kg mass; metastases to liver, pancreas, and lungs	16

17.12

17.12—Urinary Incontinence and Bladder Dysfunction

Warwick M. Bayly

Loss of control of bladder function is an infrequent problem in horses. When the condition is recognized, it is usually because a degree of incontinence develops, which by definition means that intravesicular pressure exceeds resting urethral pressure. Although a number of recognized abnormalities of bladder emptying can afflict human beings, dysfunctions of equine bladder control and micturition tend to fall into one of three categories, with the extent to which they are recognized depending on clinical signs. Basically, the three types of problems are (1) the reflex or upper motor neuron (UMN) bladder (also known as *spastic* or *autonomic bladder*);(2) paralytic or lower motor neuron (LMN) bladder; and (3) the myogenic or nonneurogenic bladder. Either of the last two conditions can be associated with the atonic bladder syndrome, which is probably appropriate given the similarity of clinical signs and subsequent treatment once either of the two types of conditions is recognized. In fact, although signs of UMN bladder problems are initially different from those of the other two groups, this condition in horses also usually is not recognized until a degree of incontinence develops. A final form of bladder neuropathy that has been described in human beings and dogs, but not in horses, is reflex dyssynergia. In this condition, loss of coordination of detrusor contraction and urethral relaxation occurs, with the result that the animal may make efforts to urinate but fail to do so. Such cases frequently appear similar to those of urethral obstruction, and one must distinguished between them.

Although treatment options are limited and tend to be the same, regardless of what type of condition is responsible for the incontinence, determining the origin of the problem is prognostically important. To accomplish this, the internist needs to have a good working knowledge of how micturition normally is controlled.

17.12.1 Control of Micturition

From a neurologic perspective, one can regard the bladder as having a body and an outlet, which can be divided further into the neck (or trigone) and the proximal urethra. Functionally, the bladder alternates between filling and storage and emptying and elimination phases.[1] Dysfunction in any of these areas or phases may result in clinical problems. Somatic innervation is primarily to the striated muscle of the urethra via a branch of the pudendal nerve, which originates from the sacral cord (S1 to S2). Other branches of this nerve go to the anal sphincter and perineum. The sympathetic nerve supply is provided via the hypogastric nerve, with the preganglionic fibers arriving from L1 to L4 and synapsing in the caudal mesenteric ganglion. From there, postganglionic fibers supply the bladder (β_2-receptors) and proximal urethra (primarily α_1- and some α_2-adrenergic receptors).[2] Parasympathetic innervation originates in the sacral cord also, with neurons combining to form the pelvic nerve. Many complex interneuronal connections exist between sympathetic and parasympathetic nerves in the wall of the bladder, as well as small adrenergic cells that facilitate contact between sympathetic and parasympathetic pathways.[3] As a result, complete denervation of the bladder is virtually impossible. During the filling phase, the tone of the smooth and striated muscles that together comprise the external and internal urethral sphincters increases. These muscles are innervated by the pudendal 1290
nerve and the sympathetic nerves, respectively. Contraction of these muscles during filling maintains 1291
continence. Although the striated muscle forms a definite sphincter around the pelvic urethra, the anatomic existence of a bona fide internal sphincter is debatable.[4] However, the restriction to urine outflow that follows stimulation of the α-adrenergic receptors at the neck of the bladder has a sphincterlike effect. The smooth muscle of the bladder, referred to as the detrusor muscle, is innervated bythe parasympathetic pelvic nerve and β_2-adrenergic postganglionic fibers.

The storage or filling phase is dominated by sympathetic nerve activity and provides an excellent example of the effects of reciprocal innervation.[5] During filling, the detrusor muscle relaxes because of α-receptor–mediated inhibition of pelvic nerve afferents and stimulation of sympathetic β_2 receptors in the smooth muscle of the bladder body. The latter is a reflex response that involves sensory input from bladder stretch and pressure receptors via the afferent pelvic nerve fibers to the sacral cord, interneurons in the cord, and pre- and postganglionic sympathetic axons in the hypogastric nerve. Relaxation of this muscle allows accumulation of large volumes of urine with little or no increase in intravesicular pressure.

Intravesicular pressure starts to rise once detrusor muscle fibers are stretched fully. Receptors in the bladder wall detect these increases, and impulses are transmitted via the pelvic nerve and ascending spinoreticular cord tracks to the pons, cerebrum, and cerebellum, where they are interpreted as the sensation of bladder fullness. Signals responsible for voluntary micturition originate in the cerebrum and exert their influence via the brainstem, from which upper motor neurons descend in reticulospinal tracts to the sacral parasympathetic nuclei. This triggers the emptying phase. From these sacral segments, pelvic nerve impulses stimulate detrusor muscle contraction, action potentials traveling via parasympathetic ganglia in the pelvic plexus or bladder wall to postganglionic fibers that stimulate the smooth muscle. Depolarization waves spread throughout the bladder via tight junctions, resulting in a strong, coordinated, contractile process. Simultaneous inhibition of the pudendal nerve and hypogastric α- and β_2-sympathetic activity further facilitates detrusor muscle activity and relaxation of the external and internal urethral sphincters, respectively. Part of this inhibitory activity represents reflex neuronal activity linking pelvic and pudendal nerve axons in the sacral cord and inhibiting internuncial connections between sacral segments and the sympathetic neurons in the lumbar cord. Urethral sphincter relaxation also is coordinated centrally in a number of areas, including the cerebellum. Detrusor muscle

contraction pulls the bladder neck open, and micturition occurs. The emptying phase ends when the bladder stretch receptors sense that the bladder is empty and afferent parasympathetic (pelvic nerve) impulses cease. Pelvic nerve efferent activity also stops, and pudendal motor and sympathetic nerve activity resumes (because it is no longer inhibited), with the result that the detrusor muscle relaxes, restoring external and internal urethral sphincter tone.

17.12.2 Clinical Signs of Bladder Dysfunction

Control of bladder function obviously is complex, and many sites exist from which disruption of normal micturition could originate. In reality, problems are usually detectable in horses only when a degree of incontinence develops, which usually is manifested as constant or periodic dribbling of urine from the vulva or penis. In chronic cases, one frequently finds evidence of scalding and associated depilation of the perineum in mares and of the ventral abdomen in males, as well as the insides of the rear limbs in all animals. Any activity that results in increased intraabdominal pressure, such as coughing or exercise, may exacerbate signs or else be associated with their initial observation. Adult horses develop these problems much more frequently than do foals.

Academically, being able to differentiate between the different neurogenic forms of bladder dysfunction and those of myogenic origin may seem important. In reality, the clinical signs and treatments tend to be the same, regardless of cause. Upper motor neuron disease is characterized by increased urethral resistance, despite the presence of a full bladder, and may make catheterization or manual emptying of the bladder via rectal compression difficult. The condition usually occurs in association with broad, deep spinal cord lesions. In horses, these problems rarely are recognized in such cases because of the severe nature of associated clinical problems such as recumbency and myopathies. Frequently, such situations are deemed incompatible with life. (Possibly, a focal lesion caused by a disease such as equine protozoal myeloencephalopathy or an aberrant parasite migration could result in the development of spastic bladder without associated neurologic signs.)

In the event that horses suffering from this type of problem are able to stand, are kept in a sling, or have an isolated problem, in time they may develop the abilityto urinate reflexively. This reflex develops because ofthe stimulation of pressure receptors connected topelvic nerve afferents, which reflexively activate pelvic (parasympathetic) nerve efferents and the pudendal nerve. This activation results in detrusor muscle contraction and relaxation of the striated urethral muscle (external sphincter) leading to frequent urination, especially if the increases in abdominal pressure are regular, as may occur with any movement. These patients usually have 1291
some residual volume in the bladder after these voiding episodes. In such cases, urine dribbling usually is 1292
reported to occur intermittently, which is an important part of differentiating this type of dysfunction from paralytic (i.e., LMN) causes of incontinence.

As for the LMN bladder, lumbosacral trauma, equine herpes virus 1 myeloencephalitis, and cauda equina neuritis are probably the most common causes of this type of dysfunction, although in some parts of the world Sudan grass toxicity[6] and sorghum cystitis-ataxia (enzootic ataxia cystitis)[6,7] are major problems. Tumors of the lumbosacral spinal cord, such as lymphosarcoma and melanomas, are also capable of inducing paralytic bladder. Finally, iatrogenic paralysis following epidural administration of alcohol occasionally has been reported in show horses. Because this practice is taboo, how frequently the procedure leads to this problem is impossible to know.

With a paralytic (LMN) bladder, one usually sees other signs of LMN and lumbosacral dysfunction, including all or some of the following: loss of anal sphincter tone, tail paralysis, analgesia or hypalgesia over the perineum, atrophy of the muscles of the hip and hindleg, and hindlimb weakness. Damage to the pudendal

nerve and loss of external urethral sphincter integrity are therefore particularly important in the development of this problem. The bladder is atonic and distended with the urethral muscles relaxed, which results in urine dribbling because of overflow from the bladder. This incontinence may appear continuous, which helps to differentiate it from spastic (UMN) dysfunction. Sometimes the penis or vulva may appear paralyzed also. The prognosis is usually poor because of the development of secondary cystitis and general damage to the bladder wall and the detrusor muscle.

Myogenic problems occur mainly in geldings. Although myogenic problems can occur following obstructive effects of cystic calculi and cystitis, the problem generally lacks a specific identifiable cause. The condition generally develops slowly, in association with the accumulation of large amounts of sabulous or mucoid urinary sediment or sludge in the bladder, which mainly is comprised of calcium carbonate crystals. In time, the weight and volume of this material, when coupled with that of normal urine accumulation, progressively stretch the detrusor muscle. Incontinence is not normally notable until the cranial aspect of the bladder begins to protrude over the edge of the pubis, which results in craniad and ventrad displacement of the sediment, with the result that the bladder muscle is stretched beyond its normal modulus of elasticity and normal contraction and micturition is no longer possible. Severe distention and stretching also lead to a breakdown in tight junctions that prevents depolarizing waves from passing from muscle fiber to muscle fiber. Eventually, overdistention becomes so significant that the ability to maintain sphincter function is lost and incontinence develops. These cases usually occur without any other signs of neurologic disease; however, because of the lack of any identifiable cause or specific pathophysiologic mechanism, specific focal lesions of a peripheral nerve suchas the hypogastric nerve in fact could lead to a similar syndrome. Certainly, retention of urine in the bladder for any period results in the deposition of large quantities of sediment that in turn exacerbate the problem. One must recognize that part of the problem in cases of myogenic atony may stem from secondary cystitis, which develops following retention of urine for any period. The urea in retained urine breaks down to ammonia, which is irritating to the mucosal wall. Subsequent inflammation helps to damage the bladder musculature further.

Cystitis and chronic urethritis per se can be nonneurogenic, nonmyogenic causes of apparent incontinence. Irritation of stretch receptors in the bladder wall apparently causes regular stimulation of stretch receptors in parasympathetic afferents and stimulates detrusor contractions that cannot be inhibited voluntarily. This effect results in an apparent increase in the frequency of urination (pollakiuria) and an inability to control when it occurs. The condition frequently is referred to as urge incontinence and also may occur in association with a unilateral ectopic ureter in which the bladder is much smaller than usual (because of disuse) and incapable of storing a normal volume of urine. The frequency of micturition again is increased.

Hypoestrogenism also has been reported as a cause of nonneurogenic incontinence in an 18-year-old female Shetland pony.[8] A similar condition has been noted in older spayed bitches. The pathophysiologic mechanism of the condition is not known but probably is linked to a modulating effect of estrogen on the effects norepinephrine exerts on α-adrenergic receptor activity in the internal urethral sphincter.[9] In the documented case, the patient responded well to small doses (2 mg) of estradiol cypionate given intramuscularly every other day.

A transient postoperative condition that results in urine retention following abdominal or perineal operations has been noted in human beings.[10] The cause has not been explained, although the hypothesis is that a reflex depression of parasympathetic nerves may be responsible for detrusor muscle stimulation. This condition is distinct from that which may be associated with pain and reluctance to contract abdominal muscles following surgery. Whether such a condition exists in horses is unknown.

17.12.3 Diagnosis

Careful general physical and neurologic examinations are the basis for characterization of the type of bladder dysfunction that exists in the equine patient and the basis for any efforts aimed at identifying a cause. Although never good, the prognosis appears to be most positive in cases in which the horse still can generate significant increases in intravesicular pressure. Therefore performance of tests aimed at evaluating bladder and urethral pressure-generating capacities may be diagnostically useful. Cystometry, which involves the inflation of the bladder with volumes of sterile water, isotonic saline, or carbon dioxide, has been described in horses and pony mares.[11,12] Briefly, one introduces a large-gauge (No. 30 French) catheter into the bladder and connects it via a three-way stopcock to an infusion pump and pressure transducer. The pressure transducer is connected to a chart recorder. One fills the bladder until micturition occurs. Intravesicular pressure is recorded continuously. Usually a gradual increase in pressure is related to the infusion of fluid until the pressure suddenly rises, reflecting the onset of detrusor muscle contraction. The pressure at the point of this sharp increase is regarded as the contraction threshold. In normal horses, this threshold is about 90 ± 20 cm H_2O.[11] One determines the urethral pressure profile in the same test by using a catheter with multiple side openings and positioning the tip at the urethral sphincter. One then fills the catheter with fluid and withdraws it at a constant rate while recording the intraurethral pressure. Normal values are usually greater than 50 cm H_2O. Pressures were significantly lower in recordings of three incontinent mares.[12] Although these tests have not been used widely, they have considerable prognostic potential. Put simply, the higher the pressures are, the better the prognosis is. One also can determine the distance over which high pressure is present in the urethra from these tests. Such determination also maybe important, for it gives some further information on the integrity of the urethral sphincters.

1292

1293

17.12.4 Treatment

Some horses with UMN disease recover gradually, especially if one can determine and treat a specific cause. A major complication with paralytic and myogenic forms of bladder dysfunction is that cases often are not recognized until the atonia is irreversible. By that time the prognosis tends to be poor and identification of an initiating cause is difficult—and likely irrelevant. In such cases, the treatment is often futile; however, one often can determine this definitively only by assessing the response to attempted treatment. Regardless of whether dealing with UMN, LMN, or myogenic disorders, treatment tends to be the same concerning the bladder.

If one identifies a definitive cause such as equine herpes virus 1 myeloencephalitis or equine protozoal myeloencephalopathy, then one should institute the specific treatment for that disease. Concerning bladder dysfunction, the basic aim is to provide support while hoping for spontaneous recovery, which may take a long time (e.g., months in cases of pelvic nerve damage). A basic aim of therapy is to avoid retention of urine because of secondary problems that this entails. Therefore promotion of bladder emptying is an important goal that one may attempt to reach by regular catheterization or the use of an indwelling catheter. (In males, one normally inserts such catheters via a perineal urethrostomy.) Although facilitating drainage, intermittent or indwelling catheterization appears to predispose the horse to secondary bacterial cystitis and therefore should not be used without some forethought. Some horses that are chronically incontinent seem to survive comfortably without any catheterization.[7] Antimicrobial therapy is important for treating any incontinence cases but is especially critical when one uses indwelling or regular catheterization.

One may give the α-adrenergic blocker phenoxybenzamine (0.7 mg/kg per os every 6 hours) to eliminate any urethral resistance, thus facilitating emptying in the reflex UMN problem or in situations of great atonic overdistention. Bethanechol chloride is a parasympathomimetic agent resistant to the action of acetylcholinesterase and apparently has a selective effect on the smooth muscle of the gastrointestinal tract and bladder. The drug is used principally to stimulate detrusor muscle activity, and it acts by stimulating postganglionic parasympathetic effector cells rather than motor end plates. The recommended dose ranges from 0.25 to0.75 mg/kg subcutaneously 3 times a day. Starting the horse on the smallest dose is recommended. This drug reportedly has varying results.[13] Bethanechol has no effect when the bladder is completely atonic or areflexic. If the muscle is capable of generating weak contractions, then bethanechol may be useful. One could determine whether contractions are possible by cystometry. Although bethanechol can increase intravesicular pressure, whether it helps evacuate the bladder also depends on the status of the urethral sphincter and striated muscle. One must remember that drugs such as phenoxybenzamine and bethanechol can have undesired side effects in other body systems. The use of general muscle relaxants and an α-adrenergic blocker may be useful for achieving urethral muscle relaxation. Diazepam (0.2 to 0.5 mg/kg intravenously) and dantrolene are the most commonly used relaxants. Diazepamis effective in large doses, which also usually result in sedation. Dantrolene (10 mg/kg per os loading dose; 2.5 mg/kg per os maintenance every 6 hours) slows release of calcium from the sarcoplasmic reticulum and has been tried in dogs with varying effects.

Surgical removal of the sabulous sludge found in a number of these horses has been tried via perineal 1293

urethrostomy or cystotomy, with poor results.[14] Removal via cystotomy is not recommended because of 1294
difficulties in evacuating the material without contaminating the peritoneal cavity. Perineal urethrotomy, combined with irrigation with large volumes of fluid while the horseis anesthetized, seems to be the most effective way of removing this material. However, the prognosis is still poor because of chronic irreversible changes in the bladder wall, which seem to prohibit any possible return of normal detrusor muscle function.

18 CHAPTER 18 DISORDERS OF THE ENDOCRINE SYSTEM

Ramiro E. Toribio

18.1 18.1—Calcium Disorders

Ramiro E. Toribio

18.1.1 Calcium

Calcium (molecular weight 40.08) is one of the most abundant elements in nature. In vertebrates, calcium is important in physiologic functions such as muscle contraction, hormone secretion, enzyme activation, cell division, cell membrane stability, neuromuscular excitability, and blood coagulation.[1] Calcium also regulates processes that result in cell injury and cell death, such as free radical production, cytokine release, protease activation, vasoconstriction, and apoptosis. Because of the importance of calcium in normal intracellular and extracellular processes, maintenance of a steady concentration of calcium is important.

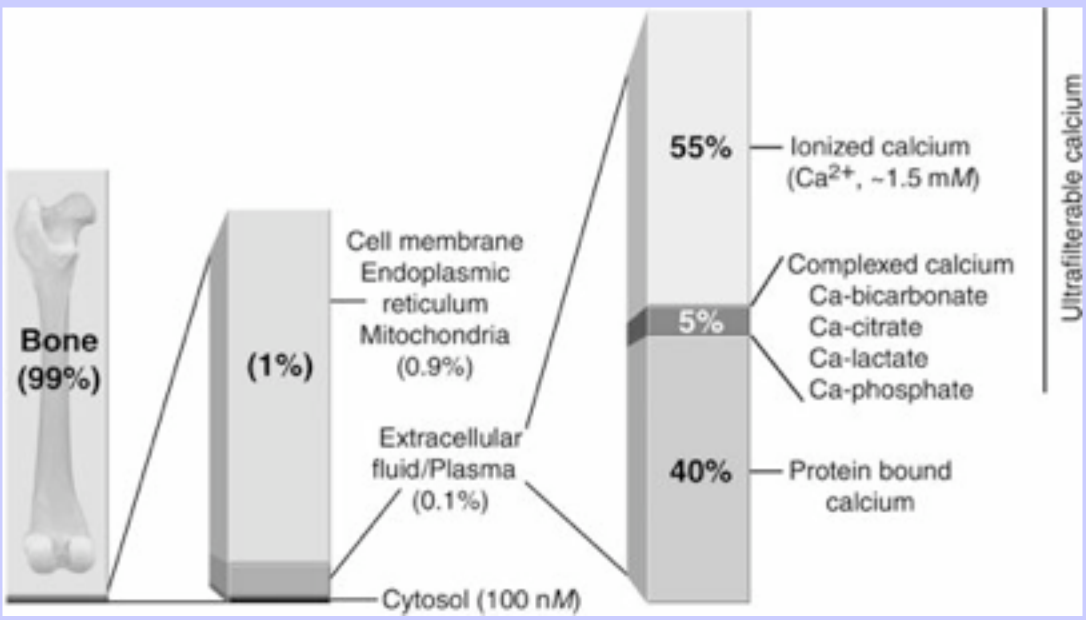
18.1.1.1 DISTRIBUTION AND PHYSICAL PROPERTIES OF CALCIUM

In the body, calcium has structural and nonstructural functions and is found in three main compartments: the skeleton, soft tissues, and the extracellular fluid. The skeleton contains approximately 99% of the total body calcium as hydroxyapatite crystals ($Ca_{10}[PO_4]_6[OH]_2$). Calcium is a major component of the skeleton, providing support against gravity, protection of vital internal organs (brain, spinal cord, thoracic organs), and a niche for blood-forming elements. The skeleton also acts as a reservoir for calcium. The nonstructural functions are related to calcium as a regulatory ion. The remaining calcium is present in the cell membrane, mitochondria, and endoplasmic reticulum (0.9%) and in the extracellular fluid (0.1%).[1] In blood, virtually all calcium is in plasma, in which calcium exists as a free or ionized form (50% to 55%), bound to proteins (40% to 45%), and complexed to anions such as citrate, bicarbonate, phosphate, and lactate (5% to 10%) (Figure 18.1-1).[1,2] In horses, serum ionized calcium represents 55% to 58% of the total serum calcium concentration.[3,4] Free or ionized calcium (Ca^{2+}) is the biologically active form of calcium. Of the protein-bound calcium, approximately 80% is associated with albumin and 20% with globulins.

Calcium binds to negatively charged or anionic proteins, and the affinity of calcium for anionic sites is pH-dependent. During acidosis, Ca^{2+} binding to anions decreases because of increased H^+ concentrations, resulting in increased plasma Ca^{2+} concentrations. Alkalosis results in lower Ca^{2+} concentrations. In human beings, for each 0.1 unit change in the blood pH, an inverse change of 0.2 mg/dl (0.05 mmol/L) in Ca^{2+} concentrations has been calculated to occur. In healthy horses, Kohn and Brooks[3] found that the plasma Ca^{2+} percentage (Ca^{2+}/total calcium) was weakly correlated with plasma pH. However, in vitro manipulation of serum pH did not reveal a statistically significant relationship between serum pH and Ca^{2+} percentage. The authors speculated that the lack of relationship between serum pH and Ca^{2+} percentage probably resulted from heterogeneity of Ca^{2+} percentage among horses and from the presence of other unmeasured variables that may affect Ca^{2+} binding. Hypoalbuminemia results in total hypocalcemia (pseudohypocalcemia), with Ca^{2+} concentrations remaining within the normal range, unless the primary cause of hypoalbuminemia also is

altering calcium homeostasis (sepsis, systemic inflammatory response syndrome, severe gastrointestinal disease).

Figure 18.1-1 Calcium distribution in the body. The skeleton contains approximately 99% of the total body calcium. The remaining calcium is present in the cell membrane, mitochondria, endoplasmic reticulum, and in the extracellular fluid. In blood, calcium exists as a free or ionized form, bound to proteins, and complexed to anions such as citrate, bicarbonate, phosphate, and lactate. In horses, serum ionized calcium represent 55% to 58% of the total serum calcium concentration.



Cytosolic calcium concentrations ($Ca^{2+}{}_i$) are low (1×10^{-6} to 10^{-3} *M*) compared with extracellular Ca^{2+} concentrations (1×10^{-3} *M*). This results in a 10,000-fold calcium gradient between the extracellular fluid and the cytosol that makes calcium an important cation in signal transduction. In the cytosol, $Ca^{2+}{}_i$ is buffered by phospholipids, dicarboxylic acids, and several calcium-binding proteins. Approximately 95% of $Ca^{2+}{}_i$ is in the endoplasmic reticulum and mitochondria (see Figure 18.1-1). Low $Ca^{2+}{}_i$ concentrations are maintained by calcium-binding proteins (caldindin, calmodulin, calsequestrin, caldecrin), calcium pumps (Ca^{2+}-ATPase), and calcium exchangers (Na^+/Ca^{2+} exchangers).

18.1.1.2 CALCIUM SIGNALING

In most cells the signaling properties of calcium depend on increasing Ca^{2+}_i. Calcium concentrations within the cells depend on mechanisms that regulate calcium influx, efflux, and calcium release.[5] Mechanisms that control changes in Ca^{2+}_i concentrations include Ca^{2+} channels in the plasma membrane, the endoplasmic reticulum, and the sarcoplasmic reticulum. Some of the mechanisms that remove Ca^{2+}_i from the cytosol include Ca^{2+}-ATPases in the plasma membrane, endoplasmic reticulum, and sarcoplasmic reticulum, and Na^+/Ca^{2+} exchangers on the plasma membrane. The mitochondria are also important in regulating Ca^{2+}_i by providing energy for active calcium transport and by acting as a calcium storage.

18.1.1.3 CALCIUM ENTRY FROM THE EXTRACELLULAR COMPARTMENT

Calcium enters the cell through cation channels, such as the fast sodium channels; however, most Ca^{2+} influx occurs through Ca^{2+}-specific channels. A vast number of Ca^{2+}-specific channels are present on the cell membrane. Voltage-operated (voltage-gated) Ca^{2+} channels (VOCCs) are present in excitable cells and are activated by depolarization. Ligand- or receptor-operated Ca^{2+} channels include a large number of channels that are present primarily in secretory cells and nerve terminals. Examples of receptor-operated Ca^{2+} channels include the nicotic acetylcholine and the *N*-methyl-d-aspartate receptors. These channels are activated by binding of an agonist (serotonin, glutamate, acetylcholine) to an extracellular domain. Mechanically activated Ca^{2+} channels are present in cells responsive to changes in cell shape such as smooth muscle cells and cardiac myocytes.

18.1.1.4 CALCIUM RELEASE FROM INTRACELLULAR STORES

The release of calcium from intracellular stores depends on messenger-activated channels present in the
endoplasmic reticulum, sarcoplasmic reticulum, and mitochondria. For example, by interacting with specific 1296
cell membrane receptors, hormones may activate phospholipase C to hydrolyze phosphatidylinositol 4,5- 1297
biphosphate to inositol 1,4,5-triphosphate (IP_3) and diacylglycerol. Inositol 1,4,5-triphosphate is highly diffusible and interacts with IP_3 receptors on the endoplasmic reticulum and sarcoplasmic reticulum, opening calcium channels and increasing the Ca^{2+}_i. The ryanodine receptors (activated by the plant alkaloid ryanodine) are similar to the IP_3 receptors; however, they are present in excitable cells (muscle and neurons), and their activation also increases the Ca^{2+}_i.

Calcium is introduced into the cytoplasm in short time (millisecond) pulses (plumes) around the mouth of the different calcium channels. These signals have to be short (spikes) because high Ca^{2+}_i is toxic to the cell. The frequency of the spikes is proportional to cell stimulation, and the sensors for the spikes are the calcium-binding proteins. The calcium-calmodulin complex then activates enzymes, resulting in protein phosphorylation. Striated muscle also has a pulsatile Ca^{2+} signaling system activated by depolarization. With the depolarization of the sarcolemma, Ca^{2+} enters the cell via VOCCs, and the VOCCs also interact with the ryanodine receptors, inducing Ca^{2+}_i release from the sarcoplasmic reticulum (calcium-induced calcium release) to promote muscle contraction.

18.1.1.5

MEMBRANE POTENTIALS

Electric potentials are present in every cell in the body, and they result from the diffusion of ions across the cell membrane. The membrane potentials result primarily from the diffusion of K^+ and Na^+ because these ions are subject to higher electrochemical gradients. Some cells (neurons and muscle cells) are excitable and capable of self-generating electric impulses because their cell membrane is “leaky” to these ions. Concentrations of K^+ are higher inside the cell, and as these ions diffuse outward, they line up along the outside of the membrane, carrying positive charges; the result is an electropositive membrane on the outside and electronegative membrane in the inside because anions remain inside. Concentrations of Na^+ are higher in the outside and their diffusion to the inside can create electropositivity inside the cell. A potential in the cell prevents the net diffusion of ions across the membrane in either direction; this is the Nernst potential that one can calculate by the *Nernst equation*. The membrane potential in nerve fibers is around –90 mV, meaning that the potential inside the fiber is 90 mV more negative than the outside. Cells maintain their membrane potentials by transporting Na^+ and K^+ across the membrane by different mechanisms. The Na^+, K^+-ATPase is an electrogenic pump that pumps three Na^+ outside the cell for each two K^+ to the inside, creating large concentrations gradients across the nerve membrane (Na^+, 140 mEq/L outside, 14 mEq/L inside; K^+, 4 mEq/L outside, 140 mEq/L inside). The K^+/Na^+ leak channels are in the nerve membrane and are more permeable to K^+ than to Na^+; this leakage is important in determining the membrane potential. The resting membrane potential in large skeletal muscle fibers is similar to that of nerve fibers (–90 mV). In small striated fibers, small nerves, neurons in the central nervous system, and smooth muscle, the membrane potential ranges between –40 to –60 mV. The role of calcium in the resting membrane potential is minimal.

18.1.1.6

ACTION POTENTIAL

Excitable cells are particular for their ability to propagate a signal in the form of action potentials, which are rapid changes in the cell membrane potential. The action potential has a resting stage in which the membrane is polarized. In the depolarization stage, the membrane becomes rapidly permeable to Na^+, positive charges move inside the nerve fiber, and the polarized state (–90 mV) is lost. Immediately after depolarization, the Na^+ channels become less permeable to Na^+, and K^+ channels open to return the cell membrane to the resting stage (repolarization). Under resting conditions, the cell membrane is relatively impermeable to Ca^{2+}, and many cells have a Ca^{2+} pump that extrudes Ca^{2+} from the inside to the outside (or into the endoplasmic reticulum or sarcoplasmic reticulum), creating a large Ca^{2+} gradient across the cell membrane that is important for Ca^{2+} to act as a signaling ion. Calcium channels (VOCCs) are slightly permeable to Na^+ and are also known as Ca^{2+}/Na^+ channels or slow channels (Na^+ channels are fast channels). Calcium ion channels are abundant in cardiac and smooth muscle. Few fast Na^+ channels are present in smooth muscle cells, and the action potential in these cells primarily results from activation of the Ca^{2+} channels.

During hypocalcemia, the fast Na^+ channels open with small changes in the membrane potential and the nerve fibers become excitable or discharge spontaneously, causing tetany. Calcium ions bind to the exterior of the Na^+ channels, altering the electric state of the channel itself and increasing the voltage (threshold) required for opening. By increasing the threshold potential, Ca^{2+} stabilizes the cell membrane, and this is the mechanism by which Ca^{2+} antagonizes the effects of hyperkalemia. Hyperkalemia increases the resting

membrane potential closer to threshold, thus increasing membrane excitability, whereas calcium administration raises the threshold potential, stabilizing membrane excitability.[2]

18.1.1.7 NEURONS

In addition to its effects on cell membrane excitability, Ca^{2+} is required for the release of neurotransmitters. When the neuronal action potential reaches the nerve terminal, VOCCs in the presynaptic membrane open to 1297
increase the Ca^{2+}_i. As a result, vesicles with neurotransmitters fuse with the terminal membrane, causing 1298
exocytosis into the synaptic space.[6]

18.1.1.8 SKELETAL MUSCLE

In the muscle fiber, Ca^{2+} is important in determining the threshold potential. Minimal increases in Ca^{2+}_i results in a series of events associated with excitation-contraction coupling. In addition, Ca^{2+}_i acts as a cofactor for enzymes important in energy release. Abnormalities in muscle fiber function are often an early sign of hypocalcemia. One may observe increased membrane excitability and muscle weakness.

In the skeletal muscle fiber the Ca^{2+} cycle starts with the depolarization of the sarcolemma and the transverse tubular system (T system), which leads to Ca^{2+} entry via VOCCs and Ca^{2+}_i release from the sarcoplasmic reticulum via the ryanodine and the dihydropyridine receptors. Approximately 95% of the Ca^{2+}_i required for muscle contraction is released by the sarcoplasmic reticulum. In the sarcoplasm, Ca^{2+}_i interacts with troponin C, causing conformational changes that release myosin-binding sites on the actin molecule, resulting in contraction. Therefore the higher the concentrations of Ca^{2+}_i, the greater the number of troponin free binding sites and the greater the force of contraction. Muscle contraction is terminated by the active pumping of Ca^{2+}_i into the sarcoplasmic reticulum. Calcium also activates glycogenolysis, providing energy for adenosine triphosphate generation, and therefore calcium works actively in skeletal muscle contraction and in the generation of energy necessary to sustain contraction.

18.1.1.9 CARDIAC MUSCLE CELLS

In the cardiac myocyte, Ca^{2+} also mediates excitation-contraction coupling. The action potential extends down T tubules where VOCCs are opened. The Ca^{2+} influx diffuses to the sarcoplasmic reticulum, triggering the release of Ca^{2+}_i (calcium-induced calcium release). As in skeletal muscle, intracellular stores of calcium are responsible for most of the calcium required for excitation and contraction. Calcium also contributes to the spontaneous depolarization of cardiac muscle through slow cation channels. Spontaneous depolarization results from a gradual increase in conductance of Na^+ and Ca^{2+}, the affinity for Na^+ being greater. Once threshold is achieved, fast Na^+ channels open, resulting in the fast upstroke (phase 0) of the cardiac action potential. As the membrane potential passes –30 to –40 mV mark, VOCCs open, allowing Ca^{2+} influx into the cell. These calcium channels remain open for a long time, resulting in the plateau (phase 2) of the cardiac action potential.

Hypocalcemia decreases the rate of the slow inward calcium current, prolonging the plateau phase of the cardiac action potential and the QT and ST segments of the electrocardiogram. With profound hypocalcemia, this prolonged phase results in slowing the heart rate, heart block, and arrhythmias and in decreasing the strength of contraction, or contractility, because of the lack of calcium to bind troponin C. Hypercalcemia, such as that induced by rapid administration of calcium for treatment of hyperkalemia, shortens the QT and ST segments, flattens the T wave, and may cause first-degree heart block. Severe hypercalcemia may cause asystole or ventricular arrhythmias, increasing heart rate and contractility. Therefore monitoring the heart rate of the horse whenever one administers calcium is always advisable.

18.1.1.10 SMOOTH MUSCLE CELLS

The smooth muscle fiber is small compared with the skeletal fiber, and Ca^{2+} ions can diffuse to most parts of the cell to induce contraction. The time for calcium to diffuse is the latent period (200 to 300 ms), which is the period before contraction begins. The latent period in smooth muscle cells is 50 times greater than in skeletal muscle.[6] Smooth muscle cells are stimulated by voltage, stretching, and hormones. Smooth muscle cells have more VOCCs and less voltage-gated Na^+ channels than skeletal muscle fibers, and therefore Na^+ is of less importance in generating the action potential. Hormones such as epinephrine, norepinephrine, acetylcholine, serotonin, vasopressin, and histamine interact with specific receptors to stimulate or inhibit Ca^{2+} influx into the cell.

In skeletal muscle almost all Ca^{2+} required for excitation and contraction comes from the sarcoplasmic reticulum. In contrast, in the smooth muscle cell the sarcoplasmic reticulum is rudimentary and most of the Ca^{2+} required for contraction comes from the extracellular fluid. This has clinical implications, for hypocalcemia may result in ileus.

18.1.1.11 COAGULATION

Calcium ions (factor IV) are necessary for the coagulation process to occur, and Ca^{2+} is a cofactor required by factors II, VII, IX, X, XI, XII, and XIII, and without $^{2+}$ blood clotting does not occur. However, the Ca^{2+} concentration required for coagulation is minimal, and even during severe hypocalcemia, low Ca^{2+} concentrations do not seem to interfere with the clotting process. Other clinical conditions associated with hypocalcemia are more likely to result in animal death than hypocoagulation.

18.1.1.12 LACTATION

Calcium demands in the growing neonate are high, and they must be provided by the mother. As a result of the high calcium needs, the daily requirements for calcium in the lactating mother at the onset of lactation are twice maintenance. Mare's milk calcium concentration ranges from 1.3 g/kg of fluid milk during the first 2 1298
weeks of lactation to 0.8 g/kg of milk on weeks 15 to 17.[7,8] In a 500-kg mare producing 15 kg of milk per 1299
day with a calcium concentration of 1.2 g/kg of milk this represents a demand of 36 g of calcium (15 kg of milk × 1.2 g of calcium/50% absorption) a day, in addition to maintenance. Most of the calcium present in milk is complexed to organic bases and casein.

18.1.2 ## Calcium in the Horse

18.1.2.1 ### REQUIREMENTS

Calcium and phosphorus requirements in horses and ponies depend on the age, physiologic status, and amount of work or exercise performed (Table 18.1-1). Horses do not have a nutritional drive to meet their calcium requirements and depend highly on the amount of calcium present in their diet. Because extracellular Ca^{2+} is under the homeostatic control of several factors, serum Ca^{2+} concentration is not a reliable indicator of dietary calcium intake. An acceptable diet for horses must contain 0.15% to 1.5 % of calcium in feed dry matter and 0.15% to 0.6% of phosphorus in feed dry matter (Table 18.1-2). A calcium/phosphorus ratio less than 1:1 may have negative effects on calcium absorption and skeletal development; however, a calcium/phosphorus ratio as high as 6:1 for growing horses may not be detrimental if phosphorus intake is adequate.[9] Adult horses should receive approximately 40 mg/kg/day of calcium. These requirements depend on the physiologic status of the animal; pregnant mares require around 50 to 60 g of calcium per day, whereas lactating mares and growing horses may require 50 to 75 g of calcium per day. The average horse has been estimated to need to absorb 20 to 25 mg of calcium and 10 to 12 mg of phosphorus per kilogram per day to balance losses.[10–12] According to the National Research Council,[13] the maximum tolerable amount of phosphorus in horses fed adequate amounts of calcium is 1%.Tables 18-3 and 18-4 present the calcium and phosphate content in some mineral supplements and equine feeds.

TABLE 18.1-1 Calcium and Phosphorus Requirements in Horses

AGE/CONDITION OF HORSE	PERCENT IN THE DIET		DAILY INTAKE (g)	
	Ca	P	Ca	P
Foals (<6 months)	0.80	0.55	33	20
Weanlings	0.60	0.45	34	25
Yearlings	0.50	0.35	31	22
Two-year-old	0.40	0.30	25	17
Mare, late pregnancy	0.45	0.30	34	23
Mare, lactation	0.45	0.30	50	34
Mature horses	0.30	0.20	23	14

TABLE 18.1-2 Acceptable Ranges of Minerals and Vitamins in Feed of Horses[23,24,208–210]

MINERAL/VITAMIN	IN DRY MATTER
Calcium	0.25%-1.5%
Potassium	0.15%-0.6%
Magnesium	0.08%-0.16% (14 mg/kg body mass)
Vitamin D	300–800 IU/kg

18.1.2.2 ABSORPTION

Equids absorb a larger proportion of dietary calcium compared with ruminants.[14] Horses absorb calcium and phosphorus with high efficiency and with little effect of age.[12,14] Studies in horses of different ages revealed that horses fed diets with adequate amounts of calcium absorb 50% to 75% of the calcium and less than half the phosphorus present.[12,15] Calcium in most forages for horses is more than 50% to 60% digestible (Table 18.1-5). The efficiency of calcium absorption is related inversely to the calcium content of the diet. The proximal half of the small intestine is the main site for calcium absorption in the horse, followed by the distal small intestine and the dorsal colon.[12,16] The amount of calcium absorbed in the dorsal colon is minimal, and the cecum and ventral colon are mainly secretory sites for calcium (Figure 18.1-2). A high content of phosphate (or phytate) inhibits calcium absorption,[17] whereas a high content of calcium in the diet has minimal effect on phosphorus absorption.[18] Oxalate reduces calcium absorption; a 1% oxalate content in an 1299
equine diet reduced calcium absorption by 66% and increased fecal calcium excretion.[19] Oxalate content in 1300
the diet higher than 0.5% or a calcium/oxalate ratio less than 0.5 can result in a negative calcium balance.[20] Diets containing 0.5% and 0.87% of oxalate had no effect in calcium absorption when the calcium/oxalate ratios were higher than 1.7.[21] Table 18.1-6 lists some plants containing harmful amounts of oxalate.

TABLE 18.1-3 Calcium and Phosphorus Content (Percent) in Some Mineral Supplements

MINERAL SUPPLEMENT	CALCIUM CONTENT	PHOSPHORUS CONTENT
Calcium carbonate	34	0
Defluorinated phosphate	32	15
Bone meal	30	14
Dicalcium phosphate	27	21
Monocalcium phosphate	17	21
Monosodium phosphate	0	22
Calcium gluconate 23%	2.14*	0

Adapted from the National Academy of Sciences: *Nutrient requirements of horses,* ed 5, Washington, DC, 1989, National Research Council.

The dietary cation-anion balance (DCAB) affects Ca^{2+} absorption; a low DCAB increases intestinal Ca^{2+} absorption, whereas a high DCAB has the opposite effect. A decrease in DCAB in horses resulted in increased Ca^{2+} concentrations.[22]

TABLE 18.1-6 Plants Containing Harmful Amounts of Oxalate

COMMON NAME	SCIENTIFIC NAME
Bermuda grass	*Cynodon dactylon*
Buffel grass	*Cenchrus ciliaris*
Dallas grass	*Paspalum* spp.
Foxtail grass	*Setaria* spp.
Greasewood	*Sarcobatus vermiculatus*
Halogeton	*Halogeton glomeratus*
Kikuyu grass	*Pennisetum clandestinum*
Lambsquarters	*Chenopodium* spp.
Napier grass, mission grass	*Pennisetum* spp.
Pangola grass	*Digitaria decumbens*
Panic grass	*Panicum* spp.
Para grass	*Brachiaria* spp.
Purple pigeon grass	*Setaria incrassata*
Purslane	*Portulaca oleracea*
Red-rooted pigweed	*Amaranthus* spp.
Rhubarb	*Rheum rhaponticum*
Russian thistle, tumbleweed	*Salsola* spp.
Setaria	*Setaria sphacelata*
Sorrel	*Rumex* spp.
Soursob, Shamrock	*Oxalis* spp.
Sugar beet	*Beta vulgaris*

These plants have an oxalate content higher than 0.5% dry matter or have a calcium/oxalate ratio of less than 0.5. Ingestion of these plants can result in calcium deficiency and clinical signs consistent with nutritional secondary hyperparathyroidism. Some of these plants also may cause gastrointestinal irritation and diarrhea.

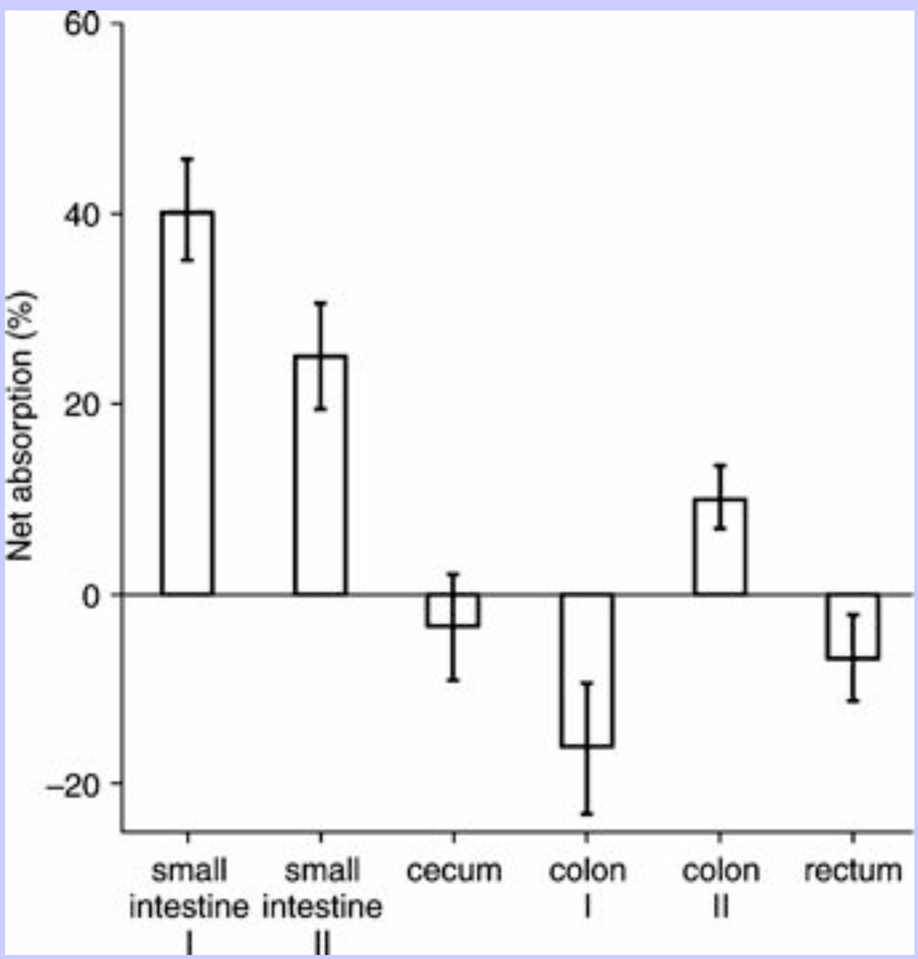
Information on the effect of magnesium on calcium and phosphorus absorption in the horse is limited,[23,24] and no controlled studies have evaluated the effects of excessive dietary magnesium. No changes in serum calcium and phosphorus concentrations were detected in foals fed a magnesium-deficient diet; however, mineralization of the aorta was present.[23]

Glucocorticoids affect the calcium metabolism in the horse. Dexamethasone administration to pony foals resulted in decreased intestinal absorption of calcium, decreased bone resorption, and an increased urinary excretion of calcium.[25,26]

Phosphorus absorption in the horse ranges from 30% to 55% and occurs in the small and large intestines. The dorsal colon and small colon, followed by the distal small intestine, are the most effective sites for phosphorus absorption in the horse[12,27,28] (Figure 18.1-3). The proximal small intestine, cecum, and ventral colon secrete phosphorus into the lumen, and most of this phosphorus is reabsorbed in the next segment of intestine. High aluminum and phytate contents in the diet reduce phosphate absorption. Some phytase activity is present in the large colon of the horse and can release some phytate phosphorus to be absorbed.[29] The mechanisms responsible for calcium and phosphorus absorption are discussed elsewhere in this section. 1300

1301

Figure 18.1-2 Net absorption of calcium from the intestine of the horse. The intestine was divided in six regions: proximal *(small intestine I)* and distal *(small intestine II)* halves of the small intestine, cecum, proximal *(colon I)* and distal *(colon II)* large colon, and transverse colon and rectum *(rectum)*. (Adapted from Schryver HF, Craig PH, Hintz HF et al: The site of calcium absorption in the horse, *J Nutr* 100:1127–1131, 1970.)

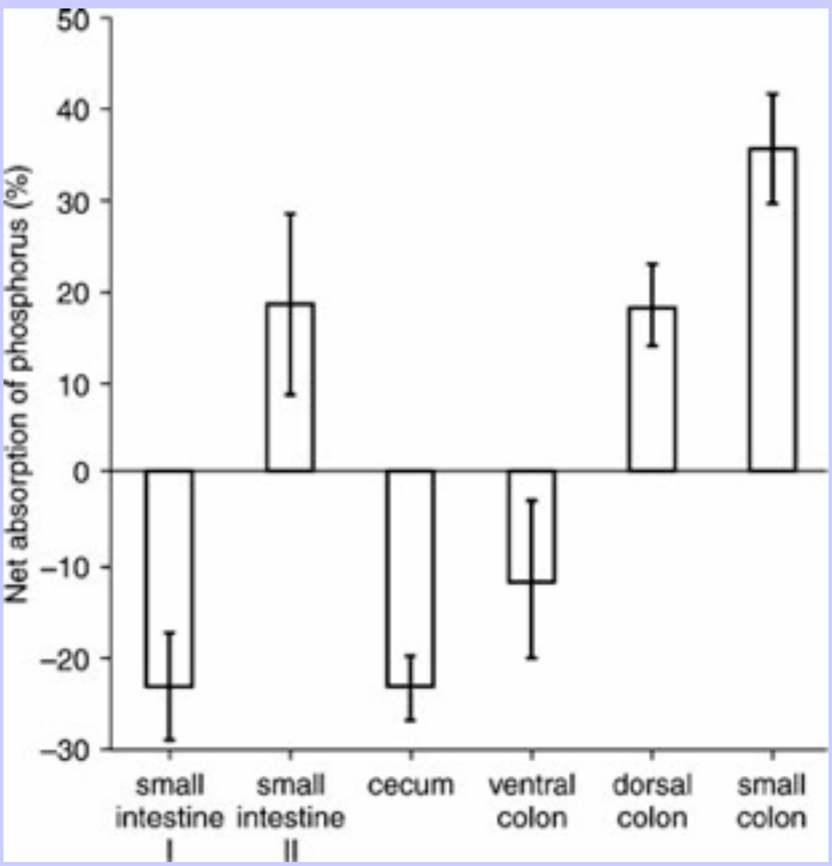


18.1.2.3 ELIMINATION

Calcium is eliminated from the animal through the kidneys, milk, sweat, feces, and the fetus. Because horses absorb a greater proportion of their dietary calcium, their feces contain a lower concentration of calcium and a lower Ca:P ratio than feces of ruminants when these animals are fed equivalent diets.[12,14]

Endogenous losses of calcium in horses have been estimated at 20 to 25 mg/kg of body mass per day.[10] Assuming a 50% calcium digestibility, a 500-kg horse would require 20 g of calcium to replace losses, or 40 mg/kg/day; growing and lactating horses can double these requirements. The amount of calcium eliminated depends on the physiologic status of the animal and on the amount of calcium ingested, the presence of substances that may interfere with calcium absorption (phosphates, oxalates, phytates), and disease. If horses receive adequate amounts of calcium and phosphorus, the urinary excretion of calcium exceeds that of phosphorus.[30,31] The urinary fractional clearances of calcium and phosphorus and the ratio of urinary to serum calcium and phosphorus have been proposed as methods to estimate calcium and phosphorus intake.[31] Interpretation of the fractional clearance of calcium could be difficult because horses eliminate large amounts of calcium in urine.[32]

Figure 18.1-3 Net absorption of phosphorus from the intestine of ponies fed an alfalfa diet.



One can calculate the fractional clearance of calcium or phosphorus using the following formula:

$$\frac{\text{Urine Ca}^{2+}\text{(or P)}}{\text{Serum Ca}^{2+}\text{(or P)}} \times \frac{\text{Serum creatinine}}{\text{Urine creatinine}} \times 100$$

18.1.2.4 DEFICIENCY

Calcium deficiency can be acute or chronic. Chronic calcium deficiency generally is manifested as abnormal cartilage and bone development (developmental orthopedic disease) and lameness. Horses with acute calcium deficiency have clinical signs associated with neuromuscular excitability. When one suspects a calcium deficiency, feed analysis is recommended to determine whether dietary calcium content is adequate.

18.1.2.5 PHOSPHORUS

The clinical signs associated with phosphorus excess generally result from calcium deficiency and include lameness, abnormal cartilage and bone development, fractures, and osteodystrophia fibrosa (nutritional secondary hyperparathyroidism). Phosphorus deficiency can be manifested as pica and developmental orthopedic disease. Serum inorganic phosphorus (P_i) concentration is more indicative of dietary phosphorus intake and status than serum calcium because the homeostatic control for P_i is not as precise as that of calcium. 1301

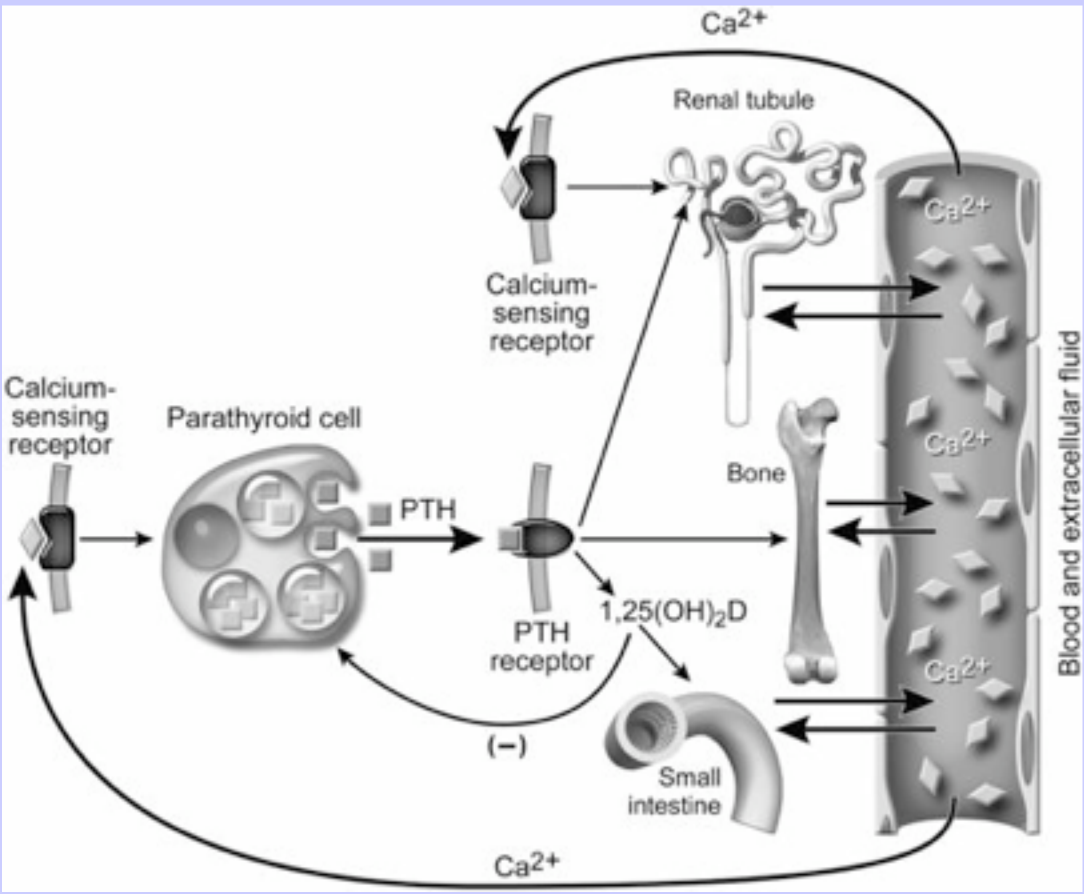
18.1.3 Calcium Homeostasis 1302

Regulation of extracellular ionized calcium (Ca^{2+}) concentration is controlled by a complex homeostatic system that includes three major hormones: parathyroid hormone (PTH), calcitonin, and 1,25-dihydroxyvitamin D_3 [$1,25(OH)_2D_3$] or calcitriol).[2,4,33] Parathyroid hormone–related protein (PTHrP) is a recently discovered protein that shares considerable homology with PTH, binds and activates the PTH-1 receptor, and is important for cell growth and differentiation and in calcium transport across membranes.[34,35] Parathyroid hormone increases during hypocalcemia, whereas calcitonin increases during hypercalcemia.

18.1.3.1 PARATHYROID HORMONE

Parathyroid hormone is responsible for the minute- to-minute regulation of extracellular Ca^{2+} concentrations. The biologic functions of PTH include stimulation of osteoclastic bone resorption, thereby increasing Ca^{2+} release into circulation, stimulation of Ca^{2+} reabsorption and inhibition of phosphate reabsorption in the renal tubules, and stimulation of calcitriol synthesis in the kidney (Figure 18.1-4). Calcitriol then increases Ca^{2+} and phosphate absorption in the intestine and inhibits PTH secretion in the parathyroid gland.[1]

Figure 18.1-4 Parathyroid hormone and calcium homeostasis. The biologic functions of parathyroid hormone include stimulation of osteoclastic bone resorption, stimulation of renal Ca^{2+} reabsorption, inhibition of phosphate reabsorption in the renal tubules, and stimulation of calcitriol synthesis in the kidney. (Adapted from Marx SJ: Hyperparathyroid and hypoparathyroid disorders, *N Engl J Med* 343:1863-1875, 2000.)



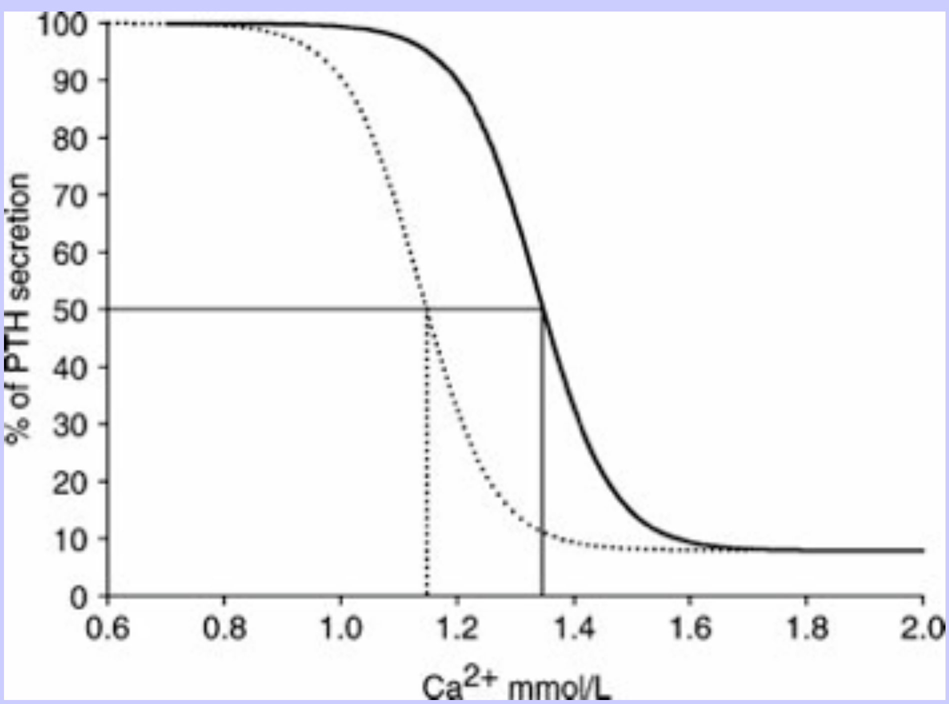
Parathyroid hormone is secreted by the chief cells of the parathyroid gland in response to small changes in extracellular Ca^{2+} concentrations. The relationship between serum Ca^{2+} concentrations and PTH secretion is inverse and sigmoidal in different species, including the horse (Figure 18.1-5).[4,36–40] This relationship rapidly enables the parathyroid gland to respond to minimal changes in Ca^{2+} concentrations. Changes in extracellular Ca^{2+} concentrations are detected by a Ca^{2+}-sensing G protein–linked cation receptor (CaR) in the parathyroid cells.[41]

18.1.3.1.1

Parathyroid Gland Anatomy and Function

In mammals the parathyroid glands develop from the endoderm of the third and fourth pharyngeal pouches and migrate during embryonic development.[2,42] Some evidence indicates that the parathyroid glands contain endodermal and ectodermal element markers (neuron-specific enolase, dihydroxyphenylalanine (DOPA) decarboxylase, chromogranin).[42–44] Human beings with multiple endocrine neoplasia develop 1302
tumors of neuroendocrine origin (medullary thyroid C carcinoma, pheochromocytoma) and often develop 1303
parathyroid gland neoplasia.[42] Multiple endocrine neoplasia recently was reported in the horse.[45]

Figure 18.1-5 Schematic representation of the relationship of Ca^{2+} and parathyroid hormone *(PTH)* and the Ca^{2+} set-point in healthy horses, human beings, and dogs. The Ca^{2+} set-point is the serum Ca^{2+} concentration at which serum parathyroid hormone concentrations are 50% of maximal during induction of hypocalcemia.[40] Horses have a sigmoidal relationship between serum Ca^{2+} and parathyroid hormone concentrations and a Ca^{2+} set-point (1.37 mmol/L) that is higher *(solid line)* than the set-point reported for human beings and dogs (1.0 to 1.2 mmol/L) *(dotted line)*.[39,40,128]



During development, the parathyroid glands III remain connected to the thymus and migrate caudally, whereas the parathyroid glands IV develop in relation to the thyroid gland and are more constant in their location.[46] In the horse the parathyroid glands IV (cranial or upper) usually are located in the fat craniodorsolaterally to the cranial pole of the thyroid gland and along the thyroid artery; however, they can be found in any location around the thyroid gland. In the author's experience, a few horses also may have parathyroid gland tissue embedded within the thyroid gland. One can locate the parathyroid glands III (lower, caudal) at the bifurcation of the bicarotid trunk, at the cranial pole of the thymus, or embedded in the thymus (young horses), and generally they are twice the size of the upper parathyroid glands.

The parathyroid gland consists of chief cells, oxyphil cells, and clear cells, which probably represent different morphologic and metabolic stages of the same parenchymal cells. These cells have a secretory cycle from inactivity under steady state conditions to an active secretory phase when extracellular Ca^{2+} concentrations are low.[47] Parathyroid chief cells have the ability to detect changes in extracellular Ca^{2+} concentrations by a calcium-sensing system, which includes CaR and megalin/gp330 (a glycoprotein of the low-density-lipoprotein–receptor superfamily).[41,48,49]

18.1.3.1.2

Parathyroid Hormone Synthesis and Secretion

Parathyroid cells in human beings and animals store small amounts of preformed PTH and rapidly respond to changes in Ca^{2+} concentrations. Mammalian PTH is synthesized from a 115–amino acid preprohormone, and after enzymatic cleavage in the endoplasmic reticulum and in the Golgi apparatus, the mature hormone is a straight chain of 84 amino acids (intact PTH; molecular weight 9500 d in human beings and 9393 d in the horse). Other forms of PTH (amino- and carboxy-terminal peptides) can be found in circulation after cleavage in different organs.[47] Fifty percent to 90% of PTH immunoreactivity in blood is from carboxy-terminal fragments.[50–52]

The plasma half-life of PTH in different species is approximately 2 minutes[52–55]; however, equine PTH half-life has not been determined. The rapid metabolism of PTH, together with the rapid response of the parathyroid chief cells to changes in Ca^{2+} concentrations, ensures that PTH concentrations can adjust rapidly to changes in Ca^{2+}. Sixty percent to 70% of PTH is removed in the liver, around 25% by the kidneys (glomerular filtration) and the rest by other organs.[52,53,55] In the liver, Kuppfer's cells are responsible for PTH clearance and proteolysis (a major source of circulating carboxy-terminal fragments), whereas in the kidney, PTH is cleared by glomerular filtration and reabsorbed by the renal tubules for extensive degradation, so low amounts or no PTH appear in the urine.[53,55] The plasma half-life of amino-terminal fragments is shorter than the inactive carboxy-terminal fragments, and carboxy-terminal fragments particularly are degraded in the kidney, and renal diseases may result in accumulation of carboxy-terminal PTH fragments.[51]

The PTH gene is expressed almost exclusively by the parathyroid glands and is under the influence of extracellular Ca^{2+} concentrations and $1,25(OH)_2D_3$. Information on the role of vitamin D metabolites on equine parathyroid gland function and calcium regulation is limited, and additional studies are necessary. However, $1,25(OH)_2D_3$ is well accepted as decreasing PTH gene transcription and PTH messenger RNA expression.[56] This concept is important in understanding the role of the kidney in vitamin D synthesis and metabolism and in parathyroid gland physiology. In the chief cells, vitamin D binds to the vitamin D

receptor, which interacts with specific DNA sequences (vitamin D responsive elements) to decrease PTH gene transcription. Unlike vitamin D, the effects of Ca^{2+} concentrations regulating PTH secretion are not mediated by affecting gene transcription but rather by altering PTH mRNA stability.[57] In the horse the effect extracellular Ca^{2+} concentrations on PTH mRNA expression has not been evaluated in vivo; however, from in vitro studies the author has found that low extracellular Ca^{2+} concentrations increase PTH mRNA expression in equine parathyroid chief cells.[58] 1303

1304

18.1.3.1.3 Physiologic Actions of Parathyroid Hormone

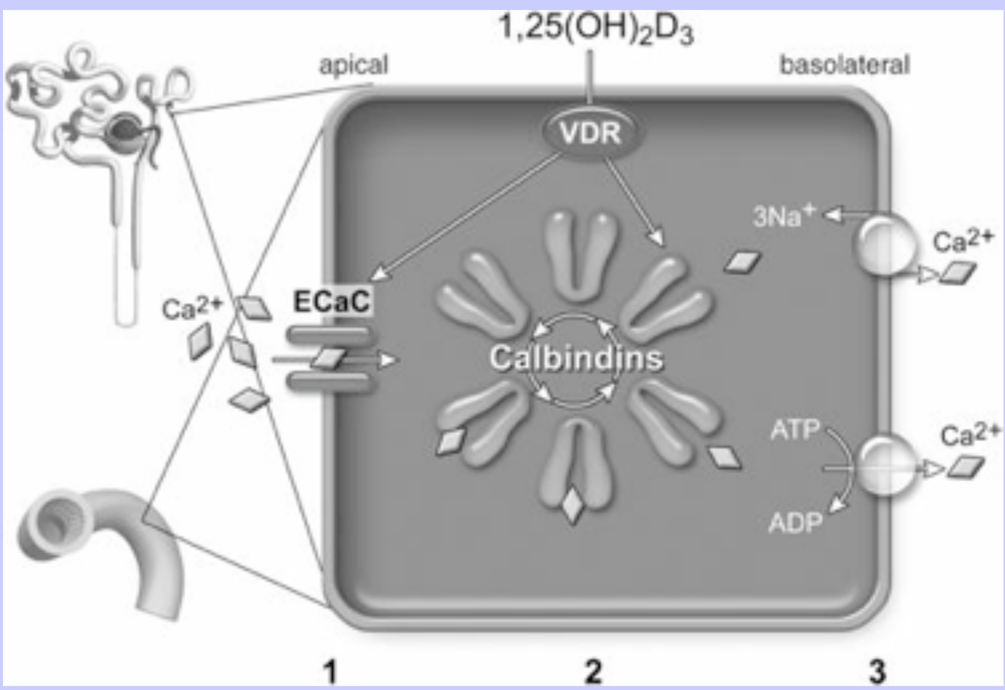
18.1.3.1.3.1 Kidney

The kidney is considered the major target organ for PTH. In the kidney, PTH regulates Ca^{2+} and phosphate reabsorption and $1,25(OH)_2D_3$ synthesis. These effects are mediated by the PTH-1 receptor, which is distributed widely in different segments of the nephron.[59] The PTH-1 receptor is coupled to G proteins, activating adenylate cyclase and increasing intracellular cyclic adenosine monophosphate (cAMP). Parathyroid hormone also activates phospholipases (A_2, C, D), protein kinase A, and protein kinase C.[59,60] The activation of any of these pathways depends on which segment of the nephron PTH is acting.

18.1.3.1.3.1.1 Effect on Ca^{2+} and Mg^{2+} Reabsorption.

Sixty percent of the filtered calcium and 20% of the filtered magnesium have been estimated to be reabsorbed in the proximal tubules. The reabsortion process in the proximal convoluted tubules is passive and is driven by the luminal positive voltage and the increased luminal concentrations of Ca^{2+} and Mg^{2+}.[61,62] In the proximal convoluted tubules, Ca^{2+} and Mg^{2+} reabsorption is paracellular, and the difference between Ca^{2+} and Mg^{2+} reabsorption in this segment of the nephron results from differential permeability. In the cortical thick ascending loop of Henle, Ca^{2+} and Mg^{2+} transport is also passive, but permeability is greater for Mg^{2+} (60% for Mg^{2+} versus 20% for Ca^{2+}). The lumen in the cortical thick ascending loop of Henle is positively charged, and the driving force for Ca^{2+} and Mg^{2+} reabsorption is the transepithelial voltage gradient generated by the $Na^+/K^+/2Cl^-$ cotransporter.[63] The effects of PTH on Ca^{2+} reabsorption in the cortical thick ascending loop of Henle are not completely clear, but apparently PTH increases the transepithelial voltage gradient, enhancing paracellular calcium transport.[62] Paracellin-1 is one of the newly discovered proteins that mediate the passive paracellular permeability of Ca^{2+} and Mg^{2+} in the cortical thick ascending loop of Henle.[64] The major site for PTH-regulated Ca^{2+} transport is in the distal convoluted tubules of the nephron, in which the effects of PTH on transepithelial (transcellular) calcium transport are mediated by epithelial calcium channels (Figure 18.1-6).[65,66]

Figure 18.1-6 Schematic representation of the epithelial calcium channel and the transcellular transport of calcium in the small intestine and kidney. The transcellular transport of Ca^{2+} is considered a three-step process in which calcium *(1)* enters the cell passively, *(2)* diffuses through the cytosol facilitated by calcium-binding proteins (calbindins), and *(3)* is extruded at the basolateral membrane by a Ca^{2+}-ATPase and a Na^{+}/Ca^{2+} exchanger. $1,25(OH)_2D$ increases all three steps of transepithelial calcium transport. (Adapted from Hoenderop JG, Willems PH, Bindels RJ: Toward a comprehensive molecular model of active calcium reabsorption, *Am J Physiol Renal Physiol* 278:F352-F360, 2000.)



Reabsorption of Ca^{2+} and Mg^{2+} in the kidney also is regulated by PTH-independent mechanisms that depend on the activation of the CaR in the basolateral membrane of the loop of Henle.

18.1.3.1.3.1.2 Effects on Phosphorus.

The effect of PTH on renal phosphate handling has been known for some time. By increasing bone resorption and by increasing $1,25(OH)_2D_3$ synthesis, PTH also increases plasma phosphate concentrations. To avoid high phosphate concentrations that may interact with Ca^{2+} to form insoluble precipitates and decrease Ca^{2+} concentrations, PTH decreases phosphate reabsorption in the kidney 1304
and therefore increases phosphate elimination. The movement of phosphate (P_i) in the proximal 1305
tubule occurs against an electrochemical gradient (negative inside the cell) and is mediated by Na^+/P_i cotransporters driven by the transcellular Na^+ gradient. Parathyroid hormone lowers Na^+ and P_i cotransport across the brush border in the proximal convoluted tubule, apparently by inducing degradation of the Na^+/P_i cotransporters.[67,68] The end result is decreased P_i reabsorption and increased fractional urinary clearance of P_i.

18.1.3.1.3.1.3 Effects on Vitamin D Metabolism.

PTH increases the synthesis of $1,25(OH)_2D_3$ by increasing gene expression and synthesis of 1α-hydroxylase and by decreasing synthesis of 24-hydroxylase. These effects are mediated by cAMP.[59]

18.1.3.1.3.1.4 Other Functions.

Parathyroid hormone also has functions associated with Na^+ and H^+ excretion in that it induces natriuresis and diuresis and inhibits $HCO^-{}_3$ reabsorption. These actions result from inhibition of Na^+/P_i cotransporters, Na^+/H^+ apical exchangers, and basolateral Na^+,K^+-ATPase.[59] Most of the effects of PTH in the proximal tubules are mediated by an increase in intracellular cAMP levels.

18.1.3.1.3.2 Bone

The bone is an active organ in a continuous process of bone resorption and bone formation. In bone, Ca^{2+} is exchanged between the extracellular fluid and the bone fluid, which is a Ca^{2+}-rich medium in equilibrium with the bone surface.[33] The bone membrane represents the lining cells that cover the bone surface and separates the bone fluid from the extracellular fluid.[69,70] Movement of Ca^{2+} across these compartments is regulated by several factors, including PTH.

The osteoclasts are multinucleated cells of hematopoietic origin (monocyte/macrophage lineage) responsible for bone resorption, whereas the osteoblasts are derived from bone marrow stromal cells and are responsible for bone formation. In adult vertebrates the process of bone resorption is in equilibrium with bone formation. In growing animals, bone formation exceeds bone resorption, whereas in old animals and human beings the opposite occurs. The effect of PTH increasing bone resorption has been known for some time; however, bone biologists were intrigued that osteoclasts, despite lacking PTH receptors, were the effectors of bone resorption. One of the earliest findings that elucidated this question was the discovery of PTH receptors in osteoblasts (Figure 18.1-7). For osteoclasts to be active they must be recruited, and this process requires the presence of osteoblasts and direct osteoblast-to-osteoclast

contact. The osteoblast-dependency for bone resorption led to the discovery of factors secreted by osteoblasts that are important in inducing osteoclast differentiation and activity.[71] Osteoblasts secrete macrophage colony-stimulating factor (M-CSF) and receptor activator of NF-κβ (RANK) ligand (RANKL),[72] with RANKL also being known as osteoprotegerin ligand and TNF-related activation-induced cytokine (TRANCE).[71] These two factors (M-CSF and RANKL) are essential for osteoclast function. Osteoclasts express RANK, which is a transmembrane receptor for RANKL, and the interaction of RANKL with RANK, and M-CSF with its specific receptor results in osteoclast recruitment and activation. To keep a balance between bone formation and bone resorption, the osteoblasts also release osteoprotegerin, which is a soluble decoy receptor for RANKL, interfering with RANKL action on the osteoclasts.[73]

Factors that can stimulate osteoclast differentiation include PTH, $1,25(OH)_2D_3$, and interleukin-11 (IL-11). Inflammatory cytokines such as IL-1 and tumor necrosis factor α may be important factors in osteoclast activation during inflammatory bone disease.[74] Prostaglandin E_2 stimulates bone resorption through a direct effect on hemopoietic precursors, inducing osteoclastic differentiation. The interaction of PTH (and PTHrP) with PTH receptors in the osteoblasts results in increased synthesis and release of RANKL and M-CSF into the bone microenvironment. Subsequently, the cell-to-cell contact together with RANKL and M-CSF release activates osteoclasts, resulting in PTH-induced bone resorption.

Serum markers of bone formation measured in horses include osteocalcin, the N-terminal extension peptide of type I procollagen, and bone-specific alkaline phosphatase.[75–77] Serum markers of bone resorption include the cross-linked carboxy-terminal telopeptide of type I collagen and total deoxypyridinoline.[75,77]

18.1.3.1.3.3

Intestine

No PTH receptors are in the intestinal tract; however, PTH indirectly increases intestinal Ca^{2+} and phosphate absorption by increasing synthesis of $1,25(OH)_2D_3$ in the kidney.

18.1.3.2

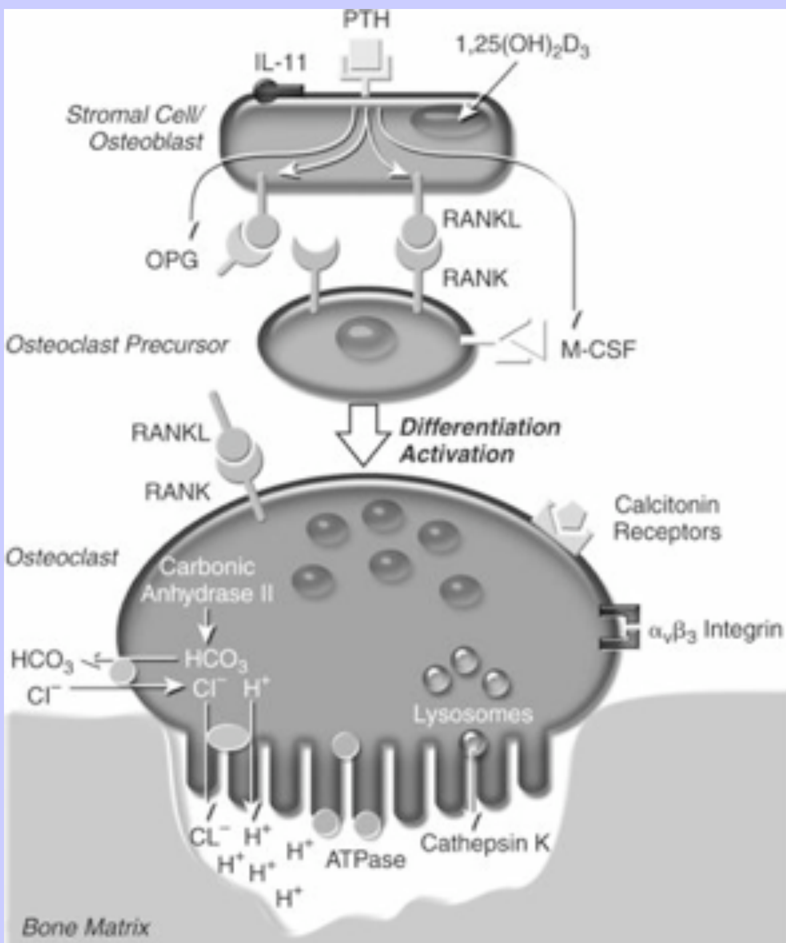
VITAMIN D

Vitamin D plays an important role in Ca^{2+} and phosphate homeostasis and to lesser extent probably in magnesium metabolism. Based on current knowledge of the physiology of vitamin D and its metabolites, vitamin D should be considered a hormone rather than a vitamin; nutritional supplementation is not required with sufficient exposure to sunlight.

The recognition by Mellanby[78] that a fat-soluble nutritional factor was associated with rickets was a major breakthrough in understanding calcium and phosphorus metabolism and bone biology. Additional studies on antirachitic substances led to the discovery of vitamin D_2 (ergocalciferol) and vitamin D_3 (cholecalciferol). These substances are secosterols derived from photolytic cleavage of the B rings of ergosterol (plants and 1305
yeasts) and 7-dehydrocholesterol (animals), respectively. The major circulating form of vitamin D in 1306
mammalians is 25-hydroxyvitamin D_3 ($25[OH]D_3$, calcidiol), which is produced primarily in the liver.[79] Soon after the discovery of $25(OH)D_3$ a new vitamin D_3 metabolite identified as 1,25-dihydroxyvitamin D_3 ($1,25[OH]D_3$, calcitriol) and mainly synthesized in the kidney was found to be the most active metabolite.[80]

The other major breakthrough in vitamin D physiology was the discovery of the vitamin D receptor.[81] Considerable analysis of this receptor revealed that unlike other hormone receptors, the vitamin D receptor is also a transcription factor. The vitamin D receptor was found initially in vitamin D target organs (intestines, bones, kidneys, parathyroid glands); however, vitamin D receptor expression also was found nontraditional target organs. Subsequently, other biologic functions for vitamin D have been described (immunomodulation, control of cell growth and differentiation), and this understanding has created new therapeutic approaches for using vitamin D and its derivatives for a variety of disorders (leukemia, hyperparathyroidism, autoimmune diseases). In veterinary medicine, the use of vitamin D metabolites is being considered for antiproliferative therapy in small animals.

Figure 18.1-7 Schematic representation of the cellular interactions responsible for osteoclastic activation and bone resorption. Factors that stimulate osteoclast differentiation include parathyroid hormone *(PTH)*, 1,25$(OH)_2$D, and interleukin-11 *(IL-11)*. Calcitonin inhibits osteoclastic activity. Osteoclast recruitment requires direct osteoblast-to-osteoclast contact. Osteoblasts secrete macrophage colony-stimulating factor *(M-CSF)* and receptor activator of NF-κβ *(RANK)* ligand *(RANKL)*. Osteoclasts express RANK, which is a transmembrane receptor for RANKL. Osteoblasts also release osteoprotegerin *(OPG)*, which is a soluble decoy receptor for RANKL. (Adapted from Rodan GA, Martin TJ: Therapeutic approaches to bone diseases, *Science* 289:1508-1514, 2000.)



18.1.3.2.1 Metabolism of Vitamin D

Vitamin D derives from dietary sources (vitamin D_2 comes from yeasts and plants and vitamin D_3 from animal-derived diets) and from activation of 7-dehydrocholesterol. In mammals, vitamin D_3 in produced in the skin by ultraviolet light (290 to 315 nm) photolytic cleavage of 7-dehydrocholecalciferol, producing 1306
previtamin D_3, which after thermal isomerization forms vitamin D_3.[82] From the skin, vitamin D_3 is 1307
translocated to the bloodstream by a vitamin D–binding protein. The next step in the formation of active vitamin D_3 is the hydroxylation of carbon 25, which occurs primarily in the liver, although other organs also may activate vitamin D_3 into 25-hydroxyvitamin D_3 [25(OH)D_3]. This reaction is catalyzed by microsomal and mitochondrial mixed function P-450 oxidases, also known as D-25-hydroxylases. The conversion of vitamin D_3 into 25(OH)D_3 is a poorly regulated reaction, and therefore plasma concentrations of 25(OH)D_3 are considered an indicator of the vitamin D status.

25-Hydroxyvitamin D_3 is transported in blood bound to vitamin D–binding protein, and at normal plasma concentrations this metabolite is considered to be inactive. The active metabolite of vitamin D_3, 1,25-dihydroxyvitamin D_3 (1,25[OH]$_2D_3$) is produced in the kidney by another cytochromone P-450 mixed-function oxidase, 25(OH)D-1α-hydroxylase (1α-hydroxylase). Under physiologic conditions the kidney is considered the main site for 1,25(OH)$_2D_3$ synthesis, although other organs (placenta, skin, monocytes) have 1α-hydroxylase activity. Unlike 25-hydroxylase, 1α-hydroxylase is a tightly regulated enzyme. Mutations of the 1α-hydroxylase gene in human beings and laboratory animals results in vitamin D-dependent type I rickets.[83] 25-Hydroxyvitamin D_2 is metabolized in the same pathways just described to produce 1,25(OH)$_2D_2$. The author will refer to both vitamin D active metabolites, 1,25(OH)$_2D_2$ and 1,25(OH)$_2D_3$, as 1,25-dihydroxyvitamin D (1,25[OH]$_2$D). In blood, 1,25(OH)$_2$D concentrations are one thousandth the concentrations of 25(OH)D. The half-life of 25(OH)D is measured in weeks, whereas the half-life of 1,25(OH)$_2$D is measured in few hours.

An alternative pathway in the metabolism of 25(OH)D and 1,25(OH)$_2$D is the 24-hydroxylation by a 25(OH)D-24-hydroxylase, which is the major catabolic enzyme in the kidney and other tissues (intestine, cartilage, bone, liver) to form the inactive metabolites 24,25-dihydroxyvitamin D (24,25[OH]$_2$D) and 1,24,25-trihydroxyvitamin D. Although a receptor for 24,25(OH)$_2$D has not been identified and this metabolite may play a physiologic role,[84] its function remains unclear.

Parathyroid hormone and hypophosphatemia induce 1α-hydroxylase activity in the kidney, whereas increased Ca^{2+} concentrations and 1,25(OH)$_2$D inhibit 1α-hydroxylase and stimulate 24-hydroxylase, making this an effective self-regulatory mechanism. The synthesis of 1,25(OH)$_2$D in other tissues is not regulated in the same manner or related to calcium homeostasis.

18.1.3.2.2 Transport of Vitamin D

Vitamin D and its metabolites are lipophilic compounds that are bound to specific plasma binding proteins, vitamin D–binding protein being the most important. Vitamin D–binding protein is synthesized in the liver and is related structurally to albumin and α-fetoprotein. The affinity of vitamin D–binding protein for vitamin D metabolites is as follows: 25(OH)D = 24,25(OH) = 25,26(OH)$_2$D > 1,25(OH)$_2$D > vitamin D.[85]

The affinity of vitamin D–binding protein for different vitamin D_2 and D_3 seems to be similar in mammals, whereas in birds, vitamin D–binding protein binds vitamin D_3 with 100 more times affinity than vitamin D_2. Because on the molar basis vitamin D–binding protein concentrations are 20 times greater than those of vitamin D metabolites, approximately 5% of the vitamin D–binding protein is occupied by vitamin D metabolites, and nearly all vitamin D is protein bound.[86] Furthermore, vitamin D–binding protein seems to be important to extend the plasma half-life of vitamin D.[87] The free, unbound vitamin D is the one that exhibits biologic activity, and in addition to buffer and transport vitamin D metabolites, vitamin D–binding protein has been proposed also to have a protective effect against vitamin D intoxication.[88] Vitamin D–binding proteins bound to vitamin D metabolites are filtered in the renal glomerulus and reabsorbed in the proximal tubular cells by an endocytic receptor (megalin). This receptor 1307
also is expressed in other cells (parathyroid gland and placenta), where it may have calcium-sensing 1308
properties.[48] The vitamin D–binding protein/megalin pathway seems to be important in vitamin D recycling and 25(OH)D activation by 1α-hydroxylase. Vitamin D metabolites also bind to albumin and lipoproteins with lesser affinity than vitamin D–binding protein; however, lipoproteins seem to be more important and efficient in transporting vitamin D_3 from the skin to the liver for 25-hydroxylation.

18.1.3.2.3 Regulation of Vitamin D Metabolism

Extracellular Ca^{2+} and phosphorus concentrations. control the metabolism of $1,25(OH)_2D$. These actions are mediated through organs involved in mineral metabolism (kidneys, intestines, bones, parathyroid glands). Blood concentrations of $1,25(OH)_2D$ are regulated by PTH, Ca^{2+}, phosphorus, and $1,25(OH)_2D$. The role of calcitonin on the vitamin D metabolism remains unclear.

18.1.3.2.3.1 Parathyroid Hormone

Low extracellular Ca^{2+} concentrations stimulate PTH release from the parathyroid gland. Subsequently, PTH interacts with PTH-specific receptors on the proximal tubular cells, increasing 1α-hydroxylase and suppressing 24-hydroxylase activities. The end result is increased $1,25(OH)_2D$ release from increased synthesis and decreased catabolism. These are indirect effects of extracellular Ca^{2+} on $1,25(OH)_2D$ synthesis.

18.1.3.2.3.2 Calcium

In addition to its indirect effects on $1,25(OH)_2D$ synthesis (via PTH), Ca^{2+} also has direct effects on $1,25(OH)_2D$ synthesis and metabolism that are mediated by a direct interaction of Ca^{2+} with the renal calcium-sensing receptors. Hypocalcemia stimulates and hypercalcemia suppresses 1α-hydroxylase synthesis.

18.1.3.2.3.3 Phosphate

Hypophosphatemia results in increased $1,25(OH)_2D$ concentrations in the blood by increasing 1α-hydroxylase activity in the kidney. The mechanism by which phosphate controls $1,25(OH)_2D$ synthesis is independent of PTH secretion. The effects of phosphate on $1,25(OH)_2D$ synthesis recently have been

found to be mediated by a type IIa sodium/phosphate cotransporter (NPT2); low phosphate directly stimulates 1α-hydroxylase synthesis and decreases 24-hydroxylase synthesis.[89]

18.1.3.2.3.4

1,25$(OH)_2$D

The synthesis of 1,25$(OH)_2$D is an autoregulatory mechanism. 1,25$(OH)_2$D exhibits effects at the level of gene expression; high 1,25$(OH)_2$D concentration decreases 1α-hydroxylase and increases 24-hydroxylase gene expression and protein synthesis. This mechanism seems to be the most important regulatory mechanisms in 1,25$(OH)_2$D synthesis when the daily intake of calcium and phosphate is adequate.

18.1.3.2.3.5

Calcitonin

The importance of calcitonin on vitamin D is unclear. Calcitonin is known to stimulate 1α-hydroxylase, inhibit phosphate reabsorption, and inhibit Ca^{2+} reabsorption. These functions are not known in the horse, and too many differences exist among species to draw any conclusions.

18.1.3.2.4

Actions of Vitamin D

Most of the biologic actions of vitamin D result from its active metabolite, 1,25$(OH)_2$D, which is important in Ca^{2+} and phosphate homeostasis. The most important function of 1,25$(OH)_2$D in Ca^{2+} metabolism is considered to be stimulation of intestinal Ca^{2+} and phosphate absorption, Ca^{2+} in the duodenum and phosphate in the jejunum and ileum. In the horse this is unclear. The actions of vitamin D are mediated by a specific receptor (vitamin D receptor) that acts as a transcription factor, controlling gene expression. Once 1,25$(OH)_2$D is bound to the vitamin D receptor, the vitamin D receptor forms a heterodimer with the retinoid acid receptor. This heterodimer binds to specific DNA sequences or vitamin D response elements, recruiting a series of transcription factors to regulate gene expression. The vitamin D receptor has been cloned in several species but not in the horse, and its control, expression, and regulation in the equine species is being evaluated currently in the author's laboratory. The vitamin D receptor is found in vitamin D target organs (intestines, bones, kidneys, parathyroid glands) and in other organs not involved in Ca^{2+} homeostasis, such as the skin, pancreas, immune system, and reproductive organs.[86]

In the intestine, as in the kidney and placenta, transepithelial Ca^{2+} transport is considered a three-step process in which calcium (1) enters the cell passively, (2) diffuses through the cytosol facilitated by calcium-binding proteins (calbindins), and (3) is extruded at the basolateral membrane calcium by a Ca^{2+}-ATPase and a Na^+/Ca^{2+} exchanger (see Figure 18.1-6.).[90,91] In the small intestine (duodenum), 1,25$(OH)_2$D increases all three steps of transepithelial calcium transport. Vitamin D increases expression of calbindins (calbindin D_{9k}) and the activity of other proteins (i.e., alkaline phosphatase, calmodulin, Ca^{2+}-ATPase) that may be important in calcium absorption. The recent discovery of an apical epithelial calcium channel (epithelial calcium channels) in 1,25$(OH)_2$D-responsive cells in the small intestine, kidney, and placenta[65,66] has provided significant understanding on the mechanism of calcium entry into epithelial cells, for until recently how calcium entered epithelial cells was unclear. The epithelial calcium channel is not a voltage-gated calcium channel; however, it is distributed in the same epithelial cells that

express calbindin and may be regulated by 1,25(OH)$_2$D. Furthermore, epithelial calcium channels have been proposed to be the gate-keeper for 1,25(OH)$_2$D-dependent transepithelial calcium transport.[65,92] In addition to its effects on intestinal calcium transport, 1,25(OH)$_2$D increases phosphate transport. These effects are mediated by 1,25(OH)$_2$D direct stimulation of the Na^+/P_i cotransporter.

Recent evidence indicates a rapid and nongenomic action of vitamin D on intestinal calcium transport. This effect is mediated by a vitamin D membrane receptor, which is an exception to the traditional understanding of steroid hormone action.[93] This nongenomic action of 1,25(OH)$_2$D on intestinal calcium absorption results in vesicular and paracellular calcium transport.

In the kidney, perhaps the most important effect of 1,25(OH)$_2$D is the suppression of 1α-hydroxylase and the stimulation of 24-hydroxylase gene expression and synthesis. In addition, 1,25(OH)$_2$D stimulates renal $^{2+}$ reabsorption by increasing the expression of calbindins (calbindin D$_{9k}$, calbindin D$_{28k}$) in the distal convoluted tubules of the nephron, which is the site with the highest vitamin D receptor concentration and where active transport of calcium occurs.[86] Horses have high concentrations of vitamin D receptor in the distal convoluted tubules of the nephron and collecting tubules (unpublished information). In the distal convoluted tubules of the nephron, epithelial calcium channels are distributed in the same cells with calbindin activity. The effect of 1,25(OH)$_2$D on renal phosphate tubular transport is considered to be minimum and mostly results from the suppressive effect of 1,25(OH)$_2$D on PTH synthesis and secretion. In addition, 1,25(OH)$_2$D increases Mg^{2+} reabsorption in the distal convoluted tubules of the nephron through gene activation and protein synthesis.[94]

In bone, 1,25(OH)$_2$D is an important hormone for skeletal development and bone mineralization. An 1308
example of vitamin D deficiency is rickets in young animals and osteomalacia in adult animals and human 1309
beings. The existence of rickets in the horse is controversial and remains to be documented. 1,25(OH)$_2$D induces bone matrix synthesis and mineralization by increasing blood concentrations of Ca^{2+} and phosphorus. In addition, 1,25(OH)$_2$D induces osteoclastogenic activity and bone resorption, which may be important to maintain normocalcemia and normophosphatemia. However, PTH is more important in bone resorption than vitamin D.

In the parathyroid gland, PTH synthesis is regulated negatively by 1,25(OH)$_2$D. Parathyroid hormone increases 1α-hydroxylase activity in the kidney, increasing plasma concentrations of 1,25(OH)$_2$D, which then inhibits PTH gene expression and synthesis and controls parathyroid gland chief cell growth and differentiation.[95] This mechanism is part of the rationale for the development of parathyroid hyperplasia in human beings and animals with chronic renal failure and vitamin D deficiency. As previously mentioned, the effects of vitamin D on parathyroid cell function are mediated through the vitamin D receptor. In the horse, what the direct effect of vitamin D metabolites is on parathyroid gland function is not known, although one may reasonably accept that the effect is similar to that in other species. The author's findings of abundant expression of the vitamin D receptor in the equine parathyroid gland support this postulation.

Vitamin D has other nonclassical functions. Anemia, predisposition to infections from impaired immune system, skeletal muscle weakness, cardiomegaly, pancreatic glucose-mediated insulin secretion, and infertility are among conditions reported with vitamin D deficiency.[86] Vitamin D is important in skin and hair development and in cell proliferation and differentiation, and significant efforts have been made in the

last few years to develop and use vitamin D analogs that have minimal or no effect on calcium metabolism but that retain their antiproliferative and prodifferentiation properties. These drugs are being used to treat different pathologic conditions in human beings (seborrhea, psoriasis, secondary hyperparathyroidism) to reduce cell proliferation in cancer (breast cancer, prostate cancer, leukemia).[86]

18.1.3.2.5

Vitamin D Metabolism in the Horse

The amount of information on vitamin D in the horse is limited compared with other species. However, an important point is that horses have unique features regarding calcium metabolism, including high serum total and ionized calcium concentrations, high urinary fractional clearance of calcium, a high Ca^{2+} set-point, and low serum concentrations of vitamin D metabolites (25[OH]$_2$D and 1,25[OH]$_2$D).[4,58,96–103] Intestinal absorption of Ca^{2+} in the horse also apparently is a poorly controlled mechanism.[12,96] As mentioned previously, 25(OH)D concentrations are considered an indicator of vitamin D status. Plasma concentrations of 25(OH)D in the horse are approximately one tenth the plasma concentrations of 25(OH)D in other species.[100–102] In human beings and in most domestic animals, plasma concentrations of 25(OH)D range from 50 to 100 nmol/L,[97] with minimal differences between young animals and adults,[98] and a plasma 25(OH)D concentration less than 40 nmol/L indicates vitamin D deficiency. In contrast, in the horse plasma concentrations of 25(OH)D_3 of 5 to 10 nmol/L or less are normal.[100–102] Despite the low vitamin D concentrations, rickets or osteomalacia are not reported in horses.[104]

When the effect of vitamin D on growth and bone development of young horses was evaluated for a period of 5 months, horses with limited access to sunlight and fed a vitamin D-deficient diet were found to have decreased growth, discomfort while standing, and lower bone density. Of interest from that study is that none of these horses developed clinical evidence of rickets, supporting the concept that rickets may be a rare finding in the horse. The authors concluded that vitamin D supplementation of horses with limited sunlight exposure is necessary.[104] In northern latitudes for example, the synthesis of 1,25(OH)$_2$$D_3$ in human beings is low during winter because of limited exposure to sunlight. When serum concentrations of 25(OH)D_2 and 25(OH)D_3 were measured in horses located in Finland during the summer and winter, 25(OH)D_3 concentrations were found to be significantly lower during winter,[99,100] suggesting that the low vitamin D_3 concentrations in horses during winter may result from limited sunlight exposure (Table 18.1-7). The authors also found that 25(OH)D_2 concentrations were low during both seasons and showed no seasonal variation, which may have resulted from small amounts of vitamin D_2 in forages. A more recent study on vitamin D metabolism also found that plasma 25(OH)D and 1,25(OH)$_2$$D_3$ concentrations were low or undetectable in healthy horses and ponies compared with vitamin D metabolite concentrations from other species.[96] No difference in plasma 25(OH)D concentrations between horses and ponies was found. In the same study, renal 1α-hydroxylase activity could not be detected, but renal 24-hydroxylase activity was present. Likewise, in a preliminary study in the author's laboratory, 1α-hydroxylase mRNA expression in equine kidneys was not detected, suggesting that perhaps 1α-hydroxylase is downregulated by the high extracellular Ca^{2+} concentrations of the horse or by other unknown mechanisms or that 1α-hydroxylase is expressed minimally in the equine kidney. Possibly some of the 1,25(OH)$_2$$D_3$ present in equine plasma results from extrarenal 1α-hydroxylase activity, as occurs in human beings and animals after nephrectomy.

1309

TABLE 18.1-7 Normal Serum Concentrations of Calcium, Phosphorus, Magnesium, Vitamin D, and Parathyroid Hormone in Healthy Horses

SOLUTE	CONCENTRATION
Total calcium	11.1–13.0 mg/dl
Ionized calcium	6.0–7.0 mg/dl
Phosphorus	1.2–4.8 mg/dl
Total magnesium	0.53–0.91 mmol/L
Ionized magnesium	0.46–0.66 mmol/L
Parathyroid hormone	<4.0 pmol/L (<40 pg/ml)
Calcitonin	<40 pg/ml
25-Vitamin D_3	<2.0 ng/ml[102]
	4.7 ±1.0 ng/ml[102*]
	1.90 ± 0.23 ng/ml, winter[99]
	2.43 ± 0.09 ng/ml, summer[99]
	4.2 ± 0.34 μg/L, winter[100†]
	6.2 ± 0.36 μg/L, summer[100†]
	11.42 ± 3.26 ng/ml[103]
1,25 Vitamin D_3	18.6 ± 7.3 ng/L, winter[100*]
	18.7 ± 8.0 ng/L, summer[100*]
	55.0 ± 24.0 pmol/L[96]

Values from the chemistry laboratory at the College of Veterinary Medicine, The Ohio State University.

* D2 metabolite.

† Includes D_2 and D_3 metabolites.

18.1.3.3

CALCITONIN

Coalcitonin (thyrocalcitonin) is a 32–amino acid peptide that functions primarily to inhibit osteoclast function during hypercalcemia. Calcitonin is secreted by the parafollicular cells (C cells) of the thyroid gland. The C cells are of neuroendocrine origin and are derived from the ultimobranchial body (ventral portion of the fourth pharyngeal pouch, also considered by some as the fifth pharyngeal pouch) that during embryologic development is incorporated into the thyroid gland.[43] Calcitonin structure is known in several species, and the author and colleagues recently cloned equine calcitonin.[105] Equine calcitonin has 90% homology with human calcitonin. Several factors control secretion of calcitonin, Ca^{2+} perhaps being the most

important. The C cells of the thyroid gland sense changes in extracellular Ca^{2+} concentrations by the same calcium-sensing receptor expressed in parathyroid chief cells and renal tubular cells.[106] Calcitonin interacts with calcitonin-specific receptors in osteoclasts and renal tubular cells, increasing cytosolic cAMP and $Ca^{2+}{}_i$ concentrations, and activating the inositol phosphate signaling pathway.

Calcitonin decreases plasma concentrations of Ca^{2+} and phosphorus by inhibiting osteoclastic bone resorption and to lesser extend by increasing urinary excretion of Ca^{2+} and phosphorus. Calcitonin also stimulates renal 1α-hydroxylase activity. Despite these effects on Ca^{2+} and phosphorus metabolism, the importance of calcitonin on mammalian Ca^{2+} homeostasis has not been established. Calcitonin is considered by some as a hormone "in search of a function." This has been demonstrated in human beings in which a minimal or no increase in plasma Ca^{2+} concentrations occurs after thyroidectomy.[2] Furthermore, some authors have concluded that calcitonin may be important in extreme hypercalcemia, but in the day-to-day Ca^{2+} variations, calcitonin may not play a relevant role.[2,107] Increases in serum calcitonin concentrations after eating suggests that calcitonin may be important in controlling postprandial increases in plasma Ca^{2+} concentrations. Gastrin, glucagons, and increases in Ca^{2+} concentrations appear to mediate the calcitonin release.

Unlike in terrestrial vertebrates, no doubt exists that calcitonin plays an important role in regulating Ca^{2+} concentrations in saltwater fish, where the ambient calcium concentrations are high (10 m*M;* 40 mg/dl). Few studies have evaluated calcitonin in the horse.[108–111] In an immunohistochemistry study, antibodies to human calcitonin cross-reacted with equine calcitonin.[108] Equine osteoclasts respond to calcitonin stimulation.[109] Serum concentrations of calcitonin in horses have been measured using human calcitonin radioimmunoassays.[112] However, defining the normal range of calcitonin is a downside of these studies. Serum calcitonin concentrations in horses have been evaluated using different human calcitonin immunoassays, resulting in a wide range of values among healthy horses (from undetectable to 40 pg/ml). Administration of calcium gluconate to healthy horses resulted in increased serum calcitonin concentrations but not of the same magnitude as reported in human beings.

18.1.3.4 PARATHYROID HORMONE–RELATED PROTEIN

The discovery of PTHrP in human beings with humoral hypercalcemia of malignancy (HHM)[34] was an important step in understanding Ca^{2+} homeostasis in health and disease. Parathyroid hormone and PTHrP share homology in their first 13 amino acids and act through the same receptor (PTH-1 receptor). In contrast to PTH, PTHrP is produced by almost every tissue in the body and has a broad range of functions, most of which have little to do with Ca^{2+} homeostasis.[33,35] Under physiologic conditions, PTHrP functions are considered to be paracrine, autocrine, and intracrine (inside the cell). For most part the endocrine functions of PTHrP are considered pathologic (HHM); PTHrP may be an important endocrine Ca^{2+}-regulating factor in the fetus. Three different isoforms of PTHrP have been identified in human beings,[35] but only one has been identified in the horse.[113] Through its different regions, PTHrP has different functions; the amino-terminal peptide interacts with the PTH-1 receptor, initiating PTH-like actions (bone resorption, renal Ca^{2+} 1310
reabsorption); the midregion PTHrP is important for transepithelial and placental Ca^{2+} transport; and the 1311
carboxy-terminal (osteostatin) inhibits osteoclastic bone resorption.[35] The functions of PTHrP can be grouped as (1) stimulation of transepithelial Ca^{2+} transport (kidney, placenta, mammary gland); (2) smooth

muscle relaxation (gastrointestinal tract, uterus, bladder, blood vessels); and (3) regulation of cell proliferation, differentiation, and death. High concentrations of PTHrP (10,000-fold higher than plasma) are found in milk of lactating human beings and animals, including the mare.[114] Although the functions of PTHrP in milk are unclear, perhaps PTHrP is important for Ca^{2+} transport into the milk, and for intestinal Ca^{2+} absorption in the newborn.

Humoral hypercalcemia of malignancy is a paraneoplastic syndrome that results from excessive production and secretion of PTHrP by some tumors. By interacting with PTH-1 receptors, PTHrP promotes bone resorption and inhibits renal Ca^{2+} excretion, causing hypercalcemia in human beings and in different domestic animals, including the horse.[115–120]

18.1.3.5 CALCIUM-SENSING SYSTEM

Mammalians maintain their extracellular Ca^{2+} concentrations within a narrow limit. Within the cells, cytosolic free or ionized calcium ($Ca^{2+}{}_i$) acts as a second messenger and as an enzymatic cofactor, controlling cellular functions such as hormone secretion, muscular contraction, cell differentiation, cell motility, and cell death. Cytosolic calcium concentration is around 100 n*M,* which is more than 10,000-fold lower than extracellular Ca^{2+} concentrations (>1 m*M;* 1.5 m*M* in the horse). Because $Ca^{2+}{}_i$ has many intracellular functions, sustained high $Ca^{2+}{}_i$ may be deleterious for the cell: rapid (greater than tenfold) and short time increases can occur. In contrast, extracellular Ca^{2+} concentrations change minimally (a few percent). Extracellular Ca^{2+} also has a large number of functions (blood clotting, skeletal integrity, membrane excitability, cell adhesion); however, it does do not change rapidly as $Ca^{2+}{}_i$ does. To support such physiologic processes, Ca^{2+} requires a tight control. Movement of $^{2+}$ across the kidney and intestine and from the skeleton is controlled, and such movement is sensed by the parathyroid gland. The molecular basis by which parathyroid cells detect changes in Ca^{2+} concentrations was not clear until a CaR was cloned.[41] In addition to being a second intracellular messenger, Ca^{2+} acts as a hormone on specific Ca^{2+} receptors, and therefore extracellular Ca^{2+} also should be considered a first messenger.[121]

Organs involved in Ca^{2+} homeostasis (parathyroid gland, thyroid gland, and kidney) express CaR. The author and colleagues have cloned a CaR from equine parathyroid gland, thyroid gland, and the kidney. Equine CaR has 90% homology with the human and bovine CaR.[58] Activation of the CaR by high extracellular Ca^{2+} concentrations inhibits PTH secretion by the parathyroid cells and stimulates calcitonin secretion from the C cells of the thyroid gland.[58,122] In the horse, hypercalcemia induces calcitonin secretion, although work from the author's laboratory indicates that the magnitude of calcitonin release in response to hypercalcemia in the horse is minimal (unpublished).

Cation receptor signaling includes the activation of phospholipases C, A_2, and D. In the parathyroid cells, phospholipase C hydrolyzes phosphatidylinositol 4,5-biphosphate to diacylglycerol and IP_3.[123] Inositol 1,4,5-triphosphate interacts with specific receptors to release $Ca^{2+}{}_i$ from intracellular stores,[124] whereas diacylglycerol activates protein kinases.[123] In addition, increased Ca^{2+} concentrations inhibit intracellular cAMP accumulation by inhibiting adenylate cyclase.[125]

In the kidney, CaR is expressed in almost all segments of the nephron, with the highest receptor concentration in the cortical thick ascending loop of Henle,[126] where Ca^{2+} is reabsorbed in a regulated manner.[90] Cation receptor is also present in the distal convoluted tubules of the nephron, where Ca^{2+} reabsorption is also stimulated by PTH. One should note that in the kidney, CaR regulates Ca^{2+} and Mg^{2+} reabsorption independently of PTH actions. By interacting with CaR, Ca^{2+} (and to lesser extent Mg^{2+}) inhibits the $Na^+/K^+/2Cl^-$ transporter, reducing transepithelial voltage gradient and decreasing Ca^{2+} and Mg^{2+} reabsorption. In fact, the effect of Ca^{2+} is similar to the effect that loop diuretics (furosemide) have in the cortical thick ascending loop of Henle; that is, the inhibition of the $Na^+/K^+/2Cl^-$ cotransporter decreases reabsorption of Na^+, $^-$, K^+, Ca^{2+}, and Mg^{2+} and causes diuresis. High concentrations of Ca^{2+} exert a diuretic effect that may result in volume depletion, as reported in human beings with hypercalcemia.[63] Calcium gluconate or calcium chloride infusions to healthy horses result in diuresis and in a rapid decrease in urine specific gravity (unpublished). The opposite is also true regarding Ca^{2+} reabsorption; hypocalcemia results in less activation of the CaR and more paracellular Ca^{2+} transport. In addition, hypocalcemia also increases PTH secretion, which stimulates the activity of the $Na^+/K^+/2Cl^-$ cotransporter in the cortical thick ascending loop of Henle, increasing Ca^{2+} reabsorption. CaR also regulates Mg^{2+} reabsorption by modulating Na^+, K^+, and $^-$ reabsorption.[127] The author has found evidence for these mechanisms in the horse, in which infusion of calcium salts (gluconate or chloride) resulted in increased fractional clearance of Ca^{2+}, Mg^{2+}, Na^+, K^+, and $^-$; diuresis; and a significant decrease in urine specific gravity. Furthermore, increasing Ca^{2+} concentrations (>7 mg/dl) decreased serum Mg^{2+} concentrations in horses receiving infusions of calcium salts. 1311

The inhibitory effects of high Ca^{2+} (and Mg^{2+}) concentrations on Ca^{2+} and Mg^{2+} reabsorption are mediated 1312
by CaR receptors located in the basolateral membranes of the cortical thick ascending loop of Henle.[61]

18.1.4 Calcium Disorders in the Horse

Abnormal Ca^{2+} homeostasis in the horse is associated with hypocalcemic or hypercalcemic disorders. Horses have unique features regarding calcium metabolism including high serum total and ionized calcium concentrations,[4] a poorly regulated intestinal Ca^{2+} absorption,[12] high urinary fractional clearance of calcium,[4] low serum concentrations of vitamin D metabolites (1,25[OH]$_2$D, 25[OH]D),[96,99–101] and an increased Ca^{2+} set-point.[58,128] Some pathologic conditions of the horse characterized by abnormal calcium homeostasis include idiopathic hypocalcemia of foals,[129] hypoparathyroidism,[130,131] primary hyperparathyroidism,[132] nutritional secondary hyperparathyroidism,[133] hypercalcemia of malignancy,[116,117,120] vitamin D toxicity,[134] renal failure,[135] exercise-induced hypocalcemia,[36,136] and sepsis.[4,137,138] Table 18.1-7 presents normal calcium concentrations for horses.

18.1.4.1 HYPOCALCEMIA

Hypocalcemia in the horse develops from different conditions (Box 18.1-1), and the clinical signs associated with hypocalcemia result from increased neuromuscular excitability and decreased smooth muscle cell contractility (Box 18.1-2). The Ca^{2+} concentrations in the extracellular fluid affect the voltage at which the Na^+ channels in nerve fibers are activated. Calcium ions bind to Na^+ channels, decreasing Na^+ permeability

and increasing the voltage required for channel opening. Calcium then is considered a Na^+ antagonist. When Ca^{2+} decrease, the Na^+ channels are activated by smaller changes in the resting potential and the nerve fibers become highly excitable, even discharging spontaneously. Spontaneous and continuous discharges may result in muscle fasciculation, tremors, and tetany. Tachycardia and cardiac arrhythmias may be present during hypocalcemia, although bradycardia may develop during severe hypocalcemia, probably from decreased cardiac muscle contractility.

18.1.4.1.1

Synchronous Diaphragmatic Flutter

Synchronous diaphragmatic flutter (SDF) or "thumbs" has been reported in horses with gastrointestinal disease,[4,139] lactation tetany (eclampsia),[140] after transport, with thoracic hematoma,[141] blister beetle toxicosis,[142] urethral obstruction,[143] endurance exercise,[144] primary hypoparathyroidism,[131,145] idiopathic hypocalcemia,[129] and sepsis.[4] Any horse with hypocalcemia potentially can develop SDF. The condition is frequent in horses after prolonged exercise in which significant amounts of electrolytes (Ca^{2+}, Na^+, K^+, Mg^{2+}, $^-$) are lost in the sweat.[146,147] In the case of SDF, depolarization of the right atrium stimulates action potentials in the phrenic nerve as it crosses over the heart. Clinically, a rhythmic movement on the flank results from diaphragmatic contractions that are synchronous with the heartbeat.

18.1.4.1.1.1

BOX 18.1-1 CLINICAL CONDITIONS IN THE HORSE IN WHICH HYPOCALCEMIA HAS BEEN REPORTED

Acute renal failure

After endurance exercise

Cantharidin toxicosis

Chronic renal failure

Colic

During lactation (lactation tetany)

During transport (transit tetany)

Dystocia

Endotoxemia

Enterocolitis

Excessive administration of $NaHCO_3$

Hypomagnesemia

Late pregnancy

Liver disease

Magnesium toxicosis

Malignant hyperthermia

Oxalate ingestion

Pancreatitis

Pleuropneumonia

Postoperative myopathy

Primary hypoparathyroidism

Retained placenta

Rhabdomyolysis

Sepsis

During alkalosis, Ca^{2+} binding to plasma anions increases, in particular to albumin, resulting in ionized hypocalcemia. Exercising horses may develop alkalosis from hyperventilation (respiratory alkalosis) and from chloride losses in sweat (metabolic hypochloremic alkalosis),[141] and the alkalosis rather than the nature of the alkalosis is what contributes to ionized hypocalcemia and SDF. Serum ionized magnesium (Mg^{2+}) concentrations may be decreased in some horses with SDF, and as in hypocalcemia, hypomagnesemia also may increase neuromuscular excitability. Some of the mechanisms responsible for hypomagnesemia are similar to those causing hypocalcemia. One always should include hypomagnesemia in the differential diagnosis of hypocalcemia. 1312

18.1.4.1.2

Hypocalcemic Tetany

Low Ca^{2+} concentrations increase cell membrane excitability. Some horses develop excessive and sustained skeletal muscular contractions or tetany. Lactation tetany occurs in mares from 2 weeks before foaling up to few days after weaning. The predisposing cause of lactation tetany is the calcium losses in milk. Mares producing large amounts of milk, eating a low-calcium ration or grazing lush pastures, and performing physical work (Draft mares) are more at risk. Some horses transported for long distances may develop hypocalcemia and transit tetany.[140] Hypocalcemic tetany can occur in any horse with hypocalcemia. Clinical signs may include anxiety, depression, ataxia, stiff gait, muscle fasciculations and tremors, tachypnea with flared nostrils, dyspnea, dysphagia, hypersalivation, and hyperhidrosis (see Box 18.1-2.).

18.1.4.1.3 Hypocalcemic Seizures

As with the peripheral nerves, decreased extracellular ${}^{2+}$ concentrations in the central nervous system may increase neuroexcitability. Hypocalcemic seizures have been reported in foals with idiopathic hypocalcemia and sepsis of unknown origin.[129] Clinical signs usually improve with calcium treatment, although some foals may require repeated treatments with calcium salts. Horses with hypocalcemic seizures have a poor prognosis for recovery.

18.1.4.1.4 Ileus

Smooth muscle cells have more voltage-gated Ca^{2+} channels and fewer voltage-gated Na^{+} channels than skeletal muscle fibers, and therefore Na^{+} is less important in the action potential. For this reason contractions are slower and prolonged (Ca^{2+} channels are slow channels). In skeletal muscle, almost all calcium ions required for contraction come from the sarcoplasmic reticulum. In contrast, in smooth muscle cells the sarcoplasmic reticulum is a rudimentary organelle and the cells depend on extracellular Ca^{2+} for contraction. For this particular reason, any pathologic condition that results in ionized hypocalcemia may affect smooth muscle contractility. This effect is evident in horses that develop ileus following hypocalcemia (after exercise, transport, sepsis). Horses with primary gastrointestinal disease (colic) may develop ileus from increased concentrations of inflammatory and pain mediators (from sepsis and endotoxemia) that affect gastrointestinal motility; however, in some of these horses the ileus may result from hypocalcemia. Treatment with calcium gluconate may restore gastrointestinal motility.

18.1.4.1.5 Retained Placenta

Incidence of retained placenta in mares has been reported to occur in up to 10% of foalings.[148] Low serum total and ionized calcium concentrations often occur in mares with retained placenta and in mares with acute endometritis. Decreased uterine tone and contractility possibly results from a mechanism similar to ileus. In a recent study, mares with retained placenta were found to have statistically lower serum total calcium concentrations than mares without retained placenta within 12 hours after foaling.[149] Furthermore, 64% of mares treated with a combination of oxytocin in a calcium/magnesium borogluconate solution responded to treatment compared with 44% of the mares treated with oxytocin in saline solution. No differences in serum magnesium concentrations were found in this study.

18.1.4.1.6 Treatment of Hypocalcemia

When treating hypocalcemia, one should consider calcium deficit, maintenance, losses, and sequestration. If parathyroid gland function is normal, the amount of calcium required is probably minimal. Calcium therapy is more critical in horses that develop rapid hypocalcemia and in horses that may have impaired parathyroid gland function (exercise-induced hypocalcemia, sepsis) to restore normocalcemia. One should 1313
base the decision to treat horses with hypocalcemia on the presence of hypocalcemia and not in the 1314
presence of clinical signs associated with hypocalcemia. In most cases, horses with ionized hypocalcemia do not show signs of hypocalcemia, or the signs are too subtle to be detected, and the lack of therapy may result in additional complications (in particular ileus). Horses with mild hypocalcemia in general restore their normocalcemia without calcium administration; however, as a good practice and to avoid

complications, one should consider calcium administration. Horses with functional kidneys can eliminate large amounts of calcium rapidly, and hypercalcemia from excessive calcium administration is rare, in particular if the horse is receiving fluid therapy. At the Ohio State University, the author and colleagues determine serum ionized calcium concentrations in every critically ill horse and foal admitted to the Veterinary Teaching Hospital and, with few exceptions, treat most horses with gastrointestinal disease with calcium gluconate.

Some important considerations when calculating Ca^{2+} deficits in horses with hypocalcemia are as follows. The use of standard formulae to calculate electrolyte deficits based on extracellular fluid and body weight may not apply to calcium. One problem when using this formula is that Ca^{2+} can be eliminated rapidly or sequestered in different compartments, and larger doses of calcium often are required. One can calculate the calcium deficit based on ionized calcium concentrations (milligrams per deciliter equals millimoles per liter × 4).

The following formula allows one to calculate the Ca^{2+} deficit:

$$\frac{(6.5 - Ca^{2+})(10)(0.3)(\text{body mass})}{Ca^{2+}\ \text{ratio}} = Ca^{2+}\ \text{deficit}$$

in which the difference between the measured Ca^{2+} and normal Ca^{2+} (6.5 mg/dl) is multiplied by the extracellular fluid volume, the body mass (kg), and a factor of 10 and then is divided by the Ca^{2+} ratio (Ca^{2+}/total calcium). For a 450-kg horse with a serum Ca^{2+} concentration of 4.5 mg/dl and a total calcium of 10 mg/dl, the estimated Ca^{2+} deficit will be 6000 mg.

$$\frac{(6.5 - 4.5)(10)(0.3)(450\ \text{kg})}{0.45} = 6000\ \text{mg}$$

This product is a deficit of elemental calcium, and calcium gluconate or calcium borogluconate are the salts of choice for parenteral treatment of hypocalcemia. Calcium gluconate contains 9.3% of elemental calcium; in other words, every 100 ml of calcium gluconate 23% solution contains 2.14 g of elemental calcium or 21.4 mg/ml. The horse in the example would require approximately 300 ml of calcium gluconate 23% solution over 24 hours to replace the Ca^{2+} deficit.

One can use total calcium concentration to estimate calcium deficit; however, total calcium concentration has more variability than Ca^{2+} concentration because it depends highly on albumin concentrations and it is not subject to tight control by the Ca^{2+}-sensing system. A horse may have total hypocalcemia, but serum Ca^{2+} concentrations may be within the normal range, and calcium administration may not be necessary. However, one must be realistic that measurement of Ca^{2+} concentrations is not readily available for many practitioners, and keeping this in mind, measurement of total calcium concentrations is acceptable. Replacing measured total calcium and normal total calcium (11.5 mg/dl) in the same formula and dividing by a 0.5 Ca^{2+} ratio gives a close approximation of calcium deficit.

Frequent monitoring of Ca^{2+} concentration is important to adjust dosage. Some horses with severe gastrointestinal disease and sepsis remain hypocalcemic despite aggressive calcium supplementation. These horses may have considerable calcium losses into the intestinal compartment and in general carry a poor prognosis. Rapid administration of calcium may result in cardiovascular complications, in particular

in septic horses, which may be more vulnerable to the toxic effects of calcium. The author holds that horses can handle calcium dosages (and serum calcium concentrations) higher than traditionally believed; however, close monitoring is advised. Toribio, Kohn, Sams, et al.[128] have induced severe ionized hypercalcemia (10 to 12 mg/dl) in a large number of healthy horses using rapid (5 minutes) and slow (120 minutes) calcium chloride or calcium gluconate infusions with no obvious complications; however, every time calcium is administered intravenously a potential risk exists for serious complications, in particular in diseased horses. Based on the authors' experiences treating critically ill horses, calcium doses of 2 mg/kg/hr are safe in the horse. This dose rate represents approximately 50 ml of calcium gluconate 23% solution for a 500-kg horse in 1 hour while receiving fluid therapy. Furthermore, the authors have treated horses with severe hypocalcemia with calcium doses of up to 4-6 mg/kg/hr.

When administering calcium, the author starts with a calcium dose of 1 mg/kg/hr (25 ml of calcium gluconate per hour for a 500-kg horse). A 500-kg critically ill horse receiving 5 L of crystalloids supplemented with 50 ml of calcium gluconate is receiving 1000 mg of calcium per 5 L bag. If that amount is given in 1 hour, then the calcium dose is 2.0 mg/kg/hr. Sometimes the author uses 100 ml of calcium gluconate per 5 L of crystalloids in horses that are volume depleted and have severe hypocalcemia. Calcium chloride may be a good option to treat hypocalcemia in horses; however, calcium gluconate is readily available and inexpensive compared with calcium chloride. In addition, calcium 1314
chloride is not available in large volumes, and at least in human beings it may cause irritation at the 1315
administration site. One must keep in mind not to add calcium salts to fluid solutions containing bicarbonate because calcium carbonate complexes may form and precipitate.

A number of studies have found that calcium administration to some septic patients may be detrimental because it may result in increased intracellular calcium concentrations, activation of proteases, cell death, and increased mortality.

Oral treatment with calcium salts is feasible in some horses with non–life-threatening hypocalcemia. One can use dicalcium phosphate and calcium carbonate (limestone) safely (see Table 18.1-3).

18.1.4.2 HYPOCALCEMIC DISORDERS

18.1.4.2.1 Hypoparathyroidism

Hypoparathyroidism is a condition characterized by hypocalcemia, hyperphosphatemia, hypomagnesemia, and decreased serum PTH concentrations. Primary hypoparathyroidism results from decreased synthesis and secretion of PTH, whereas secondary hypoparathyroidism most commonly results from hypomagnesemia. Magnesium has a permissive effect on PTH secretion, and low magnesium concentrations may impair PTH release from the parathyroid gland. Pseudohypoparathyroidism is a condition in which PTH cannot interact with its receptor, or an abnormal signal transduction exists after PTH interacts with the PTH-1 receptor. Pseudohypoparathyroidism also may result from magnesium deficiency.

18.1.4.2.2 Primary Hypoparathyroidism

Primary hypoparathyroidism recently was reported in horses. The animals have clinical signs consistent with hypocalcemia, which may include ataxia, seizures, hyperexcitability, SDF, tachycardia, tachypnea, muscle twitching or fasciculations, stiff gait, recumbency, ileus, and colic. The diagnosis in based on the

determination of serum concentrations of Ca^{2+}, Mg^{2+}, intact PTH, and phosphorus. Hypocalcemia, hyperphosphatemia, low serum PTH concentrations, and hypomagnesemia have been reported in horses with primary hypoparathyroidism.[131,145] Hypocalcemia results from decreased PTH concentrations, and hyperphosphatemia most likely results from the decreased fractional urinary clearance of phosphorus caused by low PTH concentrations. Low PTH concentrations may contribute to hypomagnesemia because PTH stimulates Mg^{2+} reabsorption in the distal convoluted tubules. The administration of magnesium sulfate may be useful in differentiating primary from secondary hypoparathyroidism; in the case of secondary hypoparathyroidism from hypomagnesemia a rapid release (within minutes) of PTH is expected after magnesium administration.

18.1.4.2.3 Secondary Hypoparathyroidism

Secondary (functional or acquired) hypoparathyroidism as a pathologic entity has not been reported in the horse; however, some septic horses with hypocalcemia and impaired parathyroid gland function most likely are suffering from a secondary hypopathyrodism resulting from hypomagnesemia and increased concentrations of inflammatory mediators. Toribio, Kohn, Chew, et al. have found that a number of septic horses with ionized hypocalcemia and inappropriately low serum intact PTH concentrations had hypomagnesemia,[4] suggesting an impairment of the parathyroid gland to secrete PTH. Increased blood concentrations of inflammatory mediators such as IL-1, IL-6, and tumor necrosis factor α may potentially decrease PTH secretion,[4,58,150,151] causing a hypoparathyroid state. The author, like others,[129] has observed a number of critically ill foals with clinical evidence of hypocalcemia in which serum intact PTH concentrations are not increased as expected, suggesting hypoparathyroidism. However, whether these foals have a primary parathyroid gland dysfunction or whether they have parathyroid gland dysfunction from hypomagnesemia, from increased inflammatory mediators, or both is unclear.

Secondary hypoparathyroidism with hypercalcemia was reported in an 11-year-old Andalusian gelding with chronic renal failure and polycystic kidney disease.[130]

18.1.4.2.4 Pseudohypoparathyroidism

Parathyroid hormone resistance is referred as pseudohypoparathyroidism. In human beings the condition is inherited in which signal transduction after PTH interacts with its receptor is abnormal. Hypomagnesemia also may impair PTH action in its target organs, resulting in pseudohypoparathyroidism.

18.1.4.2.5 Idiopathic Hypocalcemia

Beyer, Freestone, Reimer, et al. reported on a series of foals with clinical signs of hypocalcemia of unknown cause.[129] These foals had serum PTH concentrations that were undetectable or within the reference range, suggesting abnormal parathyroid gland function for the degree of hypocalcemia. Possibly these foals may have suffered some form of hypoparathyroidism; serum phosphorus concentrations were increased in some foals, as occurs in hypoparathyroidism. Serum Mg^{2+} concentrations were not measured and a distinction between primary and secondary hypoparathyroidism cannot be made. Neonatal hypocalcemia occurs in human infants born of hyperparathyroid mothers, and the hypocalcemia that these infants develop is believed to result from maternal hypercalcemia, which may suppress fetal parathyroid gland function.[152] Another human condition with similar clinical features is familial hypercalciuric 1315

hypocalcemia, in which activating mutations of the CaR result in mild to severe hypocalcemia, hyperphosphatemia, and low to normal PTH concentrations.[63,153,154]

The author believes that abnormal activation of the CaR may be involved in the pathogenesis of hypocalcemia in septic foals. The author has found that IL-1 and IL-6 decrease PTH secretion from equine parathyroid cells in vitro and that IL-1 increases the expression of CaR mRNA, which in turn decreases PTH secretion. No studies in the horse have been done to evaluate whether mutations of the CaR may be involved in the pathogenesis of neonatal hypocalcemia as occurs in human infants.

18.1.4.2.6 Sepsis

Sepsis is perhaps the most common cause of hypocalcemia in equine patients admitted to veterinary hospitals. For reasons not yet understood, hypocalcemia is a frequent finding in human beings and animals with sepsis.[4,137,138,155–157] Clinical observations have revealed that total and ionized hypocalcemia are common in horses with severe gastrointestinal disease and sepsis.[4,137,138] Hypocalcemia in septic patients often results in increased serum PTH concentrations to return serum Ca^{2+} concentrations to the physiologic range.[4,157]

Of horses with enterocolitis admitted to the Ohio State University Veterinary Teaching Hospital, 75% had total hypocalcemia, 80% had ionized hypocalcemia, and 70% had ionized hypomagnesemia.[4] Of interest from that study was that some horses with clinical evidence of sepsis and hypocalcemia had low serum PTH concentrations for the degree of hypocalcemia, indicating an inappropriate response of the parathyroid gland to low serum Ca^{2+} concentrations (parathyroid gland dysfunction). Hypocalcemia is also frequent in septic foals, and the author has some critically ill foals with ionized hypocalcemia that have low serum intact PTH concentrations for the degree of hypocalcemia. In horses with surgically managed gastrointestinal disease, serum Ca^{2+} concentrations were lower in those with more severe lesions.[137,138] Increased endotoxin concentrations may be the trigger that activates a series of mechanisms that result in hypocalcemia. Horses with gastrointestinal disease may have detectable concentrations of endotoxin in plasma.[158–160] The author,[58] like others, has found that parenteral administration of endotoxin to healthy animals results in hypocalcemia.[155,161]

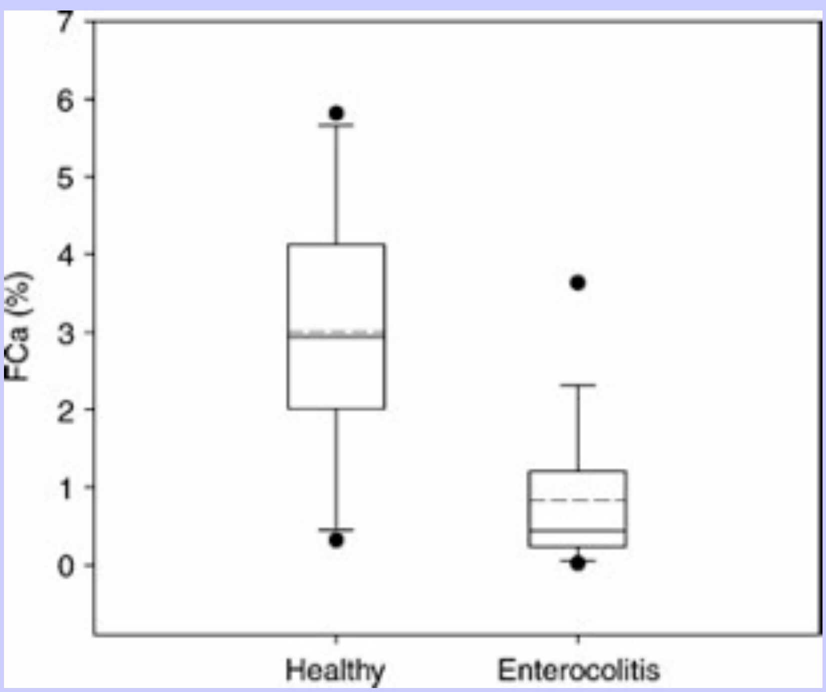
The mechanisms responsible for development of hypocalcemia during sepsis are not understood completely. Possible causes of hypocalcemia include renal loss of calcium,[162] calcium sequestration in the gastrointestinal lumen from poor absorption associated with inflammation,[161] intracellular calcium accumulation,[163] impairment in calcium mobilization,[164–166] tissue sequestration of calcium,[155,162] impairment of calcium release by the target tissue in response to PTH,[162] failure to synthesize $1,25(OH)_2D$,[156] and parathyroid gland dysfunction.[4] Renal loss of calcium as a cause of hypocalcemia in septic horses seems unlikely because horses with enterocolitis and hypocalcemia have been found to have low fractional urinary clearance calcium (Figure 18.1-8).[4]

Impaired calcium mobilization may result from impaired parathyroid gland secretion of PTH,[167] poor osteoblast-osteoclast response to PTH,[162] or high serum concentrations of calcitonin and procalcitonin.[164–166] Serum PTH concentrations are low in some human beings and horses with sepsis and hypocalcemia.[4,168] During sepsis, impaired PTH secretion could result from upregulation of the CaR in parathyroid

gland chief cells from intracellular accumulation of calcium and from hypomagnesemia.[58,151,169] Hypomagnesemia is a frequent finding in critically ill human beings.[4,138,156] Inflammatory mediators that may be increased in horses with sepsis such as IL-1 and IL-6 may increase intracellular calcium concentrations, upregulate the CaR in parathyroid chief cells, and suppress PTH secretion.[58,151,169] Upregulation of the CaR in equine parathyroid chief cells by IL-1 results in lower PTH secretion.[169]

Tissue sequestration as a cause of hypocalcemia has not been evaluated in the horse, although it may be
important in the pathogenesis of hypocalcemia. Administration of endotoxin to healthy pigs resulted in 1316
increased calcium accumulation in the liver and peritoneal fluid.[155] One proposal is that because 1317
interstitial fluid volume is much greater than the blood volume, interstitial accumulation of calcium could result in hypocalcemia.[155]

Figure 18.1-8 Box plot of fractional urinary clearance of calcium *(FCa)* in healthy horses (*n* = 20) and horses with enterocolitis (*n* = 20). Mean fractional urinary clearance of calcium was significantly lower (*P* < 0.05) in horses with enterocolitis. •, 5th and 95th percentiles. (Adapted from Toribio RE, Kohn CW, Chew DJ et al: Comparison of serum parathyroid hormone and ionized calcium and magnesium concentrations and fractional urinary clearance of calcium and phosphorus in healthy horses and horses with enterocolitis, *Am J Vet Res* 62:938-947, 2001.)



In human beings and animals with sepsis, intracellular calcium concentrations are increased in different cells, including hepatocytes, aortic smooth muscle cells, red blood cells, and skeletal muscle cells.[163,170,171] Intracellular accumulation of Ca^{2+} may play an important role in the progression from sepsis to multiorgan dysfunction syndrome, the most common cause of mortality in the intensive care unit.[163] Calcium accumulation in the cell membrane also may play some role in the pathogenesis of hypocalcemia and sepsis.

As previously mentioned, some studies indicate that calcium administration to some critically ill patients may be detrimental because it may increase the risk of mortality by increasing intracellular calcium concentrations and inducing cell injury.[156,172]

18.1.4.2.7 Exercise-Induced Hypocalcemia

Horses under intense exercise develop electrolyte and acid-base abnormalities. Unlike human beings, which may develop ionized hypo- or hypercalcemia, ionized hypocalcemia seems to be a more consistent finding in exercise in the horse. Common clinical signs in horses with exercise-induced hypocalcemia include SDF, muscle weakness, muscle fasciculation, ileus, colic, excitation, and cardiac arrhythmias.

Hypocalcemia in exercising horses may result from calcium losses into the sweat[146,173]; calcium movement to the intracellular compartment; increased calcium binding to plasma components such as albumin, lactate, phosphate, and bicarbonate,[174] which are increased during exercise; and from increased calcium binding to albumin during alkalosis. Exercising horses may develop respiratory alkalosis from hyperventilation, metabolic alkalosis from chloride losses in the sweat (hypochloremic), or a combined alkalosis. The effect of hyperalbuminemia on serum Ca^{2+} concentrations varies, and in some cases no relationship between serum albumin concentrations and Ca^{2+} has been found. Although some horses may develop alkalosis that may contribute to ionized hypocalcemia, most horses under intense exercise develop metabolic acidosis.[174]

More insight information on factors associated with calcium regulation (PTH, calcitonin, and $1,25[OH]_2D$) in the horse under exercise is lacking. In a recent study, serum Ca^{2+} and PTH concentrations were measured in jumping competition horses; serum Ca^{2+} decreased while serum PTH concentrations increased as expected, and the authors concluded that inadequate parathyroid gland function as the cause of hypocalcemia in these horses was unlikely.[36] However, the PTH increase (result of hypocalcemia or from parathyroid gland adrenergic stimulation) was not sufficient to restore normocalcemia. When serum PTH and Ca^{2+} concentrations were measured in horses competing in endurance rides,[136] serum PTH concentrations were found not to increase in all horses that developed hypocalcemia, which may indicate parathyroid gland dysfunction. In human beings, increased serum PTH concentrations are a consistent finding during exercise. Although acid-base and electrolyte disturbances are important in the development of ionized hypocalcemia, some other factors may be impairing the ability of these horses to correct their hypocalcemia. Increased serum concentrations of calcitonin may inhibit osteoclastic bone resorption. During intense exercise in human beings, serum concentrations of gastrin and glucagon increase, probably from increased energy demands and the result of transient gastrointestinal ischemia. Gastrin and glucagon cause a release of calcitonin from the thyroid gland C cells. Increased serum concentrations of gastrin[175] and glucagon[176] have been documented in exercising horses. Whether a relationship between exercise,

gastrin and glucagon release, calcitonin increase, and hypocalcemia exists in the horse still remains to be established. Renal losses of calcium as a cause of hypocalcemia during exercise are unlikely because urinary losses of calcium decrease in exercising horses.[147]

18.1.4.2.8
Vitamin D Deficiency

No evidence indicates that horses develop hypocalcemia from vitamin D deficiency. Horses have low concentrations of vitamin D metabolites, and their role in the critically ill horse is questionable. Horses with chronic renal failure and with bilateral nephrectomy[177,178] often develop hypercalcemia and hypophosphatemia, which may result from decreased glomerular filtration rate rather than from decreased $1,25(OH)_2D$ concentrations, emphasizing the important role of the kidney in calcium excretion.

18.1.4.2.9
Oxalate Toxicity

Oxalate excess reduces calcium absorption; 1% of oxalate or higher can reduce calcium absorption by 66% or more.[19] The equine diet must contain less than 0.5% of oxalate and a calcium/oxalate ratio greater than 1.0. Diets containing 0.87% of oxalate had no effect in calcium absorption when the calcium/oxalate ratios were higher than 1.7.[21] Clinical signs associated with oxalate excess are phosphate excess, calcium deficiency, and nutritional hyperparathyroidism. Oxalates are present in several tropical grasses, toxic plants, and in alfalfa hay (see Table 18.1-6).

18.1.4.2.10
Tetracycline Administration

Tetracycline chelates calcium, and its rapid intravenous administration can result in cardiac arrhythmias, recumbency, sudden collapse, or even death in horses. In most cases, these effects are transient and no treatment is necessary; however, in some cases calcium administration may be required. 1317 1318

18.1.4.2.11
Furosemide Administration

The administration of loop diuretics is a common practice in performance horses. Furosemide inhibits the $Na^+/K^+/2Cl^-$ cotransporter in the cortical thick ascending loop of Henle, decreasing the transepithelial voltage gradient required for Ca^{2+} and Mg^{2+} transport. The end result is increased Ca^{2+} and Mg^{2+} wasting into the urine. This effect can last up to 8 hours in the horse.[179]

18.1.4.2.12
Bicarbonate Overdose

The administration of bicarbonate (parenterally or orally) to horses has been a widespread practice among trainers, owners, and veterinarians. The excessive administration of bicarbonate results in alkalosis (decreasing Ca^{2+} concentrations) and in accumulation of bicarbonate ions in the distal nephron. In the presence of high anion concentrations, which alter the transepithelial voltage gradient, the kidney excretes cations in the urine, including Ca^{2+} and Mg^{2+}.

18.1.4.2.13

Cantharidiasis

Equine cantharidiasis (blister beetle toxicosis) is a condition reported in the southwestern and midwestern United States and is produced by the ingestion of alfalfa contaminated with beetles (*Epicauta* spp.), which produce cantharidin (cantharidic acid).[142,180] Horses are susceptible to cantharidin and develop clinical signs from the irritant effects that this toxin has on mucosal surfaces (gastrointestinal and urinary tracts). In addition, cantharidin causes acute hypocalcemia and hypomagnesemia. Synchronous diaphragmatic flutter and muscle fasciculation are frequent findings in horses with cantharidiasis. Because these horses may develop severe hypocalcemia, ataxia, dyspnea, laryngeal spasm, and cardiac arrhythmias may be present.[180] The reason that these horses develop acute hypocalcemia is unclear; however, the cause may be the combination of severe gastrointestinal disease, calcium losses, and sequestration in the gastrointestinal tract, associated with acute renal failure. Some horses with cantharidiasis develop myocardial necrosis, suggesting a direct effect of cantharidin in the myocardium. Possibly cantharidin increases intracellular calcium concentration in the myocardium, causing cell death. Therefore cardiac arrhythmias in these horses probably result from the direct effect of cantharidin in the myocardium and from hypocalcemia.

18.1.4.2.14

Acute Renal Failure

Hypocalcemia and hypomagnesemia are common findings in horses with acute renal failure and probably result from increased urinary losses of Ca^{2+} and Mg^{2+}. Reabsorption of Ca^{2+} and Mg^{2+} in the kidney depends highly on functional epithelial cells, and these cells are susceptible to various insults (hypoxia, toxins). The loss of the epithelial cells and their absorptive capacity results in decreased reabsorption and increased secretion of Ca^{2+} and Mg^{2+}.

18.1.4.2.15

Exertional Rhabdomyolysis

The pathogenesis of hypocalcemia in exertional rhabdomyolysis is unknown. Speculations are that muscle fiber damage during intense exercise results in Ca^{2+} influx and sequestration into the sarcoplasm and sarcoplasmic reticulum. Hypocalcemia has been reported in neonatal foals with severe rhabdomyolysis.[181] A severalfold increase in sarcoplasmic $Ca^{2+}{}_i$ concentrations have been reported in horses with exertional rhabdomyolysis,[182] indicating that elevations in $Ca^{2+}{}_i$ may be important in the pathogenesis of endoplasmic reticulum. Further discussion on exertional rhabdomyolysis can be found in Chapter 9.

18.1.4.2.16

Pancreatic Necrosis

The cause of hypocalcemia with pancreatic necrosis is unclear, but at least in human beings the cause is associated with deposition of calcium in regions of saponification of peripancreatic fat (fat necrosis). Pancreatitis principally causes colic in horses, although it may be associated with hypocalcemia.

18.1.4.3

HYPERCALCEMIC DISORDERS

Hypercalcemic disorders can be divided in two categories: (1) hypercalcemia associated with parathyroid gland dysfunction (parathyroid-dependent hypercalcemia), and (2) hypercalcemia independent of the parathyroid gland function (hypercalcemia develops despite parathyroid gland suppression). This distinction

is clinically important and emphasizes the use of specific diagnostic tests, including the determination of intact PTH, PTHrP, Ca^{2+}, phosphorus, and vitamin D_3 metabolites concentrations. Parathyroid-dependent hypercalcemia in the horse is limited to primary hyperparathyroidism, whereas parathyroid-independent hypercalcemia results from different conditions.

18.1.4.3.1 Primary Hyperparathyroidism

In primary hyperparathyroidism, an abnormality of the parathyroid gland chief cells results in excessive and autonomous synthesis and secretion of PTH, and the parathyroid gland does not respond to the negative feedback of Ca^{2+}. In the horse, primary hyperparathyroidism may result from a parathyroid adenoma or parathyroid hyperplasia. Parathyroid carcinoma has not been diagnosed in the horse. Elevated PTH concentrations result in increased renal Ca^{2+} reabsorption (hypocalciuria), hyperphosphaturia, 1318
increased bone resorption, and increased $1,25(OH)_2D_3$ synthesis. The end result is loss of cortical bone, 1319
and a condition known as osteodystrophia fibrosa. Primary hyperparathyroidism associated with osteodystrophia fibrosa has been reported in ponies and horses.[46,132,183–185] These horses may have enlargement of the facial bones, lameness, and a poor body condition. Radiographic findings reported include osseous proliferation of the maxilla and mandible, and loss of the lamina dura surrounding the molars.[132] Endoscopic examination may reveal narrowing of the nasal passages.

Hypercalcemia, hypophosphatemia, phosphaturia, and increased intact PTH concentrations are laboratory findings reported in horses with primary hyperparathyroidism. Additional tests to rule out other conditions associated with hypercalcemia in the horse may include measurement of PTHrP and vitamin D metabolite concentrations. Histologic examination of the parathyroid gland is important to confirm the diagnosis of primary hyperparathyroidism. However, finding the parathyroid glands may be a difficult task in some horses because of their small size and variable location (see anatomy section). Only in one case of primary hyperparathyroidism reported in the literature was an adenoma of the parathyroid gland found.[184] In human beings, primary hyperparathyroidism often results from one or more adenomas in previously normal parathyroid glands, and in some other cases the glands may be hyperplastic. Postmortem findings in horses affected with primary hyperparathyroidism include enlargement of the maxilla and mandible, stenosis of the nasal passages, and loosening of premolars and molars.

18.1.4.3.2 Secondary Hyperparathyroidism

In secondary hyperparathyroidism, excessive secretion of PTH is the response of the parathyroid gland to hypocalcemia, hyperphosphatemia, or hypovitaminosis D from renal dysfunction or from nutritional imbalances.

18.1.4.3.3 Renal Secondary Hyperparathyroidism

In the case of renal secondary hyperparathyroidism in small animals and human beings, phosphorus retention from renal disease (decreased glomerular filtration rate) can stimulate PTH secretion directly.[186] In addition, phosphorus lowers serum Ca^{2+} concentrations, which contributes to PTH stimulation. High phosphorus concentrations also inhibit 1α-hydroxylase, an important enzyme in the synthesis of $1,25(OH)_2D$, which has a negative effect on PTH gene expression. Therefore hyperphosphatemia indirectly stimulates PTH synthesis and secretion. Furthermore, the progressive destruction of the tubular

cells in the proximal convoluted tubule, which have 1α-hydroxylase activity, results in less $1,25(OH)_2D$ synthesis. In addition, decreased concentrations of $1,25(OH)_2D$ may result in impaired intestinal absorption of Ca^{2+}, contributing to hypocalcemia and PTH release.

In horses with chronic renal failure (CRF), hypophosphatemia and hypercalcemia are consistent findings, and hyperphosphatemia is uncommon. Horses with CRF have seen serum total and ionized calcium concentrations of up to 22 mg/dl and 12 mg/dl, respectively. The kidneys are important in eliminating calcium in the horse, and an abnormal renal function associated with normal intestinal calcium absorption may be an explanation for the hypercalcemia in these horses. Some horses with CRF have increased serum PTH concentrations, whereas others have serum PTH concentrations within or below the normal range, suggesting that hypercalcemia in most horses with CRF results from impaired renal calcium excretion. Therefore renal secondary hyperparathyroidism may not be an important cause of hypercalcemia in the horse.[130,187] The explanation for hyperphosphatemia in horses with CRF is unknown, although it possibly results from increased Ca^{2+} concentrations. PTHrP concentrations have not been measured in horses with CRF.

Calciphylaxis is a syndrome characterized by calcification of small blood vessels and necrosis of the skin, visceral organs, and subcutaneous fat.[188] These patients have chronic renal failure associated with hypercalcemia, hyperphosphatemia, or elevated calcium-phosphate complexes. This condition remains to be documented in the horse.

18.1.4.3.4 Nutritional Secondary Hyperparathyroidism

Horses that are fed a diet low in calcium, high in phosphorus, or both may develop a clinical condition known as nutritional secondary hyperparathyroidism (NSHPT). This disease also is known as bran disease, miller's disease, bighead, osteodystrophia fibrosa, osteitis fibrosa, and equine osteoporosis. The disease can affect one or many animals in one herd. Diets containing a phosphorus/calcium ratio of 3:1 or more may result in NSHPT.[133,189] Nutritional secondary hyperparathyroidism is uncommon in developed countries; however, occasionally a young horse may have clinical signs consistent with NSHPT, including enlargement of facial bones, upper respiratory noise, and lameness. In older horses, facial bone enlargement may not be evident. In the past, NSHPT commonly was associated with grain-rich diets, in particular with excessive amounts of wheat bran (miller's disease); however, with improvements in animal nutrition, NSHPT rarely is associated with excessive grain feeding. Grains with a high phosphorus content and a higher phosphorus/calcium ratio often result in excessive absorption of phosphorus with respect to calcium and decreased absorption of calcium. Various pastures contain a high content of oxalates (see Table 18.1-6), which bind dietary calcium to form calcium oxalate $(Ca[COO]_2)$ that is insoluble at high pH, predisposing horses to NSHPT.[190] 1319 1320

Excessive amounts of phosphorus in the intestinal tract reduce calcium absorption and may result in hyperphosphatemia. High-phosphorus and low-calcium diets induce parathyroid cell hyperplasia in the horse.[46] Hyperphosphatemia directly stimulates PTH secretion and inhibits $1,25(OH)_2D$ synthesis in the kidney. Because $1,25(OH)_2D$ inhibits PTH gene expression and synthesis, low $1,25(OH)_2D$ concentrations may result in parathyroid cell hyperplasia and increased secretion of PTH. One of the most important functions of $1,25(OH)_2D$ is to increase intestinal Ca^{2+} absorption by increasing the synthesis of Ca^{2+}-binding proteins (calbindin D_{9k}) in the small intestine. Therefore low $1,25(OH)_2D$ concentrations may

contribute to a calcium-deficient state. Although dietary deficiency of vitamin D may result in NSHPT in other species and has been proposed as a possible cause of NSHPT in the horse, little evidence exists that supports hypovitaminosis D as a cause of NSHPT in the horse. Hyperphosphatemia also may result in the formation of calcium phosphate, reducing blood Ca^{2+} concentrations, and stimulating PTH secretion. Parathyroid hormone increases osteoclastic activity, resulting in excessive bone resorption and bone loss. Horses given a diet high in phosphorus have increased bone resorption from increased osteoclastic activity.[191] Facial bone loss and excessive accumulation unmineralized bone matrix (osteodystrophia fibrosa) results in facial enlargement (bighead) (Figure 18.1-9).

Because NSHPT is a condition of slow progression, the homeostatic mechanisms that regulate extracellular Ca^{2+} concentrations (PTH, vitamin D, calcitonin) may be effective to maintain Ca^{2+} close to or within the normal range. These horses maintain normocalcemia at expense of the skeletal reserves, and do not develop clinical signs of hypocalcemia.

Clinical signs may include intermittent, shifting lameness and a stiff gait.[192,193] In many cases, swelling of the facial bones is typical and symmetric. Younger animals may develop physitis and limb deformities.[189] The facial changes and the bone resorption around the lamina dura of the molars and premolars may result in masticatory problems. These horses are physically weak and may be in poor body condition from the pain associated with lameness and mastication. In severe cases, teeth may become loosened and spontaneous fractures may occur. Upper airway obstruction and dyspnea may be present.[194,195]

Clinical laboratory findings may include mild hypocalcemia and hyperphosphatemia; however, these values may be within the reference ranges. Serum intact PTH concentrations are increased.[192] Fractional urinary clearance of calcium (FCa) is low and fractional urinary clearance of phosphorus is high. Serum alkaline phosphatase activity may be increased. Dietary corrections may result in rapid changes in FCa and fractional urinary clearance of phosphorus, and one must perform these tests before diet manipulation. The use of FCa to assess the calcium balance has been proposed,[30,31] and horses with a normal calcium balance are expected to have a FCa greater than 2.5%. The FCa in horses may vary from daily diet changes, and we have found a wide range of FCa in clinically healthy horses (0.2% to 6%), making the FCa alone not a good indicator of calcium balance in the horse.

Radiologic findings may include decreased bone density[192,196]; however, bone density must be decreased 30% before radiographic changes are evident.[197] Resorption of alveolar sockets and loss of the lamina dura dentes may be present before other radiographic changes are present, and long bones may be affected only in advanced cases.

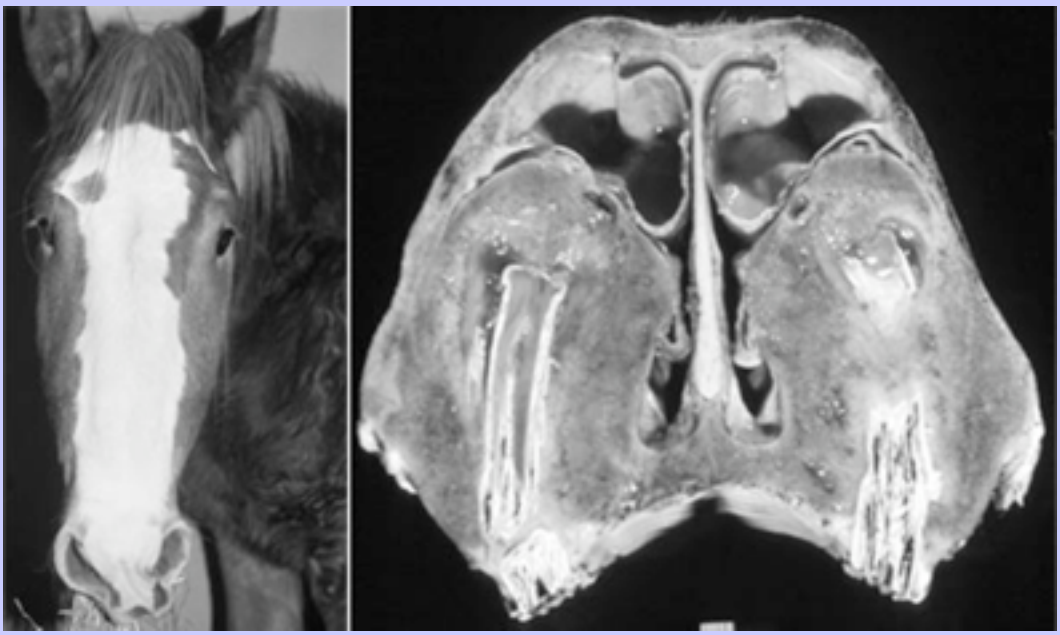
Supplementation with calcium carbonate (limestone) and dicalcium phosphate in the diet has resulted in improvement in horses treated for NSHPT.[133] For the first 2 to 3 months of calcium supplementation should be twice the daily requirements. The addition of alfalfa hay to the diet and decreasing the amount of grain may be helpful. Ground limestone, which contains no phosphorus, is recommended as a good source of calcium (35%). An affected animal may require a total of 100 to 300 g/day, and the diet should have a Ca:P ratio of 3:1 to 4:1. Limestone may decrease feed palatability, and adding molasses is recommended. Confinement of severely affected horses is advised. The use of NSAIDs may be indicated in horses with severe pain; however, one should use these drugs with caution because increased activity may result in fractures. Supplementation with vitamin D has been proposed. Horses required approximately 9 to 12 months for complete recovery and for the bony lesions to regress. Owners should

avoid using high-oxalate feeds; however, if this is not a practical option, one may increase calcium and phosphorus supplementation. For horses consuming feeds with high oxalate content, an additional 20 mg of calcium per kilogram and 10 mg of phosphorus per kilogram body mass per day may be necessary.[20]

18.1.4.3.5 Hypervitaminosis D

The accidental ingestion or administration of ergocalciferol (vitamin D_2) or cholecalciferol (vitamin D_3) results in disturbances of the calcium and phosphorus metabolism in domestic animals.[134,198–205] In the horse, intoxication with ergocalciferol and 1,25-dihydroxycholecalciferol (1,25-dihydroxyvitamin D) has been reported.[134,199,205] Ingestion of plants containing $1,25(OH)_2D$-like compounds results in typical clinical signs of vitamin intoxication.[200,202–204] The ingestion of *Solanum malacoxylon* results in a 1320
condition known as "enteque seco" in Argentina and "espichamento" in Brazil.[198,204] In Hawaii the 1321
ingestion of *Solanum sodomaeum* results in hypercalcemia. The ingestion of jessamine *(Cestrum diurnum)*, a shrub widely distributed in the southern United States (from Florida to California) may cause hypervitaminosis D.[200] In Europe, the ingestion of *Trisetum flavescens* by horses results in a condition known as enzootic calcinosis. Hypervitaminosis D results in increased intestinal absorption of phosphorus and hyperphosphatemia. Hyperphosphatemia is the most consistent and early laboratory finding in horses with vitamin D intoxication.[199] Serum calcium concentrations may be within the normal range or increased.[134,199,203,205] Vitamin D is an important regulatory factor of parathyroid cell function and proliferation, and hypervitaminosis D may decrease PTH gene expression and secretion and also cause parathyroid cell atrophy.[201] In addition, hypercalcemia inhibits PTH secretion, lowering the bone turnover. Uremia and hyposthenuria may be present.[134]

Figure 18.1-9 Belgium yearling presented to the Ohio State University Veterinary Teaching Hospital with clinical signs consistent with nutritional secondary hyperparathyroidism, including enlargement of facial bones and upper respiratory noise. The horse was fed excessive amounts of grain. Narrowing of the nasal passages, loss of bone mass, and excessive accumulation of unmineralized bone matrix (osteodystrophia fibrosa) were evident.



Clinical signs result from hyperphosphatemia. Horses often have weight loss and poor appetite, develop lameness, painful stiffness, and are reluctant to move.[199,205] Acute death from severe cardiovascular mineralization has been reported.[134] Polyuria and polydipsia are frequent findings. In cases with hypercalcemia, the deposition of minerals in the kidneys may precede mineralization elsewhere, resulting in renal failure. In addition, hypercalcemia, by direct activation of the calcium receptor in the distal convoluted tubules of the nephron may induce diuresis. Lameness probably caused by calcification of ligaments and tendons.

Radiographically, these horses have increased bone density, decreased size of the medullary cavity, and increased calcification of soft tissues.

The prognosis for horses with hypervitaminosis D is poor. Treatment may include reducing dietary calcium intake. The use of calcium-binding agents such as sodium phytate, which is high in many cereals, has been proposed.[205] Glucocorticoids are used in human beings with hypervitaminosis D, with the rationale that they may inhibit the vitamin D–mediated calcium absorption in the intestine. Dexamethasone

administration to pony foals results in decreased intestinal absorption of calcium, decreased bone resorption, and increased urinary excretion of calcium.[25,26] Dexamethasone has been administered to horses with hypervitaminosis D with variable results.[205]

Postmortem examination may reveal mineralization of soft tissues. Extensive cardiovascular mineralization of the endothelium of the aorta and pulmonary vessels and of the endocardium of the atrium and ventricles is frequent. Mineralized plaques may be present in the endothelium and endocardium. Mineralization may be found in the kidney, liver, lymph nodes, lungs, ligaments, and tendons. 1321
Osteopetrosis of epiphyses and metaphyses may be present. Atrophy of the parathyroid chief cells may be 1322
severe.[201]

18.1.4.3.6 Pseudohyperparathyroidism

The term *pseudohyperparathyroidism* has been used to describe a paraneoplastic condition known as humoral hypercalcemia of malignancy, in which human beings and animals develop hypercalcemia associated with malignancies. Parathyroid hormone–related protein was discovered to be humoral factor responsible for hypercalcemia in human beings with malignancies.[34] Humoral hypercalcemia of malignancy has been described in several domestic animals. In the horse, HHM has been reported to be associated with gastric squamous cell carcinoma,[117] adrenocortical carcinoma,[206] squamous cell carcinoma of the vulva,[115] lymphosarcoma,[116,207] and ameloblastoma.[120]

18.1.4.3.7 Neonatal Hypercalcemia and Asphyxia

Clinical observations indicates that a number of critically ill newborn foals develop hypercalcemia associated with asphyxia (F.T. Bain, personal communication, 2002). These foals have severe hypotension with somnolence; however, they cannot be differentiated clinically from foals with severe asphyxia. The mechanisms underlying this problem are unknown.

18.1.4.3.8 Treatment of Hypercalcemia

Hypercalcemia rarely is an equine emergency; however, the differential diagnosis of hypercalcemia is important in the treatment of hypercalcemia. Few disorders in the horse are associated with hypercalcemia (hyperparathyroidism, CRF, HHM, hypervitaminosis D). Mild to moderate hypercalcemia in general is not a life-threatening condition, and one should direct treatment to the primary cause (primary hyperparathyroidism, chronic renal failure). Hypervitaminosis D can be fatal with mineralization of vital organs. Surgical removal of epithelial tumors may be a successful treatment in some patients. In cases of severe hypercalcemia that may require treatment, initial therapy should include the administration of 0.9% saline solution and loop diuretics. Furosemide is the diuretic of choice because it inhibits the $Na^+/K^+/2Cl^-$ contransporter in the distal tubules, inducing urinary calcium excretion. Thiazide diuretics are contraindicated because they stimulate calcium reabsorption. One should consider glucocorticoid administration.

18.2—Pars Intermedia Dysfunction (Equine Cushing's Disease)

Ramiro E. Toribio

A clinical syndrome associated with hirsutism, laminitis, polyuria and polydipsia, and weight loss has been described in aged horses.[1–5] This condition results from dysfunction of the pituitary gland, progresses slowly, and affects horses and ponies.

The equine syndrome is similar to Cushing's disease in human beings, in which occurs excessive and autonomous secretion of proopiomelanocortin-derived peptides, including adrenocorticotropic hormone (ACTH, corticotropin), resulting in secondary hyperadrenocorticism. However, in horses, pituitary adenomas arise from the pars intermedia of the pituitary gland and rarely arise from the anterior lobe (pars distalis, adenohypophysis) as occurs in human beings and dogs. Although many of the clinical signs associated with equine Cushing's disease are frequent among affected horses, some clinical signs may vary, perhaps from variable secretion of other proopiomelanocortin-derived peptides. Compared with other equine endocrine disorders, equine Cushing's disease is a frequent clinical syndrome, and pars intermedia adenomas often are identified at postmortem examination in elderly horses with no previous history or reported clinical signs of this condition. The underlying cause of equine Cushing's disease remains unclear, although some evidence suggests that the disease results from lack of inhibitory control on the pars intermedia, as will be discussed later in this section.

Equine Cushing's disease has been described as a equine Cushing's syndrome, pituitary adenoma, hypophyseal adenoma, chromophobe adenoma, pars intermedia adenoma, diffuse adenomatous hyperplasia of the pituitary, pituitary-dependent hyperadrenocorticism, pars intermedia hyperplasia, and pars intermedia dysfunction.[1,3,6–21] The latter two terms seem to be more appropriate to describe equine Cushing's disease because, unlike human beings, adrenocortical hyperplasia and hypercortisolemia are not consistent findings in affected horses. Pars intermedia dysfunction is used in this section to refer to equine Cushing's disease.

18.2.1 Clinical Signs

Pars intermedia dysfunction (PID) is a clinical syndrome of aged horses associated with hirsutism, poor hair 1327
coat, laminitis, lethargy, narcolepsy, polyuria and polydipsia, muscle wasting, weight loss, docility, decreased 1328
responsiveness to painful stimuli, increased appetite, and recurrent infections.[1,2,15,18,20] Generally, PID is diagnosed in horses older than 7-years of age (range 7 to 40 year; average 19 to 21 years)[1,2,5,22,23] with no breed predilection, but PID seems to be more prevalent in ponies than in horses.[2] No sex preference exists,[2,5,23] although in several studies PID appeared to be more prevalent in females,[1,11,13,24] and one report found that Cushing's disease was more common in males.[2]

Figure 18.2-1 Horse diagnosed with pars intermedia dysfunction. The horse was treated with a combination of pergolide and cyproheptadine, and clinical signs improved by 8 weeks of treatment. (Courtesy Tracy Miesner, Columbus, The Ohio State University.)

Hirsutism (55% to 80%) is the most frequent clinical sign in affected horses[1,2,5,20,25] (Figure 18.2-1). These horses have a long and thick hair coat, in many cases long and curly hair, and abnormal hair coat shedding; some horses shed in late spring and grow a winter coat early in the fall, and many horses develop a patchy coat with areas of alopecia. Retention of long hair in the jugular grove, on the legs, and along the ventral abdomen are also frequent findings. The mechanisms underlying the abnormal hair coat and shedding process are not understood. Horses with adrenal exhaustion or insufficiency may also have an abnormal hair coat.[26]

Weight loss, lethargy, laminitis, and polyuria and polydipsia are also consistent clinical findings.[2,23,25] Skin infections (dermatophilosis), sinusitis, pneumonia, tachypnea (in particular in horses with long hair coat during warm weather), dental disease, abnormal estrus cycles, neurologic signs (seizures, narcolepsy), colic, abnormal vision, and bulging of supraorbital fat pads are among other clinical signs or conditions reported concomitantly with PID.[*]

Chronic laminitis is a consistent finding in these horses,[25] and laminitis is speculated to result from increased concentrations of glucocorticoids. Regardless of the underlying cause of laminitis, one should include PID in the differential diagnoses in any elderly horse that has chronic laminitis, even if other clinical signs of PID are not present.

Polyuria and polydipsia have been reported in up to 76% of horses diagnosed with PID[2]; however, the pathogenesis behind the development of polyuria and polydipsia is unclear. Compression of the pars nervosa by a pars intermedia adenoma has been speculated to result in decreased secretion of vasopressin (arginine vasopressin, antidiuretic hormone).[1,6] Hyperglycemia, which is a frequent laboratory finding in these horses, may result in osmotic diuresis. Glucocorticoids can increase glomerular filtration rate and may contribute to diuresis. One must rule out other differential diagnoses for polyuria and polydipsia, including neurogenic diabetes insipidus, nephrogenic diabetes insipidus, psychogenic polydipsia, and hyperglycemia of various origins (pancreatic disease, pheochromocytoma). Horses that are stalled are most likely to have obvious polyuria and polydipsia.

Increased docility in affected horses often is reported by owners and clinicians. Horses with PID have increased plasma and cerebral spinal fluid concentrations of β-endorphin,[12] which may explain the docility and lethargy in some of these animals. Increased β-endorphin concentrations also may explain the decreased responsiveness to painful stimuli.

The author has been recognizing narcolepsy as a presenting complaint in some horses diagnosed with PID. 1328

1329

Excessive sweating (hyperhidrosis) and, less commonly, lack of sweating (anhidrosis) are reported in horses with PID, although the mechanisms underlying abnormal sweating have not been determined.

The majority of horses with PID (up to 88%) have weight loss[2]; however, some horses may be obese or in good body condition.[23] Affected horses often have a weak and pendulous abdomen, a sway back, and lose muscle mass along the dorsum of the back. The pot-bellied appearance probably results from lack of tone in the abdominal musculature. The muscle wasting along the dorsal midline and elsewhere results in prominence of the croup, tuber coxae, and tuber sacrale regions. What the effect of different proopiomelanocortin-derived peptides is on the equine energy metabolism is unclear. Weight loss in some horses may result from other conditions associated with aging (dental problems, immunosuppression and disease, parasites) rather than the direct effect of an abnormally regulated hypothalamus-pituitary-adrenal (HPA) axis on body condition. The role

of increased concentrations of cortisol on weight loss is unclear; glucocorticoids, in addition to being immunosuppressive, have catabolic effects on skeletal muscle, and in some horses increased cortisol concentrations may be responsible in part for muscle wasting and weight loss. In horses with normal or low cortisol concentrations, other causes may be responsible for the weight loss.

The bulging supraorbital fat pads often observed in horses with PID result from fat redistribution.[25] Likewise, some horses in good body condition may have a “cresty neck” and fat accumulation around their tails.

18.2.2 Pathogenesis

Despite several excellent studies trying to elucidate the pathogenesis of PID in horses,[8,9,12,28] several questions still remain unanswered; for example, why a number of horses with PID have low cortisol concentrations in spite of high ACTH concentrations. Cortisol may be responsible for some of the clinical signs associated with PID; however, many studies have found that cortisol concentrations in horses with PID may be within or below the normal range, suggesting that unidentified factors may be as or more important than hypercortisolemia in the pathogenesis of this condition. Furthermore, these findings are consistent with the low frequency (20%) of adrenocortical hyperplasia in horses diagnosed with Cushing's disease.[1,13] Another explanation for the low cortisol concentration in some affected horses may be that glucocorticoid synthesis and secretion from the adrenal gland is downregulated from excessive and prolonged exposure to ACTH.

An important aspect to consider with this syndrome is the considerable number of differences in clinical signs and laboratory testing among horses with Cushing's disease; probably, veterinarians are dealing with two different pathologic entities, and their diagnostic and therapeutic approaches may be different.

As previously mentioned, based on histologic and pathologic findings, *pars intermedia dysfunction* and *hyperplasia* are considered to be more appropriate terms for equine Cushing's disease,[15,21] in which the lack of inhibitory control on pars intermedia cell function appears to be the trigging mechanism for excessive cell proliferation and the development of adenomas. Human beings and dogs with Cushing's disease have increased plasma cortisol concentrations, and plasma ACTH concentrations are within or above the normal range, whereas in horses diagnosed with Cushing's disease, cortisol concentrations vary.

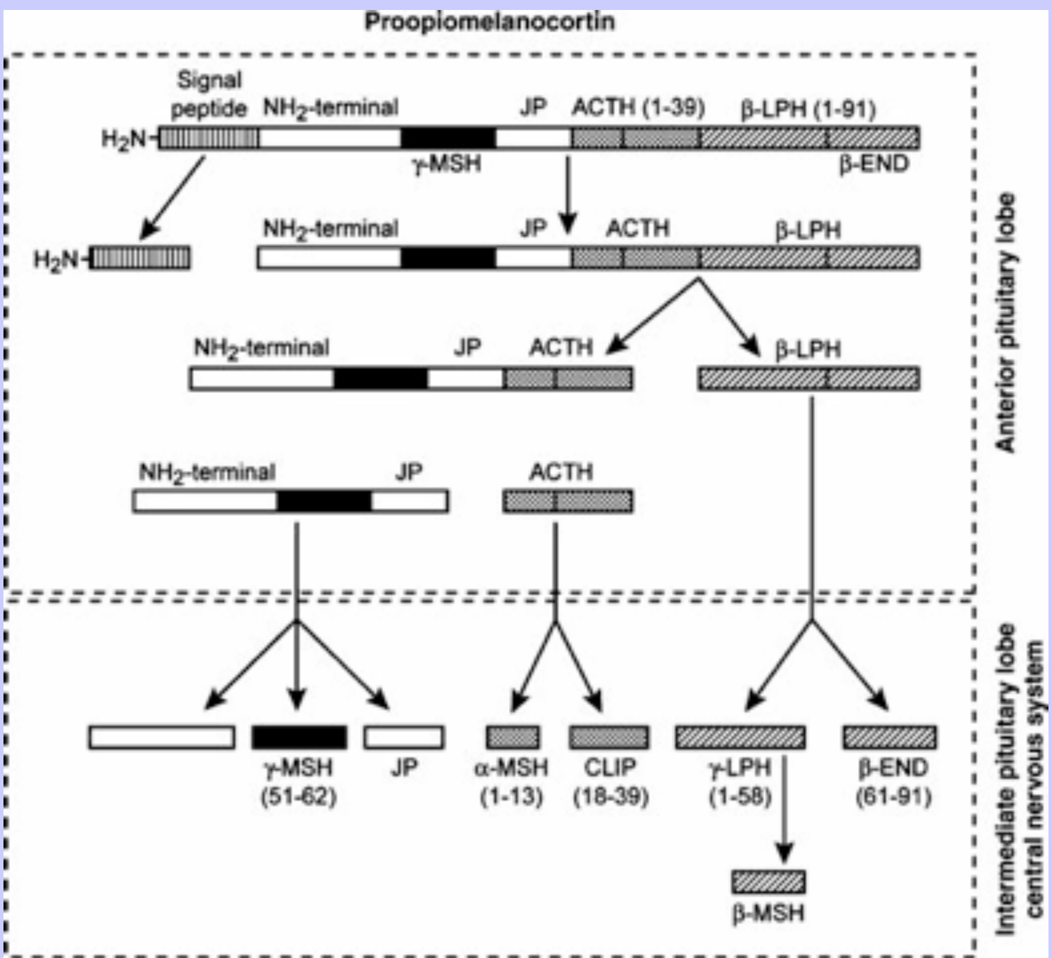
Pars intermedia dysfunction has been suggested to result from hypothalamic dysfunction associated with pituitary adenoma invasion because horses have an incomplete diaphragm of the sella turcica, and pars intermedia adenoma may extend out of the sella turcica and compress the hypothalamo-neurohypophyseal tract.[1,6,29] Compression of the pars nervosa by a pars intermedia adenoma also has been speculated to result in decreased secretion of antidiuretic hormone, resulting in polyuria and polydipsia. However, many of the clinical signs of the PID apparently result from excessive production and secretion of proopiomelanocortin-derived peptides such as ACTH, melanocyte-stimulating hormone (MSH), corticotropin-like intermediate lobe peptide (CLIP) and β-endorphin,[8,12] as well as from increased serum concentrations of cortisol. The importance of the hypothalamus (hypothalamic dysfunction) in the pathogenesis of PID remains unclear and deserves additional investigation.

Hypothalamic factors such as serotonin, dopamine, and γ-aminobutyric acid are important in regulating melanotrope function in the pars intermedia of different species, including the horse.[12,30] Low concentrations of dopamine were found in the pars intermedia of horses with PID.[12] Proopiomelanocortin synthesis is regulated differently between the anterior and intermediate lobes; in the intermediate lobe, for example, serotonine and

dopamine regulate proopiomelanocortin synthesis,[5,8,31] whereas in the anterior lobe, glucocorticoids, corticotropin-releasing hormone, and arginine vasopressin regulate proopiomelanocortin synthesis.[8,32–35]

In the anterior lobe (corticotropes) and in the intermediate lobe (melanotropes), the cleavage of proopiomelanocortin results in the same products[9]; however, in the intermediate lobe the posttranslational processing of proopiomelanocortin is different than in the anterior lobe.[12,28] In the anterior lobe the major 1329
products of proopiomelanocortin are ACTH, β-lipotropin, γ-lipotropin, and β-endorphin (Figure 18.2-2). In the 1330
intermediate lobe, ACTH is cleaved to produce α-MSH and CLIP, and the major products are α-MSH, β-MSH, β-endorphin, γ-MSH, and CLIP, and more β-lipotropin is processed to γ-lipotropin.[28,36] Therefore in the pars intermedia, ACTH is a minor (2%) posttranslational product of proopiomelanocortin.[9] Little difference also is apparent in the processing pathway of proopiomelanocortin between normal pars intermedia and pars intermedia adenomas.[9,12] Therefore proopiomelanocortin peptides (β-endorphin, α-MSH, β-MSH, CLIP) also are secreted, and their plasma concentrations are disproportionately higher than ACTH concentrations.[8,9,12] Orth and Nicholson[28] found that the pars intermedia of horses with PID had concentrations of bioactive ACTH similar to pars intermedia of healthy horses; however, the total adenoma content of bioactive ACTH was higher than the total pituitary gland ACTH content in healthy horses. Horses with PID had lower concentrations of β-endorphin in the pars distalis than control horses[12]; however, immunoreactive β-endorphin concentrations in the pars intermedia of affected horses were not different than those of control horses. Millington, Dybdal, Dawson, et al. found that the posttranslational processing of β-endorphin in normal tissues was different to that in equine pituitary adenomas, and this difference was associated with decreased concentrations of dopamine in the pars intermedia of horses with PID.[12] Alexander and Irvine[37] concluded that endogenous opioids inhibit the HPA axis and decrease ACTH secretion from the pars distalis of the horse. Therefore a decrease in anterior lobe β-endorphin concentrations, as occurs in horses with PID, probably may lead to additional ACTH secretion from the anterior lobe.

Figure 18.2-2 Processing of proopiomelanocortin in the anterior pituitary lobe, the intermediate pituitary lobe, and the central nervous system. In the anterior lobe, adrenocorticotropic hormone *(ACTH)* and β-lipotropin *(β-LPH)* are the major products of proopiomelanocortin. In the intermediate lobe and in the central nervous system, adrenocorticotropic hormone is cleaved to produce α-melanocyte-stimulating hormone *(α-MSH)* and corticotropin-like intermediate lobe peptide *(CLIP)*, and the major products are α-MSH, β-MSH, CLIP, γ-lipotropin, β-endorphin *(β-END)*, and γ-MSH. *JP*, joining peptide. (Adapted from Castro MG, Morrison E: Post-translational processing of proopiomelanocortin in the pituitary and in the brain, *Crit Rev Neurobiol* 11:35-57, 1997.)



1330

In horses with PID, plasma concentrations of proopiomelanocortin peptides and cortisol do not seem to have a diurnal rhythm.[8,13,15,38] Dopamine has been identified as an important hypothalamic regulatory factor of pituitary gland function.[8,12,39] The arcuate nucleus tuberoinfundibular dopaminergic system of the hypothalamus is important in modulating growth hormone, luteinizing hormone, and thyroid-stimulating hormone secretion from the adenohypophysis. Dopamine regulates the synthesis and posttranslational processing of proopiomelanocortin-derived peptides by the melanotropes in the intermediate lobe.[40] Through the tuberoinfundibular dopaminergic system, dopaminergic neurons from the arcuate nucleus release dopamine in the median eminence, and these neurons also make direct synaptic contact with melanotropes in the intermediate lobe.[41] The effects of dopamine on the anterior and intermediate lobes are mediated predominantly by dopamine D_2-type receptors.[42] Orth, Holscher, Wilson, et al.[8] found that D_2-receptor dopaminergic agonists (bromocriptine, pergolide) decreased proopiomelanocortin-derived peptide concentrations in horses with PID, suggesting that the pars intermedia function in horses with PID is under a control similar to that of the pars intermedia function of other species. Dexamethasone administration to horses with PID resulted in an additional decrease in ACTH plasma concentrations, but in many cases not less than normal concentrations, indicating that dexamethasone is suppressing residual pars distalis secretion. In contrast to their effect on proopiomelanocortin-derived peptides from the pars distalis, glucocorticoids have minimal inhibitory, and arginine vasopressin has minimal stimulatory effect on proopiomelanocortin-peptide secretion by the equine pars intermedia. Dopamine agonists inhibited proopiomelanocortin-secretion from the pars intermedia but had no effect on pars distalis secretion of proopiomelanocortin-derived peptides. This understanding on the pathophysiology of pituitary adenomas has made it possible to recommend dopamine agonist in the palliative treatment of PID.

Pars intermedia cell function in other species is also under positive serotoninergic influence; however, the role of serotonin on equine pars intermedia function is unclear. Millington, Dybdal, Dawson, et al.[12] found no difference in serotonin concentrations in the pars intermedia of affected versus control horses. γ-Aminobutyric acid has a tonic inhibitory effect on proopiomelanocortin synthesis in the pars intermedia of other species[30]; however, the role of γ-aminobutyric acid in the pathogenesis of equine PID is unknown.

Horses with PID have higher plasma concentrations of proopiomelanocortin-derived peptides, including immunoreactive ACTH (which includes bioactive ACTH), than do healthy horses,[*] and are not responsive to the negative feedback effect of glucocorticoids on ACTH secretion.[4,5,8,9,12]

The pathogenesis of polyuria and polydipsia is considered to be multifactorial. Some believe that compression of the pars nervosa by a pituitary adenoma results in decreased secretion of antidiuretic hormone.[1] Furthermore, hyperglycemia in these horses may result in osmotic diuresis. Glucocorticoids increase glomerular filtration rate and also may contribute to diuresis. Hypothalamic and neurohypophysis dysfunction in horses with PID deserve additional studies. Determination of plasma, pituitary, and hypothalamic concentration of neuropeptides such as arginine vasopressin and oxytocin and their hypothalamic messenger RNA expression in healthy and affected horses will provide a better understanding on the pathogenesis of this syndrome in the horse, in particular regarding polyuria and polydipsia.

Hyperphagia is believed to result from hypothalamic dysfunction and insulin resistance, and hyperinsulinemia may result from increased circulating concentrations of proopiomelanocortin peptides (in particular CLIP) and cortisol.[13] Cortisol stimulates proteolysis, glycogen formation, and gluconeogenesis. Glucocorticoids also increase glycemia by decreasing the skeletal muscle and adipocyte response to insulin-stimulated glucose

uptake. The insulin-antagonistic effect of glucocorticoids on the energy metabolism results in hyperglycemia and hyperinsulinemia (insulin resistance).[43]

Cortisol concentrations vary in affected horses,[13,15,27,44] and adrenocortical hyperplasia is not a consistent finding[1,13]; therefore to explain hyperglycemia, neutrophilia, lymphopenia, and other clinical signs such laminitis and predisposition to infections caused by glucocorticoid excess is difficult.

The pathogenesis of hirsutism is unknown. Holscher, Linnabary, and Netsky et al.[7] suggested that hirsutism in horses with PID may result from increased adrenal gland secretion of androgens, as occurs in women with Cushing's disease. Hirsutism and hyperhydrosis also have been suggested to result from dysregulation of the thermoregulatory center of the hypothalamus following pituitary compression.[6]

The underlying mechanisms responsible for the development of laminitis remain unclear. One proposal is that horses with PID develop laminitis from increased blood concentrations of glucocorticoids. However, the role of glucocorticoids in the pathogenesis of laminitis remains unclear; many horses with PID have cortisol concentrations within or below the normal range[13,15] to explain steroid-induced laminitis, suggesting that other 1331
unidentified factors may be as or more important than cortisol in the pathogenesis of laminitis in these horses. 1332
The pathogenesis of laminitis is described in other sections.

The increased docility in some horses with PID may result from increased plasma and cerebral spinal fluid concentrations of β-endorphin[12] and also may explain the decreased responsiveness to painful stimuli. The reason that some of these horses develop narcolepsy is unknown. One can speculate that the lack of dopaminergic control may be altering the sleep-wake cycle as occurs in human beings. Narcolepsy also may result from decreased orexin activity in the hypothalamus. Orexins (hypocretins) are recently discovered peptide neurotransmitters expressed in the lateral hypothalamus (orexinergic neurons) that are important in the sleep-wake cycle, and the absence of the effects of orexin results in narcolepsy.[45]

* References 8, 9, 12, 18, 20, 28, 31.

18.2.3 Pathologic Findings

Adenomas of the pars intermedia are white to yellow nodular or multinodular masses that can incorporate or compress the pars distalis and pars nervosa.[1,13] In some horses, pituitary microadenomas may be evident. Microscopically, these adenomas have a uniform cellular pattern with large columnar, spindle-shaped, or polyhedral cells that form palisades and pseudoacini. The tumor cells are slightly acidophilic with hematoxylin and eosin staining and are chromophobic with trichrome stain.[1] Pars intermedia adenomas may compress the overlying hypothalamus, resulting in necrosis of nuclei that are important in regulating body temperature, hair cyclic shedding, and endocrine and metabolic functions.

Approximately 50% of horses with PID have corticotrope hyperplasia in the pars distalis[1]; however, the explanation for this hyperplasia is unclear. One explanation may be that corticotrope hyperplasia in horses with PID results from less negative feedback from decreased plasma cortisol concentrations. Another possibility is that corticotrope hyperplasia results from decreased concentrations of endogenous opioids in the anterior lobe.[12,37]

Most cells of the pars intermedia of healthy horses are positive to immunostaining to ACTH and proopiomelanocortin, whereas approximately 10% of cells in the pars distalis are immunopositive to

proopiomelanocortin and ACTH.[1,46,47] Immunocytochemical evaluation of pars intermedia adenomas revealed that the cells have a uniform immunostaining for proopiomelanocortin; a moderate to strong staining for α-MSH, β-endorphin, β-lipotropin, β-MSH[1,13]; and a weak and patchy staining for ACTH.[1] These results agree with other studies that found increased concentrations of immunoreactive proopiomelanocortin, α-MSH, β-MSH, CLIP, and β-endorphin relative to ACTH.[8,9,12]

Adrenal cortex hyperplasia is not a consistent finding; one fifth of horses in one study[13] and 4 of 19 horses in another study[1] had adrenal cortex hyperplasia. The lack of cortical hyperplasia in most horses with PID may indicate that downregulation of ACTH receptors occurs in the adrenocortical cells or that the clinical signs in these horses do not result from hyperadrenocorticism. The variability among affected horses to the ACTH stimulation test seems to support this.

Skin biopsies reveal normal hair follicles in anagen phase, normal epidermis and dermal collagen, and a lack of the characteristic lesions present in dogs with Cushing's disease from cortisol excess (C.C. Capen, personal communication, 2002).

Laminitis is a consistent finding in horses with PID; however, the pathologic features in the lamina of these horses are nonspecific.

18.2.4 Laboratory Testing

The diagnosis of PID in many cases can be suggested by history, clinical signs, and preliminary laboratory results. Initial testing should include a complete blood count, a serum chemistry profile, and urinalysis. Horses with PID may have a normal complete blood cell count and serum chemistry profile. Clinicopathologic abnormalities reported in horses with PID include anemia, neutrophilia, lymphopenia, eosinopenia, hyperglycemia, hyperlipemia, increased liver enzymes, and glucosuria.[*] Persistent hyperglycemia is frequent in affected horses; more than 45% (94% in one study) of horses with PID had hyperglycemia.[2,5,13,20,24] Many horses with PID and hyperglycemia have insulin resistance (hyperglycemia and hyperinsulinemia).[10] Although insulin-resistant hyperglycemia can be present, another possibility is that hyperglycemia in some horses may result from stressing conditions. Glucosuria is a frequent finding (up to 77% in one study) in horses with PID and hyperglycemia.[2] Hyperlipemia may be present in horses but is more frequent in ponies.[19,49]

Additional testing to help confirm the diagnosis might include determination of resting plasma cortisol and ACTH concentrations. Significant variability exists in plasma cortisol concentrations among horses with PID,[13] and cortisol concentrations are affected by stress, exercise, and serum glucose concentrations. Therefore measurement of resting plasma cortisol concentrations is not diagnostic for PID. Resting ACTH concentrations are considered to be more reliable in the diagnosis of PID than resting cortisol concentrations.

1333

18.2.5 Diagnosis

Diagnostic testing for horses suspected of having PID is based on history, clinical signs, and laboratory findings. Many diagnostic tests for the diagnosis of PID have been evaluated; however, based on the limited number of horses studied and the variable results from some of these studies, to recommend them without additional validation is difficult. One limitation in the diagnosis of PID is establishing a gold standard, and

because opinions differ among clinicians, perhaps the only well-accepted gold standard is postmortem examination.

18.2.5.1 BASELINE CORTISOL CONCENTRATIONS

Measurement of baseline plasma concentrations of cortisol has been proposed in the diagnosis of PID. Healthy horses have diurnal variations in plasma cortisol concentrations, with significantly higher concentrations in the morning than in the evening.[50,51] No diurnal variations in cortisol concentrations are reported in horses with PID.[15] In horses with PID, resting plasma concentrations of cortisol may be within the normal range,[13] mildly increased,[15] or mildly decreased,[27,44] and therefore measuring baseline plasma cortisol concentrations to diagnose PID is not recommended.

In addition to plasma, cortisol concentrations have been determined in saliva and urine of healthy horses and horses with PID.[16,49,51] Van der Kolk, Nachreiner, Schott, et al.[51] measured salivary cortisol concentrations in healthy horses and found a trend for higher salivary cortisol concentrations in the morning than in the evening; however, the differences were not statistically significant. They also found that plasma and salivary cortisol concentrations were correlated and that administration of dexamethasone decreased and administration of ACTH increased plasma and salivary cortisol concentrations.

18.2.5.2 URINARY CORTICOID/CREATININE RATIO

The urinary corticoid/creatinine ratio has been determined in ponies and horses suffering of PID.[16,49] Van der Kolk, Kalsbeek, Wensing, et al.[16] found that horses with PID had higher urinary concentrations of corticoids and a higher corticoid/creatinine ratio than healthy horses; however, in their study the corticoid/creatinine ratio overlapped between healthy and diseased horses and a number of results were false positive and false negative, limiting the value of this test alone for the diagnosis of PID. In addition, horses were included in that study based on the ACTH stimulation test, which itself has significant variability among horses with PID and between healthy ponies and horses.[20] No ponies were included in the control group, and most of the affected animals were ponies. Additional studies comparing the corticoid/creatinine ratio to well-accepted and validated diagnostic procedures are necessary to recommend this test over other tests.

18.2.5.3 DEXAMETHASONE SUPPRESSION TEST

The dexamethasone suppression test (DST) has been a well-accepted and recommended test for the diagnosis of PID in horses.[15,38,52] This test is based on the lack of suppression of plasma cortisol concentrations in horses with PID at 19 to 24 hours after dexamethasone administration.[15] The suggestion is that in horses with PID, plasma cortisol concentrations are not suppressed by dexamethasone administration[15]; however, in a recent study,[44] cortisol concentrations were suppressed for up to 3 hours after dexamethasone administration in horses with PID. The lack of suppression in some horses with PID therefore possibly results from infrequent sampling protocols rather than from lack of suppression. Furthermore, the suppression of plasma cortisol concentration after dexamethasone administration in horses with PID does not appear to last as long as in clinically healthy horses[15,44] and is a good reason for a long sampling interval as described in the DST.[15] Two modifications of this protocol are available.

18.2.5.3.1 The 24-Hour Dexamethasone Suppression Test: Standard Protocol

One should begin the test at midnight and should collect a baseline blood sample in a heparinized tube and administer 40 μg/kg of dexamethasone intramuscularly. One should draw blood samples at 8 am, noon, 4 pm, 8 pm, and midnight and should expect plasma cortisol concentrations in healthy horses to be less than 1 μg/dl 24 hours after dexamethasone administration or to find a significant decrease in plasma cortisol concentrations compared with baseline concentrations.[15]

18.2.5.3.2 Overnight Dexamethasone Suppression Test

The overnight dexamethasone suppression test is a simplified modification of the 24-hour DST[15] and is the test the author routinely uses at the Ohio State University. One draws a baseline blood sample in heparinized tubes and administers dexamethasone (40 μg/kg intramuscularly) at 5 pm (4 to 6 pm). One takes blood samples at 15 and 19 hours (8 am and noon the next day) after dexamethasone administration. One should expect plasma cortisol concentrations to be less than 1 μg/dl in horses with an intact HPA axis. This test provides simplicity, is less expensive, is well accepted by clinicians, and is useful for distinguishing horses with PID from horses with an apparently functional HPA axis.

The 24-hour DST is useful for assessing the severity of pituitary dysfunction or for evaluating the response to treatment. Although many clinicians are concerned with steroid-induced laminitis resulting from the 1333
DST, no adverse effects of this test were reported when a large number of horses with PID were evaluated. 1334
[15]

18.2.5.4 RESTING ADRENOCORTICOTROPIC HORMONE CONCENTRATIONS

Increased plasma concentrations of ACTH and proopiomelanocortin-derived peptides have been reported in horses with PID.[*] Couetil, Paradis, and Knoll found that horses and ponies with PID had significantly higher resting plasma concentrations of ACTH compared with healthy horses and ponies. Plasma ACTH concentrations higher than 50 pg/ml in horses and 27 pg/ml in ponies strongly supported the diagnosis of PID. In this study, plasma ACTH concentrations for the diagnosis of PID had a sensitivity of 90.9% in horses and 81.8% in ponies and a specificity of 100%.[20] Based on the result of this and other studies,[18,31] plasma ACTH concentrations are considered a better diagnostic test for equine PID than the ACTH stimulation test. Some clinicians consider increased ACTH concentrations (>200 pg/ml) as the gold standard for the diagnosis of PID. However, others have claimed that resting ACTH concentrations have little value in the diagnosis of PID.[23] Measurement of plasma resting ACTH concentrations in a reliable laboratory together with the DST is reasonable combination to confirm the diagnosis of PID. Determination of resting ACTH concentrations is a good alternative when the results of the DST are nondiagnostic or when the DST is contraindicated. Compared with the DST and the thyrotropin-releasing hormone (TRH) stimulation test, resting ACTH concentrations have been reported to produce many false-positive and false-negative results.[23] One must consider when determining baseline ACTH concentrations that stressing conditions in addition to increase cortisol concentrations also increase ACTH plasma concentrations. One should collect blood samples to determine ACTH concentrations in cold EDTA tubes, kept at 4° C, centrifuge them immediately, and store them at −70° C until analysis.

* References 8, 9, 12, 18, 20, 31.

18.2.5.5 ADRENOCORTICOTROPIC HORMONE STIMULATION TEST

The administration of ACTH (1 IU/kg of natural ACTH gel intramuscularly; 25 IU ACTH$_{1-24}$ intravenously; or 100 IU of synthetic ACTH [cosyntropin] intravenously) has been used in different studies with different results.[†] A horse with PID is expected to have an exaggerated (at least fourfold) cortisol response to ACTH stimulation, and when an increased response is present in a horse with elevated resting ACTH concentrations, one can make a more accurate diagnosis of PID.[31] Dybdal, Hargreaves, Madigan, et al.[15] failed to detect a statistical difference in cortisol concentrations between control horses and horses with PID after administration of 1 IU/kg of natural ACTH gel intramuscularly between 8 and 10 am, with samples being collected in heparinized tubes before and 2, 4, 8, and 12 hours after ACTH administration. Van der Kolk, Wensing, Kalsbeek, et al.[18] found a significantly higher increase in cortisol concentrations in horses with PID after administration of 25 IU of synthetic ACTH$_{1-24}$ intravenously at 9 am, with samples being collected in EDTA tubes just before and 2 hours after ACTH administration. The ACTH stimulation test is more useful in assessing adrenal gland function or exhaustion and does not seem to be the test of choice to assess HPA axis function in horses suspected of having PID.

† References 5, 15, 16, 18, 31, 53.

18.2.5.6 COMBINED DEXAMETHASONE SUPPRESSION TEST AND ADRENOCORTICOTROPIC HORMONE STIMULATION TEST

One takes a blood baseline sample in a heparinized tube (9 am) and administers dexamethasone (10 mg intramuscularly)[54]; takes a blood sample 3 hours after dexamethasone injection and administers 100 IU of synthetic ACTH intravenously; and takes a blood sample 2 hours after ACTH administration (2 pm). This test failed to distinguish horses with PID from control horses.[15]

18.2.5.7 THYROTROPIN-RELEASING HORMONE STIMULATION TEST

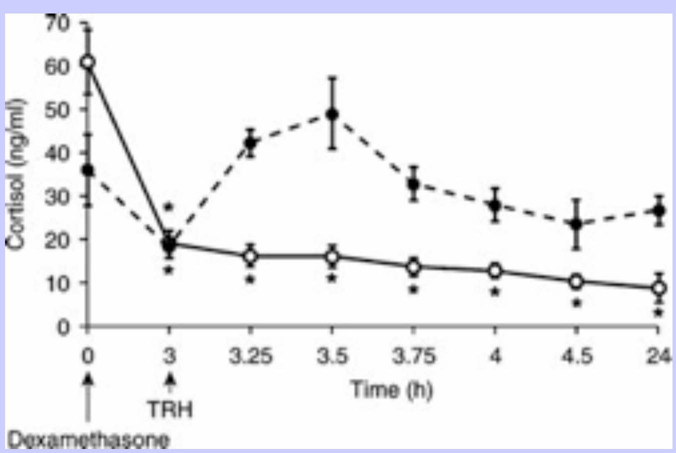
Beech and Garcia[27] evaluated the effect of TRH administration on plasma cortisol concentrations in healthy horses and in horses with PID. They found that TRH administration (1 mg intravenously) to horses with PID, in addition to increasing triiodothyronine and thyroxine concentrations, also resulted in a significant increase in plasma concentrations of cortisol within 15 minutes after TRH administration, and cortisol concentrations remained elevated for 90 minutes. No significant increases in plasma cortisol concentrations were present in healthy horses. Eiler, Oliver, Andrews, et al.[44] evaluated the TRH stimulation test in two horses suspected of having PID and three healthy horses and found that maximal cortisol concentrations overall were not statistically different between groups; however, too few horses were included to make any conclusion. Another study found increases in plasma cortisol concentrations after TRH administration to healthy horses. [17] The reason for the increase in cortisol concentrations after TRH administration is unclear, although speculation is that it results from increased blood concentrations of ACTH or CLIP. The TRH stimulation 1334
test has been advocated by some clinicians as an alternative method to the DST in horses with laminitis or at 1335
greater risk for developing steroid-induced laminitis.

18.2.5.8

COMBINED DEXAMETHASONE SUPPRESSION TEST AND THYROTROPIN-RELEASING HORMONE STIMULATION TEST

The combination of a DST with the TRH stimulation test was evaluated as a diagnostic method for PID. After baseline sampling in EDTA-containing tubes, dexamethasone (40 µg/kg intravenously) was administered at 8:30 am. A second sample was collected 3 hours later, and then TRH (1.1 mg intravenously) was administered. Serial blood samples (15, 30, 45, 60, 90 minutes, and 21 hours after TRH administration [24 hours after dexamethasone]) were collected. In this study, 3 hours after dexamethasone administration, plasma concentrations of cortisol decreased in healthy horses and in horses with PID (Figure 18.2-3). TRH administration resulted in a significant increase in cortisol concentrations in horses with PID but not in healthy horses, and 21 hours after TRH administration, cortisol concentrations were still less than baseline in healthy horses but were higher in horses with PID.[44] Based on the results of this study, the combined DST/TRH stimulation test seems to be a promising method for the diagnosis of PID.

Figure 18.2-3 Combined dexamethasone suppression/thyrotropin-releasing hormone *(TRH)* stimulation test in healthy horses (*n* = 7; ○) and in horses with pars intermedia dysfunction (*n* = 5; •). Plasma cortisol concentrations decreased 3 hours after dexamethasone administration in both groups; however, thyrotropin-releasing hormone administration resulted in a significant increase in cortisol concentrations in horses with pars intermedia dysfunction but not in healthy horses, and 21 hours after thyrotropin-releasing hormone administration, cortisol concentrations were still less than baseline in healthy horses but were higher in horses with pars intermedia dysfunction. *Significant difference from baseline value at time 0.



18.2.5.9

RESTING INSULIN CONCENTRATIONS

In horses with hyperglycemia, measurement of blood insulin concentrations together with glucose concentrations may be useful. Increased insulin concentrations in the presence of persistent hyperglycemia are highly suggestive of PID. However, if insulin concentrations are within the normal range, one should not rule out PID. Resting glucose and insulin concentrations are reported to have a sensitivity of 58% and 92% for the diagnosis of PID, respectively.[18] Baseline serum insulin concentrations were increased in ponies that had laminitis but had a normal combined DST, suggesting that insulin concentrations may not be a reliable indicator of PID.[55] When hyperglycemia and low insulin concentrations are persistent, one should consider pancreatic disease as a differential diagnosis.

18.2.5.10

GLUCOSE TOLERANCE TEST

The glucose tolerance test may be helpful in confirming the diagnosis of PID and is based on the finding that a number of horses with PID have hyperglycemia and hyperinsulinemia. When horses with PID are given dextrose (0.5 g/kg, 50% solution, intravenously) insulin concentrations do not peak as rapid as in healthy horses, and glucose concentration return to baseline values (3 hours versus 1 hour in controls) is delayed despite hyperinsulinemia, suggesting insulin resistance.[10] After 12 to 18 hours of fasting, one also can administer glucose via nasogastric tube (1 g/kg, 20% solution). In intravenous and oral glucose administration, one should take blood samples every 30 minutes for 4 hours. This test is more useful for evaluating horses known to have PID and hyperglycemia (prognosis), and in horses with hyperglycemia and possible pancreatic disease.

18.2.5.11

INSULIN TOLERANCE TEST

The rationale of this test is that many horses with PID are insulin resistant, and the administration of exogenous insulin will not result in a significant decrease in glucose serum concentrations as occurs in healthy horses.[8,22] One administers 0.05 U/kg of crystalline insulin intravenously and takes blood samples every 15 minutes for 3 hours. In healthy horses one can expect a 30% to 50% decrease in glucose concentrations at 15 minutes, 60% at 30 minutes, and normal glucose concentrations at 2 hours. Alternatively, one can administer 0.4 to 0.8 IU/kg of regular insulin intravenously and can expect a more than 50% decrease in glucose concentrations at 30 minutes. This test proves insulin resistance but is not diagnostic, and therefore one must take its validity together with other clinical and laboratory findings. When performing this test, one must have dextrose ready for parenteral use because insulin administration may result in hypoglycemic shock.[56,57] 1335

1336

18.2.5.12

DETERMINATION OF PROOPIOMELANOCORTIN PEPTIDES

Based on current knowledge of equine pars intermedia dysfunction, determination of plasma concentrations of proopiomelanocortin-derived peptides (ACTH, α-MSH, β-endorphin, β-lipotropin, CLIP) in horses suspected of having PID would be reasonable. These peptides were found to be increased in horses with PID.[*] Determination of proopiomelanocortin-derived peptides in the clinical scenario has been limited to ACTH plasma concentrations, and the use of human immunoassays to determine equine ACTH concentrations has been validated.[20]

Severalfold increases in plasma and cerebral spinal fluid β-endorphin concentrations were found in horses with PID.[12] Furthermore, proopiomelanocortin peptides were disproportionally higher compared with ACTH plasma concentrations in affected horses.[8,9]

* References 4, 8, 9, 12, 18, 20.

18.2.5.13 RADIOGRAPHIC METHODS

Allen, Barbee, and Crisman[58] used computed tomography to diagnose PID in horses. Levy, Blevins, and Janovitz[59] used ventral radiography and contrast venography successfully to diagnose PID in horses and ponies. These methods are far from being practical in the diagnosis of PID; they require anesthesia and expensive equipment and are not cost-effective compared with other diagnostic methods.

18.2.6 Treatment

Horses with pituitary tumors are difficult not only to diagnose but also to treat. The clinical signs of PID vary and, because this disease occurs primarily in older horses, one must treat the dysfunctional HPA axis and many of the pathologic conditions associated with aging. One should give special attention to good-quality feed, to deworming, to dental care, and to the hooves (because many affected horses have or may develop laminitis). One also must pay particular attention to the skin and hair coat, for many horses cannot shed their winter coat properly, may develop hyperthermia, and are prone to skin infections. The most difficult complication to manage is the laminitis, which may be complicated by overfeeding of high-energy hay or grain and by the high concentrations of cortisol and of blood glucose in affected horses. Therefore reducing the amount of soluble carbohydrates is advisable. In addition, in mildly affected horses exercise is recommended.

As discussed previously, the regulation of proopiomelanocortin peptide synthesis and secretion is under the influence of the hypothalamic tuberoinfundibular dopaminergic and serotoninergic systems. Proopiomelanocortin synthesis and secretion by the pars intermedia of horses with PID is under control similar to the pars intermedia from other species.[8] Based on this information, the medical treatment of PID involves the use of dopamine agonists or serotonin antagonists.

Bromocriptine and pergolide are the two most commonly used dopamine D_2 receptor agonists.[14,60–63] One can give bromocriptine orally or by subcutaneous injection (0.03 to 0.09 mg/kg b.i.d.),[8,60,64] but its use for treating PID is limited. Oral administration of pergolide is used and widely has been shown to be beneficial for treating horses and ponies with PID.[23,25,62] Doses of pergolide from 0.2 mg up to 5 mg/horse per day, once a day or divided twice daily, have been used in ponies and horses. Starting with a total daily dose of 0.5 mg/day is recommended, and if the horse shows no clinical evidence of improvement by 4 to 6 weeks, one should gradually increase the dose by 0.25 mg every 3 to 4 weeks. In horses that are hyperglycemic, one may assess the success of treatment by regularly determining glucose concentrations. In horses that are normoglycemic, one may need to repeat the DST. Most horses show improvement with doses of 0.75 to 1.5 mg of pergolide per day. Improvement is evident by 6 weeks of treatment, and includes a decrease in frequency of polyuria and polydipsia, shedding of the hair coat, a decrease in plasma ACTH concentrations, and a decrease in serum glucose concentrations. Measuring ACTH concentrations has been recommended in horses in which they are initially high.[25] Horses with PID treated with pergolide showed a better response to treatment than horses

treated with cyproheptadine.[23,25] Some horses treated with pergolide may develop anorexia, which one may resolve by reducing the dose.[23]

Cyproheptadine is a nonselective 5-hydroxytryptamine receptor blocking agent (serotonin antagonist) that reduces ACTH and β-endorphin secretion from ACTH-producing tumors in human beings.[65] Information on the serotonin functions in the hypothalamus and pituitary gland of the horse is limited, and no difference in serotonin concentration was found between the pars intermedia of horses with PID and control horses.[12] Cyproheptadine has been used for many years to treat horses with PID with variable results, and one third of horses with PID are estimated to show improvement when treated with cyproheptadine. This drug is recommended at 0.25 mg/kg orally once a day for 4 to 8 weeks. If the horse shows no clinical evidence of improvement and no reduction in plasma ACTH concentrations, one should increase the dosage frequency to twice a day for 1 month, at which time one can determine ACTH concentrations or repeat the DST. One notes 1336
response to treatment by a decrease in frequency of the polyuria and polydipsia 1 to 2 weeks after the initiation 1337
of treatment. In horses that fail to respond to high doses of cyproheptadine, switching to pergolide is recommended. Horses that respond to any of these drugs may require treatment for life. A combination of cyproheptadine and pergolide has been evaluated at the Ohio State University with promising results (T. Miesner, personal communication, 2002).

One key element in the decision to treat horses with PID is economic. Long-term treatment with pergolide is expensive, and in horses that respond well to pergolide therapy, one should consider decreasing the dose. Cyproheptadine therapy is inexpensive compared with pergolide and also should be considered when the budget is tight.

Alternative therapeutic compounds have been suggested or are being evaluated currently to treat horses with PID (*www.laminitis.org*). Aqueous extracts of *Vitex agnus-castus* (chasteberry, chaste tree) have been used to treat horses with PID. *V. agnus-castus* extracts contain compounds (diterpenoids) that stimulate dopamine D_2 receptor activity and inhibit different opioid receptors.[66] Because of its dopaminergic effects, *Vitex* has been recommended as an alternative phytotherapeutic agent for treating hyperprolactinemia and premenstrual syndrome in women.[67] A physiologic and pharmacologic rationale exists for the possible use of these extracts to increase dopaminergic activity in the equine pituitary; however, appropriate studies are necessary before *Vitex* can be recommended to treat horses with PID. Trilostane is an enzymatic inhibitor of 3-β-hydroxysteroid dehydrogenase, an important enzyme in steroid synthesis. Trilostane has been proposed for treating equine Cushing's disease and for treating the recently described "equine peripheral cushingoid syndrome."[68] However, little information is available on the effects of trilostane in the equine steroid metabolism.[69] Until the mid-1980s trilostane was recommended to treat Cushing's disease in human beings; however, because of its lack of potency in blocking cortisol synthesis, trilostane is no longer recommended to treat this condition.[70] Instead, more potent compounds (i.e., ketoconazole) currently are being used in small animals and human beings.

18.2.7 Pituitary-Independent Cushing's Syndrome

Primary adrenocortical tumors are rare in horses,[5,64,71,72] and the few cases reported in the literature were nonfunctional tumors. Only one case of a functional adrenocortical tumor associated with clinical signs consistent with Cushing's disease has been reported.[64] A 12-year-old Dutch Warmblood gelding had a history of polyphagia, polydipsia, reduced muscle mass, hyperhydrosis, lethargy, and delayed shedding of the hair coat. The horse had persistent hyperglycemic and normal adrenocortical response to ACTH stimulation. After

unsuccessful treatment with bromocriptine the horse was euthanized, and a unilateral adrenocortical adenoma was found.

18.2.8 Ectopic Cushing's Syndrome

In human beings and small animals, Cushing's disease results from excessive secretion of ACTH from the pituitary gland, ectopic secretion of ACTH by nonpituitary tumors, ectopic secretion of corticotropin-releasing hormone, or excessive and autonomous secretion of cortisol from adrenocortical tumors. The secretion of ACTH or corticotropin-releasing hormone from nonpituitary tumors results in a condition known as ectopic Cushing's syndrome or ectopic ACTH syndrome. Ectopic production of ACTH or corticotropin-releasing hormone has not been demonstrated in the horse.

18.2.9 Peripheral Cushingoid Syndrome

A clinical syndrome of laminitis, hypothyroidism, and obesity without hirsutism has been described recently in horses.[68] These horses have hyperinsulinemia and normal DST and TRH stimulation test results. Treatment with pergolide does not improve clinical signs. The term *peripheral cushingoid syndrome* has been proposed to separate these animals from horses with pars intermedia dysfunction. An important item to mention, however, is that in human medicine the term *cushingoid* is considered a phenotype more than a syndrome and is linked to the ectopic production of ACTH. No information is available on the pathogenesis of this condition in the horse. As in human beings, this syndrome seems to be a pseudo-Cushing's condition (typically obesity and hypothyroidism) that may be caused by different processes and should not be confused with pituitary-dependent and pituiatry-independent hyperadrenocorticism. The clinical appearance of horses with peripheral cushingoid syndrome probably results from abnormal energy metabolism, as occurs in human beings with central obesity, in which decreased concentrations of hormones important in cortisol metabolism (e.g., growth hormone and insulin-like growth factor I) result in increased cortisol production, omental adipocyte differentiation, and insulin resistance. Similar features are reported in the metabolic syndrome X or the insulin-resistance syndrome in human beings.[73] 11β-Hydrosteroid dehydrogenases (11β-HSDs) are important enzymes in regulating the interaction of glucocorticoids with their cellular receptors; they control the activation and inactivation of 1337
cortisol and cortisone (the cortisol-cortisone shuttle). 11β-HSD1 converts inactive cortisone to cortisol in the 1338
liver and adipose tissue, whereas 11β-HSD2 converts the active cortisol to inactive cortisone in the kidney.[68,74] Overexpression of 11β-HSD1 in adipose tissue may result in adipocyte differentiation and obesity. Growth hormone (and insulin-like growth factor 1) inhibits 11β-HSD1 and therefore decreases cortisol production; many human patients with hypothyroidism and insulin resistance have decreased concentrations of growth hormone and increased 11β-HSD1 activity, which promotes cortisol production, insulin insensitivity, and visceral adiposity.[73,74] This condition is known as central obesity or omental Cushing's disease. Johnson and Ganjam[68] found that 11β-HSD1 was expressed in the equine skin and lamellar tissue and that integumentary 11β-HSD expression was increased in alimentary-induced laminitis. They proposed that increased expression of this enzyme in the equine digit may magnify the biologic effects that glucocorticoids may have in the equine lamellae during laminitis.

18.3

18.3—Thyroid Gland

Ramiro E. Toribio

Wendy M. Duckett

The thyroid glands arise from two different embryologic origins: the thyroid bud and the ultimobranchial body. The thyroid bud originates from the endoderm of the primitive larynx and is the origin of the follicular cells, which are responsible for the synthesis of thyroglobulin and thyroid hormones (THs). The ultimobranchial body originates from the fourth pharyngeal pouch, contains cells from the neural crest, and gives rise to calcitonin-producing cells (parafollicular or C cells). In mammals the ultimobranchial body is a transient organ destined to join the thyroid bud. Immediately after thyroid ontogeny, thyroid function begins but remains basal until the hypothalamic structures and the pituitary portal system are organized to maintain a functional hypothalamus-pituitary-thyroid (HPT) axis.[1]

In the horse the thyroid glands are two discrete, firm lobes located in the dorsolateral aspect of the third to sixth tracheal rings.[2,3] The gland has two lobes connected by a narrow isthmus that contains fibrous tissue. In most healthy horses the thyroid glands are not visible but can be palpated as firm and movable structures. The weight of the glands as a ratio of grams of thyroid tissue per kilogram of body mass is largest for fetuses and foals (mean, 0.28 g/kg; range, 0.12 to 0.67 g/kg) and diminishes progressively with age. The mass ratio for adults is on average 0.08 g/kg (range, 0.01 to 0.15 g/kg).[4] The normal total gland mass for newborn foals is around 15 g.[5] The glands are vascular, being supplied by two major arteries arising from the external carotid and subclavian arteries, supplying the cranial and caudal poles, respectively. Gland size does not parallel function, and one must use other tests to establish an accurate diagnosis.

18.3.1 Thyroid Function

Thyroid hormones (triiodothyronine [T_3] and thyroxine [T_4]) are produced by the thyroid glands and play critical functions in nearly all tissues, most of which are related to cell growth and differentiation and to cell metabolism. An understanding of the function of the thyroid gland and physiologic effects of THs is important in recognizing, diagnosing, and managing thyroid gland dysfunction. The relative importance of the thyroid glands is reflected in the large volume of blood flow: 4 to 6 ml/min/g of tissue, which is greater than the blood flow to the kidneys.

The synthesis and secretion of TH is regulated by a negative feedback system that includes the hypothalamus, the pituitary gland, and the thyroid gland (HPT axis). Thyroid hormone synthesis and secretion is stimulated by thyroid-stimulating hormone (TSH, thyrotropin), which is a glycoprotein (28 kd) composed of two subunits (α and β) and is secreted by the thyrotropes of the pituitary gland. The α-subunit is shared with other hormones (luteinizing hormone, follicle-stimulating hormone). Thyroid-stimulating hormone secretion from the anterior pituitary (adenohypophysis) is controlled by the effects of hypothalamic neurons that release a tripeptide, thyrotropin-releasing hormone (TRH).[6] Thyrotropin synthesis and secretion is also under the control of the negative feedback (long-term inhibition) effect of THs.[7] Thyroid-stimulating hormone concentrations depend on the rate of disappearance of THs and TSH from circulation and on the rate that T_4 is converted to T_3. The hypothalamus also can inhibit (short-term inhibition) TSH secretion through dopamine and somatostatin release in the median eminence.[8]

Thyrotropin-releasing hormone–positive neurons are present in different areas of the brain. Within the hypothalamus the parvocellular division of the paraventricular nucleus contains most of the TRH-positive neurons, and their projections end in the zona externa of the median eminence. Thyrotropin-releasing hormone–positive neurons are also present in the preoptic area, suprachiasmatic nucleus, ventromedial nucleus, and dorsomedial nucleus.[9] In the pituitary gland, T_3 decreases the thyrotrope response (TSH secretion) to TRH

stimulation, and in the hypothalamus, T_3 decreases TRH messenger RNA expression and TRH secretion.[10–12] In the pituitary, T_4 is converted to T_3 by a type II deiodinase. For T_4 to gain access to hypothalamic neurons, it must be transported through the choroid plexus to the lateral ventricles bound to transthyretin (T_4-binding protein). Once within the brain, T_4 is converted to T_3 by the type II deiodinase.[13]

Thyrotropin-releasing hormone is released in the median eminence of the hypothalamus and through the pituitary portal system reaches the anterior pituitary. In the pituitary, TRH interacts with specific receptors in the thyrotropes, inducing TSH release, and also induces prolactin release; however, its role in prolactin secretion remains unclear. Injections of TRH have minimal or no effect stimulating prolactin release in mares.[14–16]

Cold temperatures stimulate and high temperatures inhibit the HPT axis. Low temperatures stimulate peripheral cold receptors and through noradrenergic pathways stimulate neurons in the paraventricular nucleus to release TRH.[7] Stress inhibits TSH release through the hypothalamic release of somatostatin.[17] Inflammation 1340
suppresses TSH secretion. Cytokines such as interleukin-1 (IL-1), IL-6, and tumor necrosis factor α inhibit TSH 1341
secretion and stimulate somatostatin secretion.[18–21]

18.3.1.1 IODINE AND HORMONE METABOLISM

One major function of the thyroid is actively to trap and conserve iodine against a large concentration gradient.[2,22,23] Iodine can be absorbed in its soluble form, iodide (I^-), via the intestinal mucosa or any moist body surface such as other mucosa or broken skin.[2] Iodide actively is transported and concentrated into the thyroid by a Na^+/I^- symporter.[24] The trapped iodide is oxidized by a thyroid peroxidase in the presence of hydrogen peroxide and incorporated into the tyrosine residues of thyroglobulin (660 kd) to form the inactive precursors monoiodotyrosine and diiodotyrosine. Coupling of these precursors results in synthesis of the active iodothyronines T_4 and T_3. The iodinated thyroglobulin containing monoiodotyrosine, diiodotyrosine, T_3, and T_4 is stored as an extracellular polypeptide in the colloid within the lumen of the thyroid follicles.[25] When needed, T_4 and T_3 are cleaved from the thyroglobulin, picked up by the follicular cells by a process of endocytosis, and transported into the circulation.[2,23] Most of the TH released into circulation is T_4, for total serum T_4 concentrations are 20 times higher than serum T_3 concentrations. Hormone synthesis and release are controlled by iodine availability and by TSH. The feedback regulation of TSH secretion is related closely to the circulating concentrations of unbound (free) thyroid hormones (fT_4 and fT_3).[2,23]

The circulating THs are T_4, T_3, and reverse T_3 (rT_3). Free T_4 and T_3 are the biologically active hormones, whereas T_3 and rT_3 are deiodination products of T_4. All of the circulating T_4 is derived directly from the thyroid gland. Only 10% to 20% of the circulating T_3 is secreted directly from the thyroid gland. The major pathway in the production of T_3 is the 5′-monodeiodination of T_4 by a type I deiodinase (which is a selenoprotein) in peripheral tissues, which is referred to as T_3 neogenesis. In the fetus, type I deiodinase activity is delayed so that T_3 neogenesis is low, and most deiodinase activity results in high concentrations of rT_3. A switch in enzymatic activity occurs at birth, partly because of the influence of glucocorticoids.[23] THs circulate in the blood bound to transport plasma proteins (thyroid-binding proteins).

Thyroxine-binding globulin is the major protein (70% of T_4 and T_3 is bound to thyroxine-binding globulin); transthyretin (thyroid-binding prealbumin) and albumin bind to a lesser degree. In horses the percentages of circulating T_4 bound to thyroxine-binding globulin, thyroid-binding prealbumin, and albumin were found to be 61%, 22%, and 17%, respectively.[26] T_3 is bound to thyroxine-binding globulin and albumin but not to thyroid-binding prealbumin. Transthyretin is important in transporting T_4 into the brain. These hormones are bound reversibly to these transport proteins, which act as TH reservoirs. The hormones in their unbound or free state readily can traverse capillary endothelium and are available to exert their biologic effects at the peripheral tissues.[27] The protein-binding properties thus in part determine the biologic activity of each hormone. Triiodothyronine is much more potent than T_4 and has a shorter half-life. Thyroxine has much greater protein-binding affinity; T_3 is therefore more readily available to interact with receptors at peripheral tissues. Thyroxine sometimes is thought of in terms of a prohormone. The half-life of T_4 in horses is approximately 50 hours.[28] Because a large fraction of THs is bound to plasma proteins, changes in protein binding may result in changes in total TH concentrations.

Metabolic degradation of the thyronine ring after deiodination includes deamination, decarboxylation, and conjugation. The enzymes responsible for the production of T_3 and rT_3 are also responsible for their destruction. The three classes of 5′-deiodoninases are as follows: Type I deiodinase is found predominantly in peripheral tissues such as thyroid, kidney, and liver; is responsible for the conversion of most of T_4 to T_3 and rT_3; and is inhibited noncompetitively by propylthiouracil. Type I deiodinase activity is increased by TSH and T_3 and is decreased in hypothyroidism. Type II deiodinase is found in brown fat tissue, the brain, and the pituitary gland; is not affected by propylthiouracil[23]; and its primary function is to convert T_4 to T_3 for intracellular use.[25] Type II deiodinase activity is increased in hypothyroidism, probably to sustain intracellular T_3 concentrations despite low peripheral T_4 concentrations, especially in the brain. Type III deiodinase is found in the placenta, developing brain, and skin, and its primary function is to inactivate T_4 and T_3 (converts T_4 to rT_3 and inactivates T_3). Type III deiodinase may be important regulating T_3 availability during development. The generation of rT_3 by type I and III deiodinases is a key step in the inactivation of THs. Metabolites are excreted via the urine, and some are conjugated and enter the enterohepatic circulation. Most iodide is returned to the thyroid gland.

The thyroid is also the site of production of calcitonin, secreted by the C cells, which are interspersed among the thyroid follicles. Calcitonin is involved in calcium homeostasis.[2,23,29]

18.3.1.2 MOLECULAR ACTIONS OF THYROID HORMONES

The TH receptors belong to the superfamily of nuclear receptors that work as transcription factors. The two
types of TH receptors are TR-α and TR-β. Triiodothyronine, whether directly transported into the cell or 1341
derived intercellularly from T_4, is considered to be the effector hormone in target cells. The thyroid receptors 1342
interact with specific DNA sequences (T_3-response elements), regulating gene expression. Growth and thermogenesis depend on the presence of THs. Triiodothyronine stimulates thermogenesis by increasing the expression of proteins associated with uncoupling oxidative phosphorylation. Thyroid hormones decrease the expression of the α- and β-subunit genes of TSH and the TRH gene. From its effects on gene expression, T_3 actions result in thermogenesis; increased oxygen consumption; increased protein synthesis; increased metabolic rate; increased carbohydrate absorption and glucose metabolism; stimulation of growth and

maturation and erythropoiesis; increased lipid metabolism and conversion of cholesterol into bile salts; activation of lipoprotein lipase; increased sensitivity of adipose tissue to lipolysis; stimulation of heart rate, cardiac output, and blood flow; increased neural transmission; and cerebral and neuronal development in young animals.[2,22]

18.3.2 Extrathyroid Factors That Affect Thyroid Function and Testing

Many endogenous and exogenous factors can affect thyroid function and sometimes test results. Awareness of these factors and interactions can help one interpret tests and establish an accurate diagnosis.

18.3.2.1 AGE

Age-related differences in TH concentrations occur in horses. Foals have high concentrations of T_3 and T_4 at birth that decrease with age.[30–36] A recent study[35] found that plasma T_3 concentrations decreased from 7.9 ng/ml at birth to 0.9 ng/ml at 6 months of age and to 0.7 ng/ml at 9 months of age. Plasma T_3 concentration in mares was 0.5 ng/ml. In the same study, T_4 concentrations decreased from 233 ng/ml at birth to 49 ng/ml at 14 days and to 35 ng/ml at 6 months.

18.3.2.2 GENDER

The correlation of gender and TH concentrations appears to vary. In one study, T_4 concentrations were not influenced significantly by sex: males had slightly higher T_3 values than females.[30] Serum TH concentrations may be lower for stallions and geldings than for females,[36,37] but others report no gender differences.[38–41] Lower TH concentrations have been reported in mares than in stallions.[42] The concentration of free T_4 was found to be higher in stallions than in other horses.[43] Mares tested at all stages of the estrous cycle were found to show no statistically significant differences according to stage of the cycle. Thyroxine concentrations, however, were decreased following ovulation, which is the converse of the hormone pattern in other species following ovulation. Individual variations were found to be greater than variations within the estrous cycle.[39] Higher than normal serum THs were reported during pregnancy in mares,[44] which is similar to findings in other species and may be due in part to increased thyroxine-binding globulin concentrations during pregnancy.[23] Furthermore, TH concentrations were found to vary with stage of gestation. Thyroxine concentrations were statistically significantly higher in the mares between days 49 to 55 of gestation compared with those in advanced stages. Triiodothyronine did not vary statistically significantly with gestational stage in mares.[45] One investigator found that hormone concentrations in mares at midgestation were no different from normal.[37] The high hormone concentrations were believed to be due more to the effect of the cold.[46] No significant differences in stages of gestation or in pregnant versus nonpregnant mares was found in one study.[28]

18.3.2.3 OTHER HORMONES

Glucocorticoids inhibit endogenous TRH secretion and decrease the response of TSH to TRH. Glucocorticoids also inhibit peripheral deiodination in adults. In neonates, glucocorticoids enhance conversion of T_4 to T_3. Glucocorticoids decrease serum thyroxine-binding globulin, increase thyroid-binding

prealbumin,[23] decrease total T_4, and increase fT_4. Catecholamines enhance the rate of deiodination of T_4 to T_3 and have a potentiating effect.[47] Estrogen enhances thyroxine-binding globulin production, and androgens tend to suppress it.[23]

18.3.2.4 BREED

No evidence indicates a difference in TH concentrations among breeds.[30,41]

18.3.2.5 DAILY RHYTHM

A daily rhythm in equine TH concentrations has been identified.[48,49] In adult geldings, T_4 was found to peak around 4 pm (mean, 2.43 ± 0.81 µg/dl) at concentrations significantly higher than the lowest T_4 values around 4 am (mean, 1.79 ± 0.63 µg/dl). Triiodothyronine was shown to peak between 8 am and 4 pm (~54 ± 13 ng/dl) at concentrations significantly different than the lowest T_3 around midnight (mean, 38.71 ± 10.81 ng/dl).[48] Higher concentrations of T_4 between 5 and 8 pm than at 8 am also have been reported.[49]

18.3.2.6 DISEASES: NONTHYROIDAL ILLNESS SYNDROME

Thyroid hormone concentrations are known to decrease during starvation and illness. First, T_3 concentrations decrease, and as the severity of the disease progresses, T_4 concentrations also decrease.[50] Because no clinical 1342
evidence of hypothyroidism exists despite decreased TH concentrations, this condition has been called the 1343
low T_3 syndrome or the euthyroid sick syndrome. A new designation, the nonthyroidal illness syndrome (NTIS) has been proposed because it does not presume the metabolic status of the patient, and it seems more appropriate based on current knowledge on thyroid gland function during disease. In this syndrome, T_3 concentrations are decreased, whereas T_4 concentrations can be low, normal, or elevated. In critically ill human patients, a significant decrease in T_4 and T_3 or an increase in rT_3 concentrations is associated with increased mortality rate.[51]

Starvation in different species, including the horse, results in decreased concentrations of T_3 and fT_3.[51–53] Carbohydrate deprivation inhibits the deiodination of T_4 to T_3 by the type I deiodinase, resulting in decreased concentrations of T_3 and increased concentrations of rT_3. Because starvation decreases the basal metabolic rate, the decrease in TH concentrations has been proposed to be an adaptive process of the organism to conserve calories by inducing a hypothyroid state. Concentrations of TSH in general are low or within the normal range despite the low TH concentrations. TSH has been proposed to decrease biologic activity from decreased TSH glycosylation. Recent evidence suggests that hypothalamic and pituitary dysfunctions are the proximal causes of NTIS.[51] Low TRH mRNA expression has been detected in the hypothalamus of starved rats and in human patients with NTIS.[54,55] Furthermore, administration of TRH to patients with NTIS results in increased TSH, T_4, and T_3 concentrations, supporting hypothalamic dysfunction as the most probable cause of NTIS.[56]

Cytokines, glucocorticoids, and more recently leptin (a 16-kd protein) are the most important candidates in the pathogenesis of NTIS. The diurnal variations in glucocorticoid concentrations control some of the diurnal

variations in THs by suppressing the pituitary response to TRH.[57] This is evident in human patients with Cushing's disease, in which increased glucocorticoid concentrations suppress TSH secretion. Increased cortisol concentrations may be present in horses under different conditions, including stress, sepsis, and pituitary gland dysfunction (equine Cushing's disease), and probably decreased TH concentrations are present in the same horses. Cytokines have received considerable attention in the pathogenesis of NTIS; IL-1, IL-6, and tumor necrosis factor α suppress TSH, T_4, and T_3 synthesis and secretion. Many of the effects of these cytokines on the HPT axis are mediated at the hypothalamic level, although some evidence suggests peripheral effects of these cytokines. Interleukin-1 can impair TH synthesis by the thyrocytes, whereas IL-6 and tumor necrosis factor α can decrease T_4 and T_3 concentrations and increase rT_3 concentrations. Therefore these cytokines can create a stage of low supply of THs to tissues. The role of leptin in the pathogenesis of NTIS may be associated with a decreased caloric intake during disease, which results in decreased concentrations of leptin, which then modulates hypothalamic functions (at the arcuate and paraventricular nuclei) and alters TRH mRNA expression.[58] Information on leptin in the horse is limited.[59,60]

Although NTIS is a hypothyroid state, evidence to suggest that the tissues are chemically hypothyroid is minimal[51]; however, decreased TH concentrations are accepted widely to be beneficial, and a process of maladaptation occurs in those cases in which low T_4 concentrations are associated with increased mortality.

In cases of low TH concentrations associated with nonthyroid illness, stimulation tests should elicit a normal response. In NTIS a reciprocal increase in rT_3 occurs because the suppressed enzyme—type I deiodinase, which is responsible for T_3 neogenesis—is also the enzyme that degrades rT_3.[23]

Based on the number of studies in human beings and animals, no clear evidence is available that TH replacement therapy is beneficial or unbeneficial to NTIS. Some have suggested that replacement therapy may be more harmful because exogenous TH may inhibit the HPT axis in a patient with decreased endogenous TH concentrations.

18.3.2.7 SEASON

Thyroid activity increases while horses are becoming acclimatized to colder temperatures.[28,61,62]

18.3.2.8 WEANING

In a study to evaluate the effect of weaning on thyroid function, no difference in hormone concentrations was found between abrupt and gradual weaning methods.[40]

18.3.2.9 ACTIVITY

Interest in the relationship of thyroid function and muscle metabolism has prompted investigation in racehorses. Irvine[31,63] found the T_4 secretion rate to be increased in horses in full training, whereas protein-bound iodine was decreased. This decrease in protein-bound iodine was not consistent with the finding of increased protein-bound iodine in human athletes.[37] Thyroxine concentrations were found to be greatly increased in the latter stages of training, and the proposal was made that T_4 measurement might be used to

monitor the training reserves in racehorses.[64] Other investigators found low T_4 concentrations in healthy Thoroughbreds and concluded that serum T_4 values were an unreliable indicator of thyroid function and that T_3 was a more accurate one.[65] They found no correlation between T_4 and T_3 concentrations and racing 1343
performance. Another investigator documented substantial increases in T_4 within 30 minutes after exercise 1344
but no differences in T_3.[38,44] Five minutes after a maximal speed race (1200 m), serum T_3 concentrations were increased in Thoroughbred racehorses (from 55.6 ± 2.9 to 81 ± 3.7 ng/dl); however, T_4 concentrations did not change (0.67 ± 0.04 to 0.70 ± 0.05 μg/dl).[66] Significant increases in T_3 and T_4 concentrations were found 1 hour after swimming.[67]

18.3.2.10 FEEDING

Feeding a high-energy, high-protein diet to weanlings 6 to 8 months of age was found to stimulate thyroid gland secretion initially, and then peripheral conversion of T_4 to T_3 resulted in a relative T_4 decrease 3 hours after a meal.[68] The soluble carbohydrate (glucose) rather than protein portion of the diet was found to increase thyroid hormone response in weanlings.[69] The accelerated T_4 to T_3 conversion following the high-carbohydrate meal was found to correlate with the increased insulin secretion that followed the glucose rise.[70] Insulin also accelerates deiodination of T_3, thus shortening its activity.[71] Furthermore, this response was found to be age related. By the time the animals were 12 to 14 months of age, feeding the high-carbohydrate and high-protein diet no longer affected TH concentrations.[70] One study on the effects of meal frequency and T_3 concentrations observed a hormone rise after meals, the rise being greater when animals were given one feeding a day than after six feedings a day.[72]

When the effect of food deprivation on baseline TH concentrations was evaluated in euthyroid adult horses,[53] serum T_3, fT_3, and fT_4 concentrations were found to decrease and rT_3 concentrations to increase after 1 day of food deprivation. Serum T_3 concentrations were lowest after 2 days of deprivation, whereas T_4, fT_3, and fT_4 reached their lowest concentrations on day 4 of food deprivation. Three days after the horses were placed on their normal ration, serum T_4 and fT_4 concentrations significantly increased and rT_3 concentrations decreased. This study provided valuable information in the interpretation of thyroid hormone tests in anorectic and sick horses. If a significant decrease (>50%) in serum T_3 and T_4 concentrations can be present in just 1 to 2 days of food deprivation, then the validity of measuring TH in diseased horses is questionable. Prolonged food restriction to Shetland ponies also resulted in decreased serum T_3 and fT_3 concentrations.[73]

The mechanisms that regulate thyroid gland function during starvation remain unclear. A decrease in caloric intake in known to result in decreased expression of TRH mRNA in the hypothalamus, but not in other areas of the brain. A reduction in TRH secretion subsequently results in decreased secretion and glycosylation of TSH. The picture on how the thyroid gland function is regulated at the hypothalamic level is becoming clearer with recent findings. Perhaps the most important signal in the central nervous system to suppress TRH expression in the paraventricular nucleus is a decrease in hypothalamic concentrations of leptin. Leptin is expressed in adipocytes, and a fall in leptin signals the hypothalamus to conserve energy, to increase appetite, and to modify the neuroendocrine system to favor survival. Thus a decrease in leptin suppresses the HPT axis, the neuroreproductive pathways, and growth and activates the hypothalamus-pituitary-adrenal axis. The effects of leptin on hypothalamic TRH expression are mediated primarily through the arcuate nucleus, although leptin also has direct effect in the paraventricular nucleus. Through the hypothalamic

melanocortin system, leptin increases proopiomelanocortin synthesis in the arcuate nucleus, which then is cleaved to produce α-melanocyte-stimulating hormone that stimulates TRH secretion from the paraventricular nucleus nucleus. A decrease in leptin results in decreased hypothalamic α-melanocyte-stimulating hormone concentrations, reducing TRH synthesis.[58] The importance of leptin in the equine HPT axis has not been investigated; however, feed restriction led to a significant decrease in leptin concentrations in mares,[60] indicating that leptin and its relationship to the HPT axis in the horse deserves attention.

18.3.2.11 EXOGENOUS COMPOUNDS

Substances that exert their goitrogenic effect by blocking or competing with iodide uptake are thiocyanate and perchlorate. Iodide oxidation and coupling of iodotyrosines are inhibited by drugs such as sulfonamides, phenylbutazone, phenothiazines, thiouracils, thiopental, and methimazole. Soybean meal, linseed meal, and plants of the *Brassica* genus (i.e., rapeseed) contain goitrogenic substances.[2,22] Phenylbutazone administration decreases TH concentrations in horses,[49,74] and this effect can last up to 10 days after discontinuation of phenylbutazone administration.[74] The thyroid-stimulating hormone stimulation test may be normal or exacerbated in horses receiving phenylbutazone.[49] Exogenous and endogenous glucocorticoids have the same effects: suppressing pituitary TSH secretion, decreasing the response of TSH to TRH, inhibiting monodeionination (except in the perinatal period), inhibiting thyroxine-binding globulin, and decreasing release of TH from the gland.[23,75] Glucocorticoid administration decreases serum T_4 and T_3 concentrations, and the effect is more profound on T_3 concentrations from decreased conversion of T_4 in T_3 in peripheral tissues. The decreased uptake and release of iodine by the thyroid gland during glucocorticoid treatment results from decreased TSH secretion.[76] One study in healthy horses found that dexamethasone administration for 5 days resulted in a significant increase in serum baseline rT_3 and fT_3 concentrations[77]; 1344
however, total T_3 and total T_4 concentrations did not change. In that study the fT_3 response to TSH 1345
stimulation was decreased after dexamethasone administration.

High levels of nitrates in the water may result in thyroid gland hypertrophy,[78] and nitrates can reduce the active transport of iodine into the thyroid gland.

Propylthiouracil, in addition to affecting iodine metabolism, inhibits peripheral conversion of T_4 to T_3. In human beings, aspirin competes for TH binding sites on transthyretin and thyroxine-binding globulin, decreasing T_4 and T_3 and increasing fT_4 and fT_3. This competition results in a hypermetabolic state from increased free fractions of T_4 and T_3 and also may lower the TSH response to TRH stimulation.[75] Phenobarbital increases TH binding to liver microsomes and increases deiodinating activity.[79] Reserpine, a catecholamine-depleting agent, inhibits secretion of TSH and inhibits deiodination.[47] Antipyrine has antithyroid activity.[23] Anabolic steroids can have an inhibitory effect on thyroxine-binding globulin concentrations[23]; however, in one study, short-term anabolic steroid use was found not to affect thyroid function tests of horses significantly.[80] Exogenous compounds containing iodine or iodides are of particular interest. Iodine excess, as well as deficiency, can cause thyroid dysfunction and interfere with thyroid tests. Horses are exposed to iodine or iodide compounds in the form of feedstuffs, expectorants, leg paints, shampoos, injectable counterirritants, radiographic contrast media, and the antiprotozoal drug iodochlorhydroxyquin. Individuals can respond to excessive amounts of iodine by suppressing or accelerating hormone production. Iatrogenic hypothyroidism following cleansing of an open wound with

povidone-iodine is documented in human beings.[81] Iodine excess reduces iodine uptake and organification, decreases TH concentrations, and decreases the response to the TSH stimulation test; this phenomenon is known as the Wolff-Chaikoff effect.

Iodine excess also may inhibit the cleavage of T_4 and T_3. The end result of iodine excess may be hypothyroidism. The second way an individual can respond to large amounts of iodide is by accelerated production, which produces elevated concentrations of THs and is referred to as Jod-Basedow phenomenom. In general the phenomenon occurs in patients with underlying thyroid disease, in particular those with iodine deficiency.[23]

Boosinger, Brendemuehl, Bransby, et al.[82] found that newborn foals of mares grazing *Neothyphodium (Acremonium) coenophialum*–infected fescue had half the concentration of T_3 of control foals; however, no difference existed in T_4 and rT_3 concentrations compared with controls. Endophyte alkaloids are dopamine D_2-receptor agonists, and dopamine is a known inhibitor of TSH secretion. Whether decreased TH concentrations in foals born of mares grazing fescue results from the effects of the endophyte alkaloids on the fetal HPT axis or from the effects of these alkaloids in placental and fetal development is unclear.

18.3.3 Diagnostic Tests

Thyroid tests can be classified according to the information they provide in functional, etiologic, and anatomic tests. Thyroid tests are direct when one measures serum concentrations of THs or of thyroid-regulating hormone and indirect when one calculates TH concentrations by index or mathematic models or when one determines the relation of other metabolites to thyroid function.

18.3.3.1 DIRECT TESTS

Irvine[61] was one of the first investigators to develop and use quantitative thyroid function tests for horses. The T_4 secretion rate was calculated after injecting iodine-131 and plotting the fall of protein-bound iodine. The volume of distribution was calculated by extrapolation from the disappearance curve to zero time. The product of volume of distribution and the protein-bound iodine was used to calculate the T_4 pool. From the half-life of protein-bound ^{131}I, one obtained the fractional turnover of the pool and thus the daily loss of T_4. Assuming loss and replacement to be equal, the amount was designated the T_4 secretion rate. This method of measurement was not clinically practical.[31]

For years protein-bound iodine was the standard determination for estimating serum hormone concentrations.[2,37] All iodine, hormonal or not, was measured. This measurement is influenced greatly by substances containing iodine and by iodine in the diet.

With the development of new immunoassay technology, the approach to diagnosing thyroid gland dysfunction in human medicine has changed. Sensitive assays for TSH now are being accepted in the initial screening of thyroid function in patients with normal pituitary gland function. In these patients, increased TSH concentrations are expected in hypothyroidism and the opposite in hyperthyroidism. Free T_4 concentrations are determined when TSH concentrations are abnormal. This determination is known as the TSH-centered strategy for evaluation of thyroid gland function and is considered efficient and cost-effective.[83] Unlike human laboratories, in which tests for thyroid function are commercially available in preexisting

forms, in equine medicine veterinarians are far from assessing thyroid gland function in an organized manner. The traditional approach has been to determine TH concentrations, compare them to reference values, and make a diagnosis and specific recommendations, in many cases without considering the underlying cause of abnormal TH concentrations. 1345

Competitive immunoassays are the method of choice to measure total T_4 concentrations, and they measure 1346
free and protein bound T_4. To obtain an accurate measurement, T_4 must be dissociated from the transport proteins by using different blocking agents. These immunoassays can be isotopic and nonisotopic and are available to be used in automated systems. Serum is preferred to measure T_4 concentrations, although heparin or EDTA can be used. Thyroxine is stable in serum at 4° C for several weeks. One should avoid hemolyzed and turbid samples and samples from patients receiving thyroid supplements, a common practice in the equine industry.

To determine total T_3 concentrations, methods (isotopic and nonisotopic) to those similar for measuring T_4 concentrations are available. As with T_4, protein-bound T_3 must be released from the binding proteins; serum is preferred, and one must avoid hemolysis.

Free THs circulate in blood in equilibrium with protein-bound THs, and changes in thyroid-binding protein (thyroxine-binding globulin, thyroid-binding prealbumin, albumin) can affect the total TH concentration. At steady state, free TH concentrations remain constant despite changes in thyroid-binding protein. One also can estimate free TH concentrations using indirect methods. For example, the index method uses two separate tests to estimate free TH, one to determine total TH (T_3 or T_4) and another to determine thyroxine-binding globulin; and by mathematical models, one calculates free TH concentrations.

Thyroxine-binding globulin is the most important T_4-binding protein, and measuring thyroxine-binding globulin concentrations is relevant for assessing TH concentrations. Immunoassays and two-site immunometric assays are available to determine human thyroxine-binding globulin concentrations but are not readily available for horses at this time.

Radioimmunoassay has been used to measure THs in horses since 1978[41] and is validated for horses.[84] Radioimmunoassay quantification of T_4 and T_3 is not affected by the presence of hemolysis of the blood sample.[85] Enzyme-linked immunosorbent assays (ELISA) techniques are available to measure TH concentrations.[2,86] The big advantage of this method is that no radioactive agents are required. New

immunometric assays with higher sensitivity than radioimmunoassay and ELISA are available to measure TH concentrations. The most precise way to quantify the actual amount of hormone available to target tissues is to determine the unbound or free fractions.[46]

Normal TH concentrations have a wide range of values and vary among laboratories and measurement techniques (Tables 18.3-1 and 18.3-2), complicating the interpretation of results, in particular when one uses different laboratories. For most consistent results the practitioner always should use the same laboratory and become familiar with its values. Ratios of circulating hormones may indicate dysfunction. In general, among species the ratio of circulating total T_4 to T_3 is 20:1. In horses the ratio was found to be 23:1. The ratio of fT_4 1346 1347
to fT_3 was found to be 1.83:1 in horses.[43] An increased ratio of T_3 to T_4 has been associated with 1347 1348
hypothyroidism in dogs[87] and in human beings. With iodine deficiency, the thyroid produces and secretes more T_3 as a way of conserving iodine, thus increasing the ratio of T_3 to T_4.[23] If the rT_3 value is available in addition to T_4 and T_3 values, certain patterns may suggest and support dysfunction. For instance, rT_3 may be increased in hyperthyroidism and in euthyroid sick syndrome (NTIS).[23] Because rT_3 is a breakdown product of T_4, its concentrations depend on the T_4 concentrations. Thus rT_3 may be increased along with T_4 in hyperthyroidism. In euthyroid sick syndrome the activity of type I deiodinase is decreased. This enzyme is responsible for T_3 neogenesis and rT_3 breakdown; therefore in that syndrome, T_3 is decreased and rT_3 is increased. Likewise, in hypothyroidism, where T_4 is decreased, rT_3 also may be decreased.[23]

T4, Thyroxine; *T3,* triiodothyronine; *fT4,* free thyroxine; *fT3,* free triiodothyronine.

Sensitive immunometric assays to determine TSH concentrations have been developed. In these assays, one monoclonal antibody (to β-subunit) is fixed to a solid phase, and the bound hormone then is quantitated by a second detection antibody (i.e., directed to α-subunit). The detection antibody is labeled with ^{125}I (immunoradiometric assays) or with alkaline phosphatase or peroxidase (immunochemiluminometric assays). Immunometric assays to measure human TSH are currently available for use in automated systems and are more sensitive than radioimmunoassay or ELISA. The validity of human TSH assays to measure equine TSH is unknown; however, the results are expected to be acceptable based on a 90% homology between human and equine TSH amino acid sequences. Serum TSH concentrations from horses with hypothyroidism are not available.

Breuhaus[88] recently validated an equine-specific double-antibody TSH radioimmunoassay in an equine model of hypothyroidism. In that study the author induced a hypothyroid state in healthy horses by administering propylthiouracil for 6 weeks. Serum T_3 and fT_3 fell rapidly in the first week of propylthiouracil administration, whereas fT_4 and T_4 did not decrease until weeks 4 and 5, respectively. TSH remained steady during propylthiouracil administration and then increased after week 5. Furthermore, the TSH response to TRH stimulation (1 and 5 mg) was exaggerated on weeks 5 and 6 of propylthiouracil administration, and the TH response was blunted. In this study, using the propylthiouracil model of

hypothyrodism, the equine-specific TSH assay together with the measurement of TH concentrations was able to differentiate euthyroid from hypothyroid horses.

No direct tests are available to evaluate the effect of THs on the target tissues. The most direct measure of metabolic activity is basal metabolic rate. Routine determination of basal metabolic rate is not clinically practical.

18.3.3.2

INDIRECT TESTS

Serum cholesterol is elevated in human beings and dogs with hypothyroidism,[2] but this is not a specific response to thyroid dysfunction. Increased cholesterol concentrations have been found in some hypothyroid horses but not others, so this is not a reliable indicator in horses.[61,89] A normochromic, nonresponsive anemia of chronic disease, once again, is not specific but may be seen with hypothyroidism.[2] This finding of anemia responsive to thyroid supplementation has been documented in horses.[89–91] Low body temperature and bradycardia may indicate hypothyroidism.

18.3.3.3

TROPHIC RESPONSE TESTS

Trophic hormone response tests are useful to help differentiate primary from secondary thyroid dysfunction, and they remove the variability of endogenous and exogenous factors that influence other tests.

18.3.3.3.1

Thyroid-Stimulating Hormone

The TSH stimulation test protocol consists of injecting 5 IU of TSH intravenously and comparing pre- and postinjection TH concentrations.[92,93] In normal horses, T_4 peaks 3 to 4 hours after injection at a concentration 2.4 times the preinjection value. Triiodothyronine doubles within 30 minutes and peaks at 2 hours at a concentration 5 times baseline.[87] Normal responses are characterized by a rise in T_3 that antedates the T_4 rise and is also greater. When 5 IU TSH was given intramuscularly, T_4 peaked at 2 times baseline value 3 to 12 hours after injection, and T_3 peaked in 1 to 3 hours.[49] The suggested protocol for the intravenous TSH response test is to measure hormone concentrations at baseline and 4 hours after injection.[87] No difference in T_4 concentrations was found between 2.5 and 5 IU of TSH.[92] For the intramuscular protocol, one should measure hormone concentrations at baseline and 3 and 6 hours after injection.[49] The protocol for 1-day-old foals is to measure T_3 concentrations at baseline and 1 and 3 hours after intravenous injection of 5 IU of TSH. A normal response is a 50% increase by 3 hours. Thyroxine values were too variable.[94] An insufficient increase in hormone indicates a primary thyroid dysfunction. The ability to perform a TSH stimulation test may be limited by the cost or availability of TSH.

Phenylbutazone administration to horses decreases TH concentrations but does not affect the response of the TSH stimulation test.[49] Dexamethasone decreases the TH response to the TSH stimulation test. When the TSH stimulation test was performed in healthy horses treated for 5 consecutive days with dexamethasone (0.04 mg/kg), the response to the TSH stimulation (5 IU intramuscularly) test was found to be blunted by dexamethasone administration.[77] This study raised questions in the interpretation of the TSH stimulation test from previous studies,[49,87] as well as concerning the utility of the test in differentiating thyroidal and nonthyroidal causes of hypothyroidism in the horse.

18.3.3.3.2

Thyroid-Releasing Hormone

Thyroid-releasing hormone stimulation tests have been done in horses.[92,95–98] One administers TRH intravenously at 1 mg to horses and 0.5 mg to ponies. An inadequate hormone response to TRH would occur in primary or secondary hypothyroidism. In normal animals, T_4 peaks at 4 hours[92,97] and T_3 at 2 hours after intravenous TRH administration.[97] In another study, T_3 increased significantly at 1 to 2 hours after TRH injection and peaked at 2 to 4 hours. Thyroxine increased by 2 hours and peaked at 4 to 10 hours. Both hormones should increase two- to threefold in a normal response. The suggested protocol is an intravenous dose of 1 to 3 mg TRH with hormone measurements at baseline and 4 to 5 hours later. Side effects of TRH administration include salivation, urination, defecation, vomiting, pupillary constriction, tachycardia, and tachypnea.[96] An abnormal (low) response to TRH administration suggests dysfunction at the pituitary gland or the thyroid gland. Additional tests (TSH concentrations, TSH stimulation test) may be necessary to differentiate primary thyroid disease from pituitary disease. Low baseline TH concentrations with high TSH concentrations and an abnormal response (low) to the TSH stimulation test suggest thyroid gland dysfunction. Low baseline TH concentrations with a normal or low TSH concentration suggest hypothalamic or pituitary gland dysfunction. Low baseline TH and TSH concentrations with a normal TSH and TH response to TRH stimulation test may suggest hypothalamic dysfunction as the cause of hypothyroidism. The TRH stimulation test also has been used as a diagnostic aid to evaluate pituitary adenomas in horses.[95]

18.3.3.3.3

Thyroid Suppression Test

One can demonstrate the presence of autonomous or TSH-independent thyroid gland function by the thyroid suppression test. The exogenous administration of THs in quantities sufficient to suppress TSH secretion results in decreased TH synthesis and secretion. The lack of TH suppression indicates that thyroid gland function is independent of TSH. The administration of T_3 (T_3 suppression test) to healthy individuals is expected to cause a decrease in serum T_4 concentrations, whereas hyperthyroid individuals are expected not to have a significant decrease in serum T_4 concentrations. This test was useful in diagnosing hyperthyroidism in a horse with a thyroid adenoma[99]; 2.5 mg of T_3 were administered intramuscularly, and serial sampling revealed no decrease in T_4 concentrations.

18.3.3.4

IMAGING

Pertechnetate (technetium-99m) is a diagnostically useful compound that is taken up by the iodine-trapping mechanism.[2] Scintigraphic imaging has been used clinically to evaluate the thyroid glands of horses.[100] Abnormal uptake patterns have been seen with thyroid carcinoma in horses.[101–103] Ultrasonographic 1348
evaluation of the glands can differentiate solid structures from cystic ones.[23] Ultrasonography has been used 1349
to evaluate thyroid gland morphology in horses.[99,104]

18.3.3.5

BIOPSY

Aspirate or biopsy sampling can help differentiate cysts, neoplasia, hyperplastic goiter, colloidal goiter, and inflammation.

18.3.4
Hypothyroidism

Hypothyroidism is defined as a deficiency of THs, a deficient thyroid activity, or as a disruption in the HPT axis. Hypothyroidism occurs from diseases that affect thyroid function or from exogenous compounds that may affect the thyroid tissue or interfere with TH synthesis and less frequently by disorders that affect the hypothalamus or the pituitary gland. Hypothyroidism occurs because of the actions of THs on cell differentiation and metabolic rate regulation.[27] Liver, muscle, kidney, heart, salivary gland, and pancreatic tissue are sensitive targets of thyroid hormone action.[23] Hypothyroidism can manifest in many ways, and the diagnosis can be a challenge because few tests for thyroid function are equine-specific and many nonthyroidal factors can lead to misinterpretation of the results. Hypothyroidism, or thyroprivia, results when thyroid tissue is removed or thyroid function is suppressed. Hypothyroidism can be classified as primary, secondary, or tertiary. Primary gland dysfunction can be caused by iodine deficiency (endemic goiter) or excess (Wolff-Chaikoff effect), thyroiditis, neoplasia, biochemical defects, thyroid agenesis, or ingestion of goitrogenic compounds that can block hormone synthesis. Of these, iodine excess, iodine deficiency, and neoplasia have been reported as causes of hypothyroidism in horses. Based on the existing knowledge on thyroid gland function, individuals with primary hypothyroidism have decreased T_4 and T_3 concentrations and increased TSH concentrations; this seems to be true in horses with experimentally induced hypothyroidism.[88] Secondary (central) hypothyroidism results from pituitary (trophoprivic) or hypothalamic dysfunction. Authors report hypothyroid activity in horses with pituitary adenoma,[90,105] but all horses with pituitary adenoma do not have concomitant hypothyroidism.[95] Tertiary hypothyroidism denotes a defect in hormone use at the peripheral tissues. The condition has not been identified or reported in horses. In one report, a defect in T_4 to T_3 deiodination was suspected, and a hair coat started to grow after T_3 supplementation began.[106] In many of the reported cases of hypothyroidism in horses, a specific cause has not been identified.

The consequences of inadequate circulating THs are potentially devastating and life threatening to fetus and foal. The poor prognosis is associated with the essential role of THs in normal growth and development. Chances of recovery are unlikely once critical developmental stages are passed. Tests to evaluate thyroid gland function may be within normal limits at the time of examination, making it difficult to confirm a previous transient or in utero TH deficiency.[27] The equine placenta is permeable to iodine but is impermeable to T_3 and T_4, and excessive ingestion of iodine may result in hyperplastic goiter.

18.3.4.1
SIGNS

Because decreased iodine intake is considered the main cause of neonatal hypothyroidism and goiter, pituitary gland function in these foals may be normal or increased. Decreased TH concentrations stimulate the pituitary gland to secrete excessive amounts of TSH, which then stimulate the thyroid cells, resulting in thyroid enlargement. Most clinical signs thus far reported in hypothyroid foals are attributable to the crucial role of THs in the development and maturation of the nervous and musculoskeletal systems. Thyroid hormones have major effects in brain development during the pre- and postnatal periods, and TH deficiency results in decreased axonal growth, dendritic arborization, and myelinization in several areas of the central nervous system. Thyroid hormones are so important in neonatal brain development that early treatment of hypothyroid infants with T_4 prevents intellectual impairment and is a major reason for screening thyroid function in human neonates. Hypothyroid foals often are affected at birth, have difficulty standing, and have a weak or absent suckle reflex. Physeal dysgenesis[107]; weakness, death, or incoordination in newborns[32];

defects in ossification with tarsal bone collapse[108]; hypoplastic carpal bones, common digital extensor tendon rupture, forelimb contracture, and mandibular prognathism[109,110]; stillbirths, weakness, and long haircoat[111]; weak suckle reflex[112]; respiratory insufficiency[113]; and premature, weak foals that die shortly after birth[5] have been reported. Foals can be born apparently normal but may develop skeletal lesions weeks later.[114] Thyroid hormones are required for the biochemical maturation, hypertrophy, and capillary penetration of growing cartilage. Triiodothyronine may act indirectly to promote chondrogenesis by stimulating anterior pituitary synthesis and secretion of growth hormone. Thyroid hormones also increase fetal skeletal growth hormone receptor and insulin-like growth factor I gene expression,[115] and therefore THs influence the growth and skeletal development by local activity of the somatotrophic axis.

An age-related, carbohydrate diet–responsive, insulin-T_4-T_3 interaction has been identified that may play a role in cartilage maturation defects in weanlings.[116] Thyroxine also plays a role in maturation of the lungs 1349
and in surfactant production.[23] One report in the literature describes a foal with respiratory distress syndrome 1350
and hypothyroidism.[113] Doige and McLaughlin[117] described two foals that died in respiratory distress. Neonatal thermogenesis is also T_4 dependent[27]; thus cold intolerance and hypothermia could be a problem. In one study, when young, growing animals were thyroidectomized, physeal plate closure and incisor eruption were delayed. Very young foals suffered severe growth retardation and died.[118] In a second study in which day-old foals were thyroidectomized, lethargy, depression, and rough, dry hair coats were seen.[114]

18.3.4.2 CAUSE

The major cause of hypothyroidism in foals is believed to be nutritional. Congenital thyroid enlargement (goiter) (Figure 18.3-1) with decreased function is associated with inadequate iodine intake and excessive iodine intake by the mare. Thyroxine is transported transplacentally and via the milk.[119] No cases of hypothyroidism caused by an inborn error of metabolism have been described in foals.

Several reports in the literature describe goiter and hypothyroidism in foals associated with ingestion of excessive amounts of iodine in kelp-supplemented rations.[5,111,119–121] The dams of these foals may or may not be affected. Feeding 40 mg or more of iodine daily can produce this syndrome.[112]

18.3.4.3 DIAGNOSIS

Foals that exhibit any of the aforementioned signs, with or without enlarged glands, are suspect. One should examine the mare and determine her nutritional status. Because enlargement of the thyroid gland alone does not automatically imply hypo- or hyperthyroidism, one should perform function tests to confirm a diagnosis. One crucial point to remember is that high TH concentrations are normal in foals (see Table 18.3-2). Not only does a powerful central drive exist to stimulate the thyroid axis late in gestation,[27] but also thyroxine-binding globulin concentrations are increased in neonates[23] and hormone protein binding is more pronounced in neonates than in adults. Thyroid hormone concentrations measured in umbilical cord blood of newborn foals were found to be 14, 5, 7, and 3 times adult concentrations, respectively for total T_4, fT_4, total T_3, and fT_3. For most of fetal life, T_4 is deiodinated to rT_3, concentrations of T_3 are negligible, and concentrations of T_4 and rT_3 are high. At birth, rT_3 production decreases, and the deiodination pathway leads to T_3. The plasma rT_3 concentrations in foals fall rapidly as T_3 rises for 24 to 48 hours after birth, plateaus for 2 to 3

days, then declines to parallel the T_4 value.[27] A decline in T_4 concentrations occurs during the first 16 days of life. Free T_4 concentrations decline over the first 3 months of life.[32] In term foals, serum T_3 concentrations are elevated far above adult concentrations for the first 6 to 12 hours; by 24 hours they have declined significantly. The rT_3 concentrations in premature foals are lower than those of term foals, but a further decline is not observed up to 48 hours. This observation is consistent with a surge of 5′-deiodination resulting in T_3 production and rT_3 degradation about 6 to 12 hours after birth for term foals. Deiodination is impaired in preterm foals.[122] McCall, Potter, Kreider, et al.[40] found T_3 concentrations in foals 4 months of age comparable to adult concentrations; however, mean T_4 concentrations were higher at 2.9 µg/dl. When evaluating TH concentrations in foals suspected of having hypothyroidism, one must compare their TH concentrations to age-matched healthy foals. A foal may have clinical evidence of hypothyroidism, but THs may be within the normal range, suggesting that perhaps a TH deficiency occurred during development. Hypothyroidism in foals carries a poor prognosis, even after thyroid supplement therapy.

Figure 18.3-1 Goiter in a foal. The dam inadvertently was given a ration that contained too much iodine.

18.3.4.4 CONGENITAL HYPOTHYROIDISM AND DYSMATURITY SYNDROME IN FOALS

A syndrome characterized by thyroid gland hyperplasia and multiple congenital musculoskeletal deformities has been described in neonatal foals in western Canada.[40,109,117,123–126] In some farm outbreaks, this syndrome is reported to affect 30% to 100% of foals.[126] The syndrome is unique, with no sex or breed predilection.[124] Abnormal musculoskeletal findings include prognathia, osteochondrosis and inappropriate ossification of carpal and tarsal bones, angular limb deformities, and rupture of the common digital extensor tendons. These foals have signs of dysmaturity, including a silky and short hair coat, floppy ears, tendon 1350

laxity, and incomplete closure of the abdominal wall.[126] Thyroid gland hyperplasia also is associated with hypothyroidism.[125] The syndrome is referred as *thyroid hyperplasia and musculoskeletal deformities* or as *congenital hypothyroidism and dysmaturity*. The cause of this condition is unknown. A case-control study found that foals with congenital hypothyroidism and dysmaturity had a longer gestation time and that mares grazing irrigated pastures or fed green feed or mares that were not receiving mineral supplements or that left their home farm were statistically more likely to produce affected foals.[126] High dietary nitrate concentrations have been proposed as the possible cause of this syndrome. Nitrates can impair thyroid gland function[78] and also can cross the placenta in different species. Green feed can concentrate high levels of nitrates and nitrites. Alfalfa, ryegrass, timothy, and cereal crops such as wheat, oats, rye, and barley also accumulate nitrates. In addition to the high content of nitrates in these plants, they also have low levels of iodine. Nitrates also can be present in high concentrations in the water, in particularly in areas with high use of fertilizers, feedlots, and dairies.[126] 1351

18.3.4.5 HYPOTHYROIDISM IN ADULT HORSES

Hypothyroidism in adults is a rare condition and unlike that in foals is not life threatening. Low-grade anemia responsive to thyroid supplementation has been described in thyroidectomized horses[89,90] and in racehorses with myopathy.[91] Decreased body temperature, heart rate, respiratory rate, and cardiac output were reported in thyroidectomized horses.[89,127] Reproductive problems in mares are irregular and absent estrus cycles.[5,89] Thyroidectomized mares could conceive and carry a foal to term.[128] Stallions exhibit decreased libido.[89,106] Thyroidectomized stallions had decreased total sperm count but normal semen characteristics and testicular histology, and they could sire foals.[118,128] Bradycardia, obesity, and lethargy were seen in mares with thyroid function suppressed because of ingestion of excess iodine.[5] Lethargy, rear limb edema, coarse hair coat, and decreased appetite were seen in thyroidectomized mares.[128] One case describes failure to grow a normal hair coat in a stallion.[106] Alopecia attributed to iodinism and low circulating TH values were documented in a horse being treated with an expectorant containing iodide and topical povidone-iodine.[129] The hair coat grew and thyroid function returned to normal when the medications were discontinued. One report described agalactia associated with decreased thyroid function.[15] Thyrotropin-releasing hormone has been shown to stimulate pituitary secretion of prolactin in many species; however, TRH injections have minimal or no effect stimulating prolactin release in mares.[14–16] Poor performance in racehorses during the season when ambient temperatures are increasing may be related to seasonal thyroid function changes. At this time hormone concentrations may drop too low to support optimal muscle performance.[63]

Hypothyroidism has been implicated as a cause of anhidrosis. In one study, mean T_3 and T_4 values were found to be lower in anhidrotic horses than in unaffected horses.[130] Another report found that thyroid function was not abnormal in some horses selected from a group affected with anhidrosis.[131] Low TH concentrations may be present in horses with laminitis, but whether hypothyroidism is a cause or a contributing factor in laminitis has yet to be proved.[132] Many horses with laminitis and Cushing's disease also have decreased TH concentrations; however, hypothyroidism in these horses has not been documented.

18.3.4.6

TREATMENT OF HYPOTHYROIDISM

When the diagnosis is low circulating hormone concentrations or hyperplastic goiter, one must ascertain whether dietary intake of iodine is adequate. In addition, differentiating hypothyroidism from NTIS is important because animals with NTIS may not require treatment for thyroid hypofunction. Furthermore, TH therapy to euthyroid horses with NTIS may be harmful, causing inhibition of the HPT axis and suppressing endogenous TH synthesis and secretion.

The National Research Council recommends a minimum daily intake of iodine of 0.1 mg/kg of feed. Total daily intake of 1 to 2 mg iodine per animal also has been reported.[5] The soils of some geographic areas are low or marginal in iodine, for instance, the Great Lakes region.

Iodinated casein or thyroprotein, 5 g orally per day, reversed the effects of thyroidectomy in adults.[118] Iodinated casein, 5 to 10 g orally per day, reversed the thyroid-associated anemia and myopathy in racehorses.[91] Desiccated thyroid extract, 2 mg/kg body mass given orally each day, has been used successfully.[111] The responses to the iodinated casein and thyroid extract may not be consistent, for hormone concentrations in the products can vary.

Hormone supplementation with T_4 should be effective unless a deiodination defect exists. A starting dose of 20 μg of T_4 per kilogram body mass given orally daily is recommended.[38] If T_3 is to be supplemented, an oral dose of 1 mg/kg body mass once a day is recommended.[133] Whether the use of thyroid supplements is beneficial remains controversial and requires large scale studies.

One should monitor the animal for clinical response to therapy, which can take at least 2 weeks. One should monitor hormone concentrations periodically and reassess function and dosages, particularly if the desired response is not achieved. 1351

1352

18.3.5

Hyperthyroidism

Hyperthyroidism is a hypermetabolic disorder resulting from high concentrations of free T_4 and T_3. Few reports of equine hyperthyroidism document the condition. A syndrome of tremors, excitability, tachycardia, sweating, and weight loss in spite of a good appetite has been described in racehorses.[63,134] Plasma thyroid hormone concentrations were elevated, and the horses improved greatly in response to antithyroid treatment of 1 g potassium iodide orally per day.[61,63] The use of thyroidectomy as a means of behavior modification for high-strung, unmanageable horses has had variable success.[118] In these cases, whether a diagnosis of hyperthyroidism was confirmed by hormone concentrations or function tests was not stated. High concentrations of THs can occur in physiologic states not associated with abnormal clinical signs, such as pregnancy[45] and the well-documented high concentrations needed for normal fetal growth and development.[30,32] No reports describe hyperthyroidism associated with an autoimmune condition in horses. Hyperthyroidism associated with a thyroid adenocarcinoma recently was reported in a 21-year-old gelding.[104] The presenting complaint was an enlarging mass on the right cervical region, weight loss, and tachypnea. Serum T_3 and T_4 concentrations were elevated. The T_3-suppression test decreased serum T_4 concentrations in control horses but not in the affected horse.

Horses are at risk for accelerated TH production because of exposure to increased quantities of iodine, as in expectorants, counterirritants, contrast media, drugs (e.g., iodochlorhydroxyquin), and leg paints and shampoos containing iodine. This is called the Jod-Basedow phenomenon.[23] The phenomenon is recognized in human medicine, and certain persons (such as those with multinodular goiter) are predisposed to this effect. The phenomenon would be typified in a horse by transiently elevated THs that return to normal after the source of the excess iodine is discontinued. Human beings who respond this way to excessive iodine would not be expected to respond to the supplemental potassium iodide that causes suppression of TH production in others (Wolff-Chaikoff effect). In a racehorse that shows appropriate signs and elevated hormone concentrations, one must determine whether an iodine compound has been used or whether the horse may have received a TSH "jug." If severe distress of thyrotoxicosis is present, administration of glucocorticoids should alleviate the signs.[23]

18.3.6 Thyroid Tumors

Tumors of the thyroid in horses tend to occur more frequently in light-weight breeds than in Draft horses and in general more often in aged horses than in young ones.[135] Based on immunohistochemical techniques, three cell types are distinguishable in the thyroid glands of horses. The first type is undifferentiated and does not react to antibodies; the second type is parafollicular cells, which have calcitonin-positive secretory granules; and the third type is thyroglobulin-positive follicular epithelial cells. Moreover, cell aggregations have three classifications. The first is ultimobranchial remnant embedded in thyroid tissue without compression of adjacent cells. The second is nodular hyperplasia of the ultimobranchial remnant that compresses adjacent follicular cells. The third is adenoma of the ultimobranchial segment surrounded by fibrous capsule. Researchers found that in horses all cell aggregations had undifferentiated cells that retained embryonic characteristics such as those of ultimobranchial remnant.[135]

In a survey of thyroid glands of aged horses, gross tumors were found in 11 of 29 horses.[136] No tumors were found in horses younger than 18 years old, and most tumors were microfollicular adenomas.

18.3.6.1 ADENOMA

Adenoma is the most common neoplasia of the equine thyroid.[121,136–142] The phenomenon is age related, occurring mainly in horses older than 16 years; is benign; is usually unilateral; and is not associated with thyroid dysfunction. Occasionally the size of the adenoma may warrant surgical excision. Prognosis is good. Horses with thyroid adenoma or pituitary adenoma were found to have exaggerated insulin responses following oral glucose tolerance testing and failed to maintain cortisol suppression 24 hours after a dexamethasone suppression test. These findings were observed also in preclinical cases that were diagnosed at necropsy.[140] A thyroid adenoma associated with hyperthyroidism was diagnosed in a 23-year-old gelding.[99] In this case the diagnosis was aided by percutaneous biopsy and the use of a T_3-suppression test, in which T_4 concentration was not suppressed after the intramuscular administration of 2.5 mg of T_3. Hemithyroidectomy of the affected gland restored TH concentrations.

18.3.6.2

ADENOCARCINOMA

Malignant neoplasia of the thyroid occurs less frequently. In four reported cases of thyroid adenocarcinoma, one horse was euthyroid, two were hypothyroid, and one was hyperthyroid, based on serum T_3 and T_4 concentrations.[101–104] One case of thyroid carcinoma with systemic metastasis and concurrent pituitary adenoma is reported.[143] One report describes a horse with a diagnosis of carcinoma and adenoma in the same gland. The low T_3 concentration seen with this horse was felt to be caused by euthyroid sick syndrome because the TSH stimulation response was normal.[139] 1352

1353

18.3.6.3

MEDULLARY CARCINOMA

Medullary carcinoma (C cell or parafollicular cell tumors) have been reported in horses.[3,144,145] In these cases the youngest horse was 8 years old and the tumors were unilateral. In two horses a complaint of constant gulping was alleviated by surgical removal of the enlarged glands, and the horses returned to athletic function.[3] Two horses had no associated clinical signs.[145,146] A C cell adenoma was reported in a 13-year-old horse with no clinical evidence of endocrine disease.[146] In this case the diagnosis of C cell adenoma was confirmed by immunohistochemistry. In one horse a C cell adenoma associated with multiple endocrine neoplasia was a necropsy finding.[144] Thyroid function tests were not done. C cell hyperplasia has been described in horses as young as 3 years.[138] Electron microscopy or immunohistochemical techniques may be necessary to distinguish C cell tumors from other thyroid neoplasms.

18.3.6.4

MULTIPLE ENDOCRINE NEOPLASIA

Multiple endocrine neoplasia is a human syndrome characterized by multiple neoplasia of glands with a neuroendocrine origin. One case of a 22-year-old Thoroughbred mare with a C cell adenoma, a pheochromocytoma, and a multicentric bilateral nodular hyperplasia of the adrenal medulla was reported recently.[144] A retrospective evaluation of endocrine tumors in horses that underwent necropsy suggested that hyperplasia and neoplasia of the thyroid and adrenal glands, as occur in human beings with multiple endocrine neoplasia syndrome, also occur in the horse.[143,144]

18.3.6.5

TREATMENT

In circumstances that warrant surgical excision, prognosis is best when the condition is unilateral without a concurrent systemic abnormality. Potential complications of the surgery include infection, hemorrhage, laryngeal hemiplegia on the side of the surgery, and scar tissue at the surgical site. The parathyroid glands of the horse generally are not connected to the thyroid glands, and hypocalcemia is not a complication. When hypo- or hypercalcemic states were induced in bilaterally thyroidectomized horses, normocalcemia was not achieved until T_4 was supplemented, suggesting that the absence of calcitonin alone was not responsible for the abnormal calcium homeostasis.[29]

18.4—The Adrenal Glands

Ramiro E. Toribio

The adrenal glands in the horse lie retroperitoneally, embedded in the fat on the medial cranial pole of each kidney. They are red-brown, 7 to 8 cm long, 3 to 3.5 cm wide, and 1.2 to 1.5 cm thick and weigh 15 to 20 g each. Blood supply to the adrenal gland is through the adrenal artery, which branches from the aorta or the renal artery.

Innervation involves sympathetic fibers from the splanchnic nerve. In the horse, accessory adrenal cortical tissue may be found in the capsule of adrenal glands, in the periadrenal or perirenal adipose tissue, in the mesorchium, and in the vicinity of the equine testis.

The adrenal gland comprises two different organs that differ in their embryologic origin, type of secretion, and function: the medulla and the adrenal cortex. The medulla is related functionally to the sympathetic nervous system and secretes epinephrine and norepinephrine in response to sympathetic stimulation. The adrenal cortex secretes an entirely different group of hormones: corticosteroids, which are synthesized from cholesterol. The adrenal cortex consists of three zones: the outermost zona glomerulosa, which secretes mineralocorticoids (aldosterone) in response to the renin-angiotensin system and to changes in extracellular fluid osmolality; the zona fasciculata that secretes glucocorticoids (cortisol) in response to adrenocorticotropic hormone (ACTH, corticotrophin) stimulation; and the zona reticularis that secretes androgens.

The adrenal cortex is involved in a variety of body functions, including maintenance of fluid and electrolyte balance, immunity, defense, and energy metabolism. Removal or destruction of the adrenal glands leads to death unless exogenous adrenocortical hormones are administered. Aldosterone increases renal sodium reabsorption and increases renal excretion of potassium. Hyperkalemia and increased activity of the renin-angiotensin system are the most important factors to increase aldosterone secretion. Hypernatremia decreases aldosterone secretion. Cortisol increases gluconeogenesis by stimulating the enzymes required to convert amino acids into glucose in the liver. Cortisol also causes mobilization of amino acids from extrahepatic tissues to enter the gluconeogenesis. In addition, cortisol decreases the rate of glucose use. The increased rate of gluconeogenesis and the decreased rate of glucose use cause blood glucose concentrations to rise. The increase in the glucose concentration from increased adrenal glucocorticoid secretion is occasionally great enough that this condition in human beings is called adrenal diabetes.[1] Cortisol promotes fatty acid mobilization, apparently from decreased transport of glucose into the adipocytes. Cortisol is also important in stress and by increasing fat and amino acid mobilization can make these substances immediately available for energy. In addition, during trauma, endogenous cortisol concentrations are antiinflammatory. Increased concentrations of cortisol result in eosinopenia and lymphopenia.

18.4.1 Adrenal Insufficiency

Adrenal insufficiency—also known as adrenal exhaustion, hypoadrenocorticism, turnout or steroid letdown syndrome—is a poorly documented condition in horses. Horses with adrenal insufficiency often have decreased cortisol concentrations and do not respond to the ACTH stimulation test. Hypoadrenocorticism may occur in critically ill horses (colic, enterocolitis, endotoxemia, sepsis, disseminated intravascular coagulation) because the adrenal gland is a shock organ, and severe adrenal damage from sepsis, hemorrhage, venous thrombosis, and cortical necrosis may lead to adrenal atrophy and dysfunction. Most documented cases of adrenal insufficiency involve discontinuation of chronic administration of glucocorticoids or anabolic steroids[2,3]; however, adrenal insufficiency does not seem to be a common condition in horses that have not been treated with steroids. Wilson, Kingery, and Snow found in Thoroughbreds in training that the adrenal gland response to exogenous ACTH was not altered by training and that baseline ACTH and cortisol concentrations decreased as the fitness of the horses increased.[4] Furthermore, low serum cortisol concentrations were not found in stressed racehorses with a history of poor performance,[5] and high plasma cortisol and ACTH concentrations were found in horses after maximal exercise.[6–8] Dybdal, Gribble, Madigan, et al.[9] measured plasma cortisol concentrations in endurance horses in a 160-km ride and found that midride cortisol concentrations were significantly higher than preride cortisol concentrations. They also found that postride cortisol concentrations were lower than midride concentrations. The ACTH stimulation test was not performed in these horses to determine their

adrenal gland function. Lassourd, Gayrard, Laroute, et al.[10] found that exercise resulted in a sixfold increase in adrenal gland cortisol secretion rate and in a two- to threefold increase in plasma cortisol concentrations.

Horses suspected of having adrenal insufficiency have a history of depression, anorexia, exercise intolerance, weight loss, poor hair coat, and lameness, and therefore one must obtain a complete history, including performance, previous diseases, drug administration, and stressing conditions. Endogenous and exogenous glucocorticoids suppress the hypothalamus-pituitary-adrenal axis, resulting in atrophy of the zona fasciculata of 1357
the adrenal gland from decreased concentrations of ACTH. The zona glomerulosa is affected minimally, 1358
although electrolyte abnormalities may be present in some cases of adrenal insufficiency.

Clinical signs include depression, anorexia, exercise intolerance, weight loss, mild abdominal discomfort, poor hair coat, lameness, and seizures.[2,3,11,12] Serum biochemical analysis may be normal or hyponatremia, hypochloremia, hyperkalemia, and hypoglycemia may be present.[2,3,11]

Although adrenal insufficiency is an uncommon clinical diagnosis in equine practice, one should suspect it in any horse with a history of anorexia, lethargy, poor body condition, poor exercise performance, glucocorticoid administration, electrolyte imbalances (hyponatremia, hypochloremia, hyperkalemia), and hypoglycemia. Because cortisol has daily fluctuations, a single measurement of cortisol concentrations does not provide enough information to make a diagnosis of hypoadrenocorticism. Therefore one must take multiple measurements of cortisol concentrations and more importantly perform an ACTH stimulation test.[11,12] Horses with adrenal insufficiency have decreased cortisol concentrations and do not respond or minimally respond to the ACTH stimulation test.[11,13] Measuring ACTH concentrations may be important to determine other causes of hypoadrenocorticism. Exogenous glucocorticoid administration is expected to result in decreased ACTH concentrations (secondary hypoadrenocorticism), whereas adrenal insufficiency from adrenal gland dysfunction (primary hypoadrenocorticism) results in increased ACTH concentrations from decreased endogenous glucocorticoid concentrations (lack of negative feedback). In horses with increased plasma ACTH concentrations, one must rule out pars intermedia dysfunction (see Chapter 18.2).

In the ACTH stimulation test, one administers 1 IU/kg of natural ACTH gel intramuscularly[13]; takes a pre-ACTH administration sample in a heparinized tube to measure plasma cortisol concentrations and administers ACTH between 8 and 10 am; and takes post-ACTH samples for cortisol concentrations 2 and 4 hours after ACTH administration. Horses with a functional adrenal gland should have a two- to threefold increase in plasma cortisol concentrations compared with baseline concentrations.[3,13] In the cosyntrophin stimulation test, one administers 100 IU (1 mg) of synthetic ACTH intravenously between 8 am and noon.[14] One takes a pre-ACTH sample for plasma cortisol concentrations, administers ACTH, and takes a post-ACTH sample 2 hours later. As in the ACTH stimulation test, plasma cortisol concentrations should be at least twice baseline. Doses of $ACTH_{1\text{-}24}$ as little as 25 IU intravenously may increase cortisol concentrations up to twice baseline.[15]

Necropsy findings of horses with hypoadrenocorticism include adrenocortical hemorrhages and necrosis, as well as adrenal atrophy and fibrosis.

Treatment of hypoadrenocorticism involves rest and glucocorticoid supplementation. The duration and dosage of exogenous steroid treatment that induces adrenocortical atrophy in healthy horses is unknown. Total dexamethasone doses as low as 4 mg may suppress the hypothalamus-pituitary-adrenal axis for 18 to 24 hours.[3] Doses of 0.044 and 0.088 mg/kg of dexamethasone every 5 days for six treatments did not change the response to ACTH stimulation, even though dexamethasone administration reduced cortisol concentrations for up to 4 days. Both doses of dexamethasone resulted in maximal cortisol concentrations suppression; however, this

protocol did not result in adrenal atrophy.[16] Toutain, Brandon, de Pomyers, et al. found that dexamethasone (50 μg/kg intravenously or intramuscularly) suppressed adrenocortical function for up to 4 days; prednisolone sodium succinate (0.6 mg/kg intravenously or intramuscularly), for less than 24 hours; and prednisolone acetate suspension (0.6 mg/kg intramuscularly), for up to 21 days.[17] A single dose of dexamethasone (0.044 mg/kg intramuscularly) or triamcinolone (0.044 mg/kg intramuscularly) suppressed the hypothalamus-pituitary-adrenal axis for 7 and 14 days, respectively.[18] Based on this information, prednisolone sodium succinate (up to 300 mg daily) is the first choice to treat hypoadrenocorticism, low doses of dexamethasone are the second choice, and one must avoid triamcinolone. A case of hypoadrenocorticism following prolonged anabolic steroid administration was treated successfully with 300 mg of prednisone orally every 48 hours for 9 months.[2] With this therapeutic regimen, glucocorticoids were supplied and adrenal gland function was restored. Prednisone (40 mg p.o. b.i.d. or 50 mg intravenously) also was used to treat a foal diagnosed with adrenal insufficiency.[11] The efficacy of prednisone as a therapeutic agent in horses is questionable because prednisone in poorly absorbed from the intestinal tract, and the active metabolite, prednisolone, rarely is produced.[19] In contrast, orally administered prednisolone has excellent bioavailability and may be more useful as a therapeutic agent in horses. As with any long-term glucocorticoid therapy, slow withdrawal is recommended.

Some of the clinical features of equine hypoadrenocorticism (hyponatremia and hyperkalemia without evidence of renal disease) resemble Addison's disease in human beings and small animals; however, Addison's disease has not been documented in the horse.

18.4.2 Pheochromocytoma

Pheochromocytomas are tumors that arise from the chromaffin cells of the adrenal medulla, which are part of the sympathochromaffin system (together with the sympathetic nervous system). During fetal life, the 1358
chromaffin cells are associated with the sympathetic ganglia, and after birth most of them degenerate, and the 1359
few remaining cells constitute the adrenal medulla. In human beings, approximately 90% of pheochromocytomas arise from the adrenal medulla and often are diagnosed associated with a condition known as multiple endocrine neoplasia.[20] Extraadrenal pheochromocytomas have been found in human beings, but not in horses. Pheochomocytomas may be functional or nonfunctional. In the horse these are tumors of low incidence of malignancy and predominantly are unilateral.[21,22] Functional pheochromocytomas secrete catecholamines at a rate sufficient to cause clinical signs.[22] In horses, functional pheochromocytomas are diagnosed with more frequency than nonfunctional pheochromocytomas, probably as a result of the clinical signs,[23] although most of the pheochromocytomas in horses are believed to be nonfunctional and therefore go undiagnosed.[24] Epinephrine and norepinephrine have been identified as the predominant catecholamines produced by equine pheochromocytomas.[25]

Functional pheochromocytomas in horses have no breed or gender predilection[22] and have been described only in horses older than 12 years.[23,26] Because clinical signs exhibit acute onset and rapid progression and result from intense adrenergic stimulation, the clinical signs resemble those of more common conditions such as colic, rhabdomyolysis, acute laminitis, impending enterocolitis, and hyperkalemic periodic paralysis. The most common clinical signs include anxiety, tachycardia, tachypnea, profuse sweating, muscle tremors, and mydriasis (with intact pupillary light reflex).[22] Horses also may show abdominal pain from large hematomas or gastric and intestinal distention caused by ileus,[23,26] hyperthermia, dry and pale mucous membranes, increased capillary refill time, bladder paralysis, and ataxia. Ileus may result from increased intestinal adrenergic stimulation. Noninfectious abortion also has been documented.

Hematologic abnormalities associated with functional pheochromocytomas include hemoconcentration, stress leukogram (mature neutrophilia with lymphopenia),[26] and leukopenia with neutropenia.[23] Hemoconcentration may result from epinephrine-induced splenic contraction rather than from dehydration.[23,24,26] Epinephrine and epinephrine-induced steroid release may be responsible for the stress leukogram; however, in severe cases, tumor rupture with gastrointestinal disease and neutropenia with or without a leftward shift may be present.[23,24]

The serum biochemical profile of horses with a functional pheochromocytoma is nonspecific. Azotemia, metabolic acidosis, hyperkalemia, and hyperglycemia are among the most consistently abnormal laboratory findings.[22,26] Renal and muscular vasoconstriction induced by catecholamines is believed to result in reduced renal blood flow (causing azotemia) and reduced muscle blood flow (causing lactic acidosis and exit of potassium from cells). The mechanisms of hyperglycemia involve direct and indirect actions of the catecholamines, as well as stimulation of glucose production and limitation of glucose use; these effects are mediated through α- and β-adrenergic receptors.[20] A combination of hyponatremia, hyperkalemia, hypocalcemia, and hyperphosphatemia suggests acute renal failure; however, these findings have been reported in horses with pheochromocytoma without evidence of renal lesions at necropsy.[23,24] Hyperkalemia, hypocalcemia, and hyperphosphatemia in part could result from prolonged muscle activity and ischemia, although serum concentrations of creatine kinase were normal or only mildly increased.[22–24,26] Hyperkalemia is unlikely to result from increased catecholamine concentrations because catecholamines induce hypokalemia rather than hyperkalemia by inducing shift of potassium from the extracellular to the intracellular compartment (β-receptor–mediated) and by increasing the activity of the renin-angiotensin system.[27] Glucosuria is also a frequent finding, likely the result of the hyperglycemic action of epinephrine. Pheochromocytomas also may secrete other hormones of neuroendocrine origin (calcitonin, parathyroid hormone, ACTH, corticotropin-releasing hormone, somatostatin, vasoactive intestinal peptide, leu-enkephalin).[23,28–30] Increased concentrations of some of these hormones are expected to be present in horses with functional pheochromocytomas; however, they remain to be determined. Increased concentrations of calcitonin also may be responsible for hypocalcemia in some of these horses.

Functional pheochromocytomas are infrequent in equine practice; however, one may suspect a functional pheochromocytoma in old horses with paroxysmal attacks of anxiety, tachycardia, tachypnea, increased sweating, and muscle tremors, along with azotemia, metabolic acidosis, hyperkalemia, and hyperglycemia.[22,23] Once one rules out other common conditions (colic, impending enterocolitis, acute laminitis, rhabdomyolysis) associated with these clinical signs, one can pursue a specific diagnosis of pheochromocytoma. The clinician and the owner should be aware that this condition carries a poor prognosis, and euthanasia may be a reasonable decision. Measurement of high serum concentrations of catecholamines or their metabolites in urine is valuable in establishing a diagnosis; however, catecholamines are labile substances and not many laboratories are equipped to measure them.[22,23,26,31] Alternatively, ultrasonographic evaluation and measurement of blood pressure can support the diagnosis.

If one reaches a diagnosis, one may attempt adrenalectomy; however, surgery may be difficult because of the 1359
anatomic proximity of the adrenal glands and major blood vessels, tumor size, arrhythmias before surgery, the 1360
risk of inducing fatal arrhythmias (interaction between catecholamines and anesthetic agents),[24] and the complications of prolonged muscle ischemia and recumbency.[22,24,26] Hypotensive α-adrenergic antagonists such as phentolamine, phenoxybenzamine hydrochloride, and prazosin hydrochloride are used in human beings with functional pheochromocytomas before surgery.β-Adrenergic blockers (i.e., propanolol hydrochloride) in general are not recommended before surgery unless an arrhythmia is present. Another alternative is to use the

tyrosine hydroxylase inhibitor α-methyl-L-tyrosine. None of these compounds have been used in the horse to treat functional pheochromocytomas.

Functional pheochromocytomas in horses do not appear to metastasize, are unilateral, tend to bleed, and the adrenal capsule initially may contain the hemorrhage, although at necropsy the tumor frequently is found to be ruptured. Myocardial infarction and degeneration may be present, probably the result of increased concentrations of catecholamines.[22–24]

Nonfunctional pheochromocytomas in general result in clinical signs consistent with abdominal pain.[22,24,26]

Malignant pheochromocytomas have been reported in young and old horses.[32,33] A malignant pheochromocytoma was reported in a 6-month-old filly with a history of hindlimb lameness and spinal cord disease.[33] Both adrenal glands had multiple and well-circumscribed yellow masses, and metastasis were found in the liver, lungs, vertebral canal, left scapula, and azygous vein. A malignant pheochromocytoma also was diagnosed in a 22-year-old mare that died of massive intrauterine hemorrhage.[32] This mare also had a thyroid C cell medullary adenoma and bilateral nodular hyperplasia of the adrenal medulla, findings that were consistent with multiple endocrine neoplasia. This was the first documented case of multiple endocrine neoplasia in the horse, although a previous report was also consistent with multiple endocrine neoplasia.[34]

Other tumors of neuroectodermal origin such as paragangliomas have been reported in horses.[35,36]

18.4.3 Hyperadrenocorticism

Hyperadrenocorticism resulting from pituitary pars intermedia dysfunction (equine Cushing's disease) is discussed elsewhere in this text. Iatrogenic and adrenal hyperadrenocorticism, although far less common than pituitary-dependent hyperadrenocorticism, also has been described in horses.[37–39]

Iatrogenic hyperadrenocorticism was induced in a horse treated for a pruritic skin condition after injection of 12 mg of triamcinolone acetonide followed by two injections of 200 mg of the same compound within 6 weeks.[37] Clinical signs included depression, polyuria and polydipsia, weight loss, and laminitis. Blood and urinalysis abnormalities (neutrophilia, lymphopenia, hyperglycemia, glucosuria) were similar to those of pituitary-dependent hyperadrenocorticism. However, this horse also had increased serum concentrations of γ-glutamyltransferase, aspartate transaminase, and bile acids, suggesting hepatopathy. Steroid-induced hepatopathy has been reported only in iatrogenic hyperadrenocorticism. Diagnosis of iatrogenic hyperadrenocorticism is based on clinical history, abnormally low baseline cortisol concentration, and abnormally low cortisol response to an ACTH-stimulation test. Treatment for this condition consists in discontinuing administration of exogenous steroids. Steroid-induced hepatopathy was reversible in this case.

One case of pituitary-independent (adrenal-dependent) hyperadrenocorticism has been documented in the literature.[39] In this case a 12-year-old gelding had clinical signs consistent with pituitary-dependent hyperadrenocorticism. Baseline cortisol and ACTH concentrations were within the normal range, and the horse had a normal cortisol response to the ACTH-stimulation test. The horse was treated unsuccessfully with bromocriptine, and over the next 11 months the clinical signs worsened. On necropsy the horse had unilateral enlargement of one adrenal gland and the pituitary gland was small. Histologically, significant cortical atrophy was present in the opposite adrenal gland, the pituitary gland and pancreas were normal, and an adrenocortical adenoma was present in the affected gland. The small pituitary gland in this horse probably resulted from a negative feedback from increased glucocorticoid concentrations, and decreased secretion of ACTH from the

pituitary gland may have resulted in adrenocortical atrophy on the opposite adrenal gland. Adrenal-dependent hyperadrenocorticism also may be diagnosed by a negative dexamethasone suppression test and a delayed peak concentration of cortisol (at 12 hours instead of 8) following ACTH gel administration. [38] No treatment for this condition has been tried.

18.4.4 Adrenocortical Neoplasia

Adrenocortical tumors are rare in horses,[15,39–41] and the few cases reported in the literature were nonfunctional tumors. One case of a 12-year-old Dutch Warmblood gelding with a functional adrenocortical adenoma and clinical signs consistent with Cushing's disease (hyperadrenocorticism) was reported recently.[39]

18.5—Endocrine Pancreas

Ramiro E. Toribio 1361

1362

The islets of Langerhans are endocrine functional units of the pancreas. Histologically, four cell types can be identified: the α- or A cells that secrete glucagon, the β- or B cells that secrete insulin, the δ- or D cells that secrete somatostatin, and the PP-cells that secrete pancreatic polypeptide. The β-cells represent approximately 80% of the islet, and the α-cells the remainder. β-Cells are stimulated by glucose and glucagon and are inhibited by somatostatin. Blood glucose and amino acids concentrations are important regulators of glucagon and insulin secretion; however, circulating islet hormones are the dominant means of pancreatic endocrine secretory control. Pancreatic endocrine function also is regulated by sympathetic and parasympathetic fibers that have nonsynaptic release of norepinephrine, epinephrine, and acetylcholine. The sympathetic system is important in inhibiting insulin and stimulating glucagon secretion, whereas the parasympathetic system is important in stimulating insulin secretion during food intake.[1,2]

Insulin is the primary hormone controlling the metabolism and storage of body fuels. Therefore insulin actions involve three major fuels (carbohydrates, proteins, and fats) and three major tissues (liver, skeletal muscle, and adipose tissue). In the liver, insulin decreases glycogenolysis, gluconeogenesis, and ketogenesis and stimulates gluconeogenesis and fatty acid synthesis. In adipose tissue, insulin decreases lipolysis and stimulates fatty acid uptake, synthesis, and esterification. In skeletal muscle, insulin decreases proteolysis and amino acid output and increases amino acid uptake, protein synthesis, and glycogen synthesis.[3]

Insulin resistance is defined as a decreased response to endogenous insulin (hyperinsulinemia associated with normal or elevated glucose concentrations) or exogenous insulin. Insulin resistance results from changes in insulin receptors, postreceptor effects, or both. Because a number of insulin receptors must be occupied to achieve biologic action, if most receptors are nonfunctional, higher insulin concentrations may be required to activate functional or spare receptors. If higher insulin concentrations are required to achieve a biologic effect, then *decreased insulin sensitivity* exists. If a maximal effect is not achieved, then *decreased insulin responsiveness* exists.

Insulin resistance is reported in horses and ponies with pars intermedia dysfunction, granulosa cell tumors, and hyperlipemia. Obese ponies are less sensitive to endogenous and exogenous insulin, and because of this, insensitivity hyperinsulinemia develops. Defective insulin receptors have not been reported in the horse, and postreceptor kinetic studies are lacking. Few studies have been done on glucose transporters in the horse,[4] and at least in human beings, decreased glucose transporters (in particular GLUT-4) are reported in cases of insulin resistance. An increase in muscular activity increases the GLUT-4 protein expression in the skeletal muscle fibers, and good evidence indicates that exercise is beneficial in human patients with insulin resistance because it increases insulin sensitivity and GLUT-4 protein expression and translocation.[5] An increased number of GLUT-4 transporters have been demonstrated in human athletes with increased insulin sensitivity.[6] Moderate-intensity exercise training in horses increased skeletal muscle GLUT-4 protein content.[4]

Glucagon and insulin have opposing effects on the hepatic glucose metabolism. Glucagon increases glucose concentrations by stimulating hepatic glycogenolysis and gluconeogenesis. Glucagon is important in amino acid uptake, degradation, and conversion to glucose. Glucose inhibits glucagon secretion and stimulates insulin secretion.

Catecholamines inhibit glucose-stimulated insulin secretion. In addition, catecholamines raise glucose concentrations by stimulating glycogenolysis and gluconeogenesis, inhibiting insulin-mediated glucose uptake, increasing lipolysis, and stimulating glucagon secretion.

Growth hormone counteracts insulin action on lipid and glucose metabolism.[7] Growth hormone decreases glucose use and storage and promotes protein synthesis and lipolysis. Growth hormone is important in setting the basal glucose concentrations, also known as the glucostat effect.[3] Low growth hormone concentrations have been associated with insulin resistance in human beings; however, little is known on the role of growth hormone on the pathogenesis of insulin resistance in the horse. Growth hormone deficiency in human beings is associated with the metabolic syndrome X, a condition associated with insulin resistance, central obesity, hyperlipidemia, and hypertension. Some of these clinical findings are similar to those of ponies with Cushing's disease and hyperlipemia and with the recently described peripheral cushingoid syndrome in horses (see Chapter 18.2). Patients with metabolic syndrome X have an abnormal peripheral glucocorticoid metabolism, which is associated with increased cortisol concentrations in adipose tissue.[8]

Glucocorticoids stimulate proteolysis, increase glycogen formation, and stimulate gluconeogenesis. Glucocorticoids also increase glycemia by decreasing the skeletal muscle and adipocyte response to insulin-stimulated glucose uptake. The insulin-antagonistic effects of glucocorticoids in general are accompanied by hyperglycemia and hyperinsulinemia.[3] Increased glucocorticoid concentrations may be associated with insulin 1362
resistance; however, information is lacking on the role of glucocorticoids on insulin resistance in the horse. 1363

18.5.1 Diabetes Mellitus

Diabetes mellitus (DM) is defined as persistent hyperglycemia and glucosuria from hypoinsulinemia or insulin resistance. Diabetes mellitus is characterized by changes in the fuel metabolism (carbohydrates, fats, and proteins) and is associated with disturbances in the secretion and sensitivity to hormones such as insulin, glucagon, catecholamines, growth hormone, and glucocorticoids.[3]

In human beings with Cushing's disease and in horses with pituitary pars intermedia dysfunction (PID, equine Cushing's disease), hyperglycemia, glucosuria, hyperinsulinemia, and insulin resistance are common findings.

Diabetes mellitus is a rare condition in horses and most frequently is associated with insulin resistance following PID.[9–13] *Primary DM* is a term used to describe DM resulting from pancreatic β-cell dysfunction, with decreased insulin concentrations (insulin-dependent DM, type I DM). This distinction is important because most cases of equine DM develop as a consequence of Cushing's disease and abnormal pars intermedia pituitary function. Increased concentrations of adrenocorticotropic hormone and cortisol are considered responsible for the development of secondary DM in horses with Cushing's disease, and the role of growth hormone is unknown.

Horses suspected of having DM often have with a history of depression, polyuria, polydipsia, polyphagia, progressive weight loss, and a rough haircoat. These same clinical signs are present in horses with PID.

Hypoinsulinemia (primary DM) is an uncommon cause of DM in horses and results from chronic pancreatitis, often induced by parasite migration (*Strongylus equinus* larvae).[14–17] Because invasion of the pancreas by *S. equinus* larvae occurs around 8 to 10 weeks after infection, one can observe insulin-dependent DM in younger horses.[15] Primary DM resulting from chronic pancreatitis was reported in a 7-year-old pony that had weight loss, depression, polyuria, polydipsia, polyphagia, hyperglycemia, glucosuria, and ketonuria.[16] Treatment with regular insulin failed to bring the glucose concentration to the normal range; however, protamine zinc insulin successfully decreased glucose concentrations and improved clinical signs.

Insulin resistance and the resulting DM may be induced by different hormonal imbalances. Diabetes mellitus was suspected in a mare with bilateral granulosa cell tumors.[18] The exact cause of DM was not determined, and no lesions were found in the pituitary gland and pancreas; however, the mare had abnormal glucose and insulin tolerance tests, suggesting insulin resistance probably resulting from endocrine factors released by the ovarian tumors. Insulin resistance has been demonstrated in another mare with DM, hyperinsulinemia, normal plasma concentration of growth hormone, and no lesions in the pituitary gland or adrenal glands.[19]

Because persistent hyperglycemia and glucosuria defines DM, to reach a correct diagnosis, one must avoid factors in the horse that can result in temporary hyperglycemia such as carbohydrate diets, stress, exercise, glucocorticoid treatment, and sedation with xylazine and detomidine.[20] Ketonemia, ketonuria, and ketone odor have been reported in diabetic ponies and in a horse with insulin resistance.[9,13,14,16,19] Laboratory abnormalities suggestive of cholestasis may be present in insulin-dependent DM when an inflamed pancreas compresses the common bile duct.[15] Persistent hyperglycemia may be present in horses with pheochromocytomas.[21]

Once one has established a clinical diagnosis of DM, one must rule out PID as the cause of hyperglycemia and insulin resistance. Many test protocols are available for the diagnosis of PID; however, the dexamethasone suppression test is considered the test of choice (see Chapter 18.2).

The *glucose tolerance test* is indicated to characterize the type of DM further. The test can be oral or intravenous, and depending on the situation, one may be preferred over the other. The intravenous administration of glucose has less confounding factors (gastrointestinal motility and absorption, fasting) than the oral test.[22] One administers a 50% solution of glucose, 0.5 g/kg, intravenously and determines serum concentrations of glucose and insulin. In a healthy horse, insulin is released immediately and serum glucose concentration returns to baseline value within 3 hours. In the case of insulin-dependent DM, insulin concentration does not rise and the glucose concentration remains elevated. In the case non–insulin-dependent DM (insulin resistance, type II DM), insulin concentrations rise, but the return of glucose concentration to normal is delayed more than 3 hours.

One also can perform the *insulin tolerance test*.[9,13,16,18,23] One administers soluble (regular) insulin at 1 to 8 IU/kg intravenously and determines the plasma concentration of glucose every 15 minutes for 3 hours. Alternatively, one administers 0.05 IU/kg of crystalline insulin intravenously and takes blood samples every 15 minutes for 3 hours. In healthy horses, one can expect a 30% to 50% decrease in glucose concentrations at 15 minutes, 60% at 30 minutes, and normal glucose concentrations at 2 hours. Failure of insulin to lower the concentration of glucose to normal values suggests insulin-resistant DM. When performing the insulin tolerance test, one must have glucose available for rapid intravenous administration because insulin administration may result in hypoglycemic shock.[16,24] 1363

1364

Measurement of serum insulin concentrations may aid in the diagnosis of DM.[12,18] An elevated concentration suggests insulin resistance, and a reduced concentration suggests insulin-dependent DM.

The treatment of DM depends on the primary cause. Obese ponies with insulin resistance require a decrease in caloric intake and increase in exercise. Treatment of insulin resistance and hyperglycemia following PID is discussed in the section on equine Cushing's disease. If one reaches a diagnosis of primary DM, treatment with insulin is indicated. During treatment with insulin, one must monitor blood glucose concentrations to adjust insulin dosage. In cases of neoplasia (granulosa cell tumor, pheochromocytoma) resulting in hyperglycemia, surgical removal is indicated if possible.

Treatment with insulin (Lente) was attempted in a valuable stallion with pituitary adenoma. Relief of symptoms was achieved initially for 6 weeks, but subsequent worsening of hyperglycemia, polyuria, and polydipsia, along with swelling at the injection sites and development of antibodies against porcine and bovine insulin suggested refractoriness to treatment by exacerbation of the hyperadrenocorticism (insulin resistance) or insulin interference by antibodies.[12] Treatment with regular insulin (8 IU/kg intravenously) failed to bring the glucose concentration to the normal range in a pony with insulin-dependent DM. However, treatment with protamine zinc insulin (8 IU/kg intramuscularly) successfully decreased glucose concentrations. For the next 6 weeks the pony was treated with a daily dose of protamine zinc insulin of 1 IU/kg (0.5 IU/kg intramuscularly b.i.d.), and glucose remained stable (67 to 140 mg/dl). Treatment with this protocol resulted in improvement of body condition and remission of clinical signs. When treatment was discontinued, the clinical signs returned. Insulin administration to this pony often resulted in hypoglycemic shock that responded to intravenous administration of dextrose.[16] A possible complication of insulin administration is insulin-induced hyperglycemia (Somogyi phenomenon), a rebound or paradoxical hyperglycemic result of catecholamine, cortisol, and growth hormone release from acute hypoglycemia.[3,25] The Somogyi phenomenon has been reported in dogs and human beings, but not in horses.

New antihyperglycemic compounds such as biguanides (metformin), sulfonylureas, and thiazolidinediones are indicated to treat insulin-resistant DM but have not been evaluated in the horse.

Exercise may be indicated in affected horses based on information that exercise increases insulin sensitivity and glucose transport across the muscle fiber cell membrane in human beings[5] and that exercise increases skeletal muscle GLUT-4 protein content in horses.[4]

18.5.2 Hyperinsulinemia and Hypoglycemia

Hyperinsulinemia may result in hypoglycemic shock. Hyperinsulinemia with accompanying hypoglycemia may result from therapeutic[16] or fraudulent[24,26] injections of insulin or from increased secretion of insulin by pancreatic tumors.[27]

Depending on the degree of hypoglycemia, the affected horse may show trembling, ataxia, hyperexcitability, tachycardia, tachypnea, mydriasis, nystagmus, profuse sweating, and unawareness of surroundings followed by recumbency, violent seizures, coma, and death. One may suspect injection of insulin in insured horses that suddenly show these clinical signs.[24,26] Hyperinsulinism following an adenoma of pancreatic islet cells was documented in a 12-year-old Shetland pony broodmare.[27] The clinical signs were episodic and consistent with seizures and often were associated with feeding. The pony was hypoglycemic during seizure episodes.

The *glucagon tolerance test* has been used in dogs to diagnose hyperinsulinemia but has not been validated in the horse. Glucagon administration increases glucose and insulin concentrations. The glucagon tolerance test was performed in a pony suspected of having hyperinsulinism from a pancreatic adenoma. Glucagon administration (1500 μg intravenously) to the subject and to a control pony resulted in a rapid increase in glucose concentrations; however, the ponies showed no differences. Insulin concentrations increased in both ponies; however, the subject pony had an exaggerated and sustained insulin response.[27] Major side effects of glucagon administration are cardiovascular effects.

In addition to increased insulin concentrations, hypoglycemia also may result from an abnormal hypothalamus-pituitary-adrenal axis (pituitary destruction, adrenal gland insufficiency). Measurement of insulin and adrenocorticotropic hormone concentrations and the adrenocorticotropic hormone stimulation test to evaluate adrenal gland function may be useful to determine the cause of the hypoglycemia.

During the second half of their pregnancy, mares may develop hyperinsulinemia and have an enhanced β-cell response to exogenous glucose infusion.[28]

One can differentiate between endogenous (pancreatic neoplasia) and exogenous (injected) insulin using high-pressure liquid chromatography.[26]

18.5.3 Neoplasia

Exocrine pancreas tumors (adenocarcinomas) are more frequent than endocrine (islet cell) tumors. Pancreatic
adenocarcinomas reported in the literature resulted in anemia, hyperammonemia, protein-losing enteropathy, 1364
and biliary obstruction.[29–31] No pancreatic endocrine dysfunction has been documented in horses with 1365
pancreatic adenocarcinoma. Likewise, no endocrine dysfunction has been documented in horses with inflammatory bowel disease or lymphosarcoma involving the pancreas.

18.6
18.6—Magnesium Disorders

Allison J. Stewart

18.6.1
Magnesium

Magnesium is an essential intracellular cation that is required for cellular energy-dependent reactions involving adenosine triphosphate (ATP), including nucleic acid and protein synthesis, ion pump function, glycolysis, and oxidative phosphorylation. Magnesium has an important role in regulating the calcium channel function and therefore neurotransmitter release, neuronal excitation, skeletal muscle contraction, vasomotor tone, and cardiac excitability. Because of the importance of Mg in several physiologic processes, homeostatic mechanisms normally maintain intracellular and extracellular concentrations within narrow limits. Severe Mg deficiency 1365
results in neuromuscular disturbances, but such overt clinical signs rarely are documented in horses. In contrast, 1366
subclinical hypomagnesemia is common in critically ill human beings and animals. Subclinical hypomagnesemia increases the severity of the systemic inflammatory response syndrome, worsens the systemic response to endotoxin, and can lead to ileus, cardiac arrhythmias, refractory hypokalemia, and hypocalcemia.

18.6.1.1
CHEMISTRY

The atomic weight of magnesium is 24.3. Therefore 1 mEq (0.5 mmol) of Mg is equal to 12.156 mg. Magnesium concentration in body fluids may be reported as milliequivalents per liter, milligrams per

deciliter, or millimoles per liter. Values reported as milliequivalents per liter can be converted to milligrams per deciliter by multiplying by 1.2156 and to millimoles per liter by dividing by 0.5. Magnesium concentration in feed material may be reported in grams per kilogram of feed, which can be converted to parts per million or milligrams per kilogram by multiplying by 1000 or which can be expressed as a percentage by dividing by 10. Magnesium for oral use is commonly available as MgO (Magox), which contains 60.25% elemental Mg. One also can feed horses $MgCO_3$ and $MgSO_4$. For intravenous injection, $MgSO_4$ is commercially available as $MgSO_4 \cdot 7H_2O$ in a 50% solution (Abbott Laboratories, North Chicago, Illinois). Although the $MgSO_4$ compound is 20.2% elemental Mg, the $MgSO_4 \cdot 7H_2O$ solution contains only 9.9% elemental Mg. Each milliliter of 50% $MgSO_4 \cdot 7H_2O$ solution contains 99 mg (8 mEq or 4 mmol) of elemental Mg. The 50% solution (500 mg/ml or 4 mEq/ml) is hypertonic, with an osmolarity of 4000 mOsm/L and should be diluted to at least a 10% solution before intravenous administration.

18.6.1.2

DISTRIBUTION OF MAGNESIUM WITHIN THE BODY

Magnesium is the fourth most abundant cation in the mammalian body and the second most common intracellular cation after potassium. Fifty percent to 60% of total body Mg is in bone, of which only one third is readily exchangeable.[1–3] Most Mg in bone is combined in a hydroxyapatite lattice and can be released only during active bone resorption. The remaining 40% to 50% of Mg present in the body is located in soft tissues (skeletal muscle, heart, and liver), with the intracellular concentration proportional to the metabolic activity of the cell. Red blood cells contain approximately 3 times the concentration of Mg in serum. Less than 1% of the total body Mg is contained in the extracellular fluid; therefore serum Mg concentration may not reflect total body Mg stores adequately. Serum Mg is present as protein-bound, chelated, or ionized forms. In human beings, 25% of serum total magnesium (tMg) is bound to albumin and 8% to globulins; 55% is ionized, and the remainder is chelated to divalent anions such as phosphate and sulfate. The protein-bound and chelated Mg is unavailable for biochemical processes and only ionized Mg (Mg^{2+}) has biologic activity. Therefore measuring serum ionized rather than total Mg concentrations is preferable. In the horse 65% to 80% of serum Mg is the ionized form,[4] which is much higher than in human beings. Serum tMg concentration depends on protein concentration, whereas Mg^{2+} concentration depends on acid-base status. Feeding a diet with a low dietary cation-anion balance, which is acidifying, increases the percentage of Mg in the ionized form (unpublished observation).

Within the cell, most Mg is bound to proteins and negatively charged molecules, with 80% to 90% of Mg complexed to ATP. Intracellular ionized Mg makes up only 1% to 5% of the total cellular Mg. The intracellular ionized Mg concentration is similar to the extracellular ionized Mg concentration, providing little concentration gradient, which is in contrast to calcium, for which a 10,000-fold extracellular to intracellular concentration gradient exists. Intracellular ionized magnesium concentration is maintained relatively constant even when the Mg concentration in the extracellular fluid varies to high or low concentrations[5] and is due to limited permeability of the plasma membrane to Mg.

18.6.1.3

PHYSIOLOGIC ROLE OF MAGNESIUM

Magnesium serves as an essential cofactor for more than 300 enzymatic reactions involving ATP, such as replication, transcription and translation of genetic information, and the cellular energy metabolism reactions of glycolysis and oxidative phosphorylation.[2,6] Magnesium is also necessary for membrane stabilization, nerve conduction, ion transportation, and regulation of calcium channel activity.[6] Magnesium is required for

normal function of the sodium-potassium activated adenosinetriphosphatase (Na^+,K^+-ATPase) pump, which maintains the Na^+/K^+ gradient across all membranes and regulates intracellular potassium balance. The Ca^{2+}-ATPase and proton pumps also require Mg as a cofactor. Consequently, Mg plays an important role in excitable tissues. Defective function of ATPase pumps and ion channels may result in interference with the electrochemical gradient, alteration in resting membrane potential, and disturbances in repolarization, resulting in neuromuscular and cardiovascular abnormalities.[6–9] The role of Mg in regulating movement of calcium into the myocyte is pivotal for cardiac contractile strength, peripheral vascular tone,[9] and visceral peristalsis.

18.6.1.4 MAGNESIUM ABSORPTION

Metabolic and hormonal effects on gastrointestinal absorption and renal excretion regulate body stores of 1366
Mg. In human beings, Mg is absorbed uniformly from the small intestine. In horses, 25% of ingested Mg is 1367
absorbed in the proximal half of the small intestine and 35% from the distal small intestine and only 5% from the cecum and large and small colons. The mechanisms of Mg absorption and regulation are not well understood, but serum concentrations can be elevated in response to dietary intake and digestibility. The average absorption of Mg by horses fed a variety of feedstuffs was 49.5% (30% to 60%),[10] which is higher than the range of absorption reported in ruminants (10% to 40%).[11] Meyer found that in clover or meadow hay, Mg was 31% digestible, whereas in rations containing hay and grain Mg was 38% digestible.[12] The type of diet does not appear to affect the site of Mg absorption.[10] Forms of MgO, $MgSO_4$, and $MgCO_3$ for oral use have equivalent digestibilities, with absorption rates higher than from organic sources, being approximately 70% in growing foals.[13]

In contrast to Ca, for which increasing the intake of Ca decreases the digestibility of Ca,[14] an increase in Mg intake increases the digestibility of Mg. When MgO concentration in feed was increased from 1600 to 3100 ppm, the absorption in the horse increased from 53% to 62%, with no further increase in absorption with excessive supplementation at 8600 ppm. Apparently the response of Ca absorption to Mg intake is biphasic, with increased Ca absorption with Mg deficiency or excess.[15] High levels of dietary phosphorus decrease absorption of magnesium.[10]

18.6.1.5 MECHANISMS OF RENAL MAGNESIUM EXCRETION AND REABSORPTION

Free or ionized Mg is filtered by the glomerulus, whereas protein-bound Mg passes directly through the renal efferent arteriole without passing into the glomerular filtrate. In human beings, serum Mg concentration is regulated by tubular reabsorption, and tubular secretion is minimal. Renal excretion of Mg varies directly with dietary changes and thus the serum concentration of Mg presented to the kidney. During Mg depletion, the kidney avidly conserves Mg and virtually no Mg is excreted into the urine.[16] Conversely, when excess Mg is ingested, it is excreted rapidly into the urine because of diminished renal tubular reabsorption. Microtubule nephron puncture studies in several mammalian species indicate that the proximal tubule reabsorbs 5% to 15%, and the thick ascending limb of the loop of Henle absorbs 70% to 80% of the Mg filtered by the glomerulus.[17,18] The distal convoluted tubule only absorbs approximately 10% of the filtered Mg, but this is 70% to 80% of that delivered from the loop of Henle. Because absorption is minimal beyond the distal tubule, this segment is responsible for determining the final urinary Mg excretion.

Reabsorption of Mg in the proximal convoluted tubule is via the paracellular route. The process is passive and is driven by positive luminal voltage and the high concentration gradient of Mg in the glomerular filtrate. In the cortical thick ascending loop of Henle, transport of Mg is also passive, with a permeability of 60%, and is mediated by paracellin-1.[19] The driving force provided by the $Na^+/K^+/^-$ cotransporter creates a transepithelial voltage gradient that maintains a positive luminal voltage that drives divalent cations such as Ca and Mg down their respective concentration gradients.[20]

18.6.1.5.1 Hormonal Regulation of Magnesium

Despite the precise regulation of serum Mg concentration by the kidney, Mg does not have a complex homeostatic endocrine regulating mechanisms.[21] This lack of regulation is in contrast to calcium, which is tightly regulated by parathyroid hormone (PTH), calcitonin, and calcitriol (1,25-dihydroxyvitamin D) (see Chapter 18.1). Parathyroid hormone, vitamin D, calcitonin, arginine vasopressin, glucagons, and calcium concentrations influence Mg absorption and excretion to some degree.

Parathyroid hormone acts on the renal tubules to increase Mg reabsorption.[22] Micropuncture studies have shown that PTH changes the cortical thick ascending limb of the loop of Henle potential difference, which increases the transepithelial voltage gradient and paracellular Mg reabsorption.[16–18,23–25] Other peptide hormones such as calcitonin, arginine vasopressin, and glucagon enhance Mg absorption in the distal convoluted tubule similar to PTH, but the physiologic relevance of these actions is unknown.[25] Magnesium uptake in the renal tubules is concentration and voltage dependent.[23] In the kidney the calcium receptor regulates Ca and Mg resorption independent of PTH. When Ca or Mg interact with the calcium receptor, they inhibit the $Na^+/K^+/2Cl^-$ transporter, which reduces the transepithelial voltage gradient[20] and directly decreases the reabsorption of Ca and Mg.

In other species, vitamin D increases intestinal Mg absorption, but the effect of calcitriol and calbindins on renal handling of Mg is unclear. Vitamin D_3 administration in other species causes increased intestinal absorption of Ca and Mg, resulting in hypercalcemia and hypermagnesemia, which decreases Mg reabsorption in the loop of Henle and distal tubule because of stimulation of the extracellular Ca^{2+}/Mg^{2+}-sensing receptor, increasing urinary excretion of Mg and Ca.[23] In human beings with sepsis, vitamin D synthesis is impaired because of a deficiency of renal 1α-hydroxylase because of the action of calcitriol.[26] The importance of vitamin D in Ca and Mg metabolism in the horse is poorly understood.[27] Horses have low plasma concentrations of vitamin D metabolites (calcitriol, calcidiol) and no detectable 1α-hydroxylase activity in renal cortex homogenates.[28] Vitamin D has little effect on Ca and phosphorus 1367
homeostasis in the horse (see Chapter 18.1), and whether vitamin D has any influence on Mg regulation is 1368
unknown.

18.6.1.5.2 Pathophysiologic Consequences of Hypomagnesemia and Inflammation

Recent information implicates Mg in cell messaging and cytokine production. Hypomagnesemic rats exhibit elevated circulating cytokine concentrations (interleukin-1, interleukin-6, tumor necrosis factor) indicative of a generalized inflammatory state.[29,30] Hypomagnesemic rats are acutely sensitive to the effects of experimentally administered endotoxin, and this vulnerability is correlated with higher plasma tumor necrosis factor concentrations.[30] In a rodent model, progressive Mg deficiency lead to increasing

mortality rates from the effects of endotoxin administration, whereas Mg supplementation reduced the endotoxin-induced mortality.[31] Hypomagnesemia also predisposed animals to free radical–associated injury,[32,33] leading to the formation of cardiomyopathic lesions and altered vascular tone.[34,35] The author and colleagues have found that experimental endotoxin administration in the horse results in an acute decrease in Mg^{2+} concentration (personal communication with Joanne Hardy and Ramiro Toribio, 2002). Not only does endotoxemia appear to induce acute hypomagnesemia, but also Mg administration may have a protective effect in patients with hypomagnesemia and endotoxemia. Human beings with endotoxemia and concurrent hypomagnesemia have a worse outcome compared with normomagnesemic patients.[31] Considering that approximately 40% of horses with colic are endotoxic and that free radical injury is an important mechanism in intestinal ischemia-reperfusion injury,[36] the role of Mg and its therapeutic importance in equine disease warrants investigation.

18.6.2 Hypomagnesemia

18.6.2.1 INCIDENCE OF HYPOMAGNESEMIA IN HUMAN PATIENTS

Hypo- and hypermagnesemia are reported to be the most common and most underdiagnosed electrolyte disorders in adult and pediatric human medicine.[37–39] The prevalence of Mg deficiency has been documented in 61% and 65% of surgically and medically critically ill human patients, respectively.[40,41] Whether one should use assessment of tMg or Mg^{2+} to define serum hypomagnesemia is controversial. In 115 critically ill human patients, 51.3% had serum tMg below reference range, but 71% of these had normal serum Mg^{2+}. None of these patients had mononuclear blood cell or erythrocyte Mg concentrations below the reference limit.[42] In contrast, 60% (40 of 67) of critically ill pediatric patients had low Mg^{2+}, and of these, 60% (24 out of 40) had normal tMg concentrations.[43] Other studies also revealed Mg^{2+} to be a more sensitive indicator of hypomagnesemia than tMg.[44] Measurement of Mg^{2+} generally is recommended over tMg concentration as an assessment of the physiologically active component in the serum.[7,43,45–48]

18.6.2.2 INCIDENCE OF HYPOMAGNESEMIA IN VETERINARY PATIENTS

Until recently, Mg therapy was considered unconventional in veterinary medicine,[49] with serum Mg concentrations being assessed infrequently. In the Ohio State University canine and feline intensive care unit, 28% to 39% of patients were hypomagnesemic.[50] Recently a high prevalence of hypo- and hypermagnesemia was found in feline patients in intensive care, with period prevalence of 28% (16 of 57) and 18% (10 of 57), respectively.[51] A retrospective study found that 48.7% of hospitalized horses had Mg values below the reference range. Hypomagnesemia was associated with gastrointestinal disease, infectious respiratory disease, and multiorgan system disease.[52] In an earlier study, 54% of equine surgical colic patients had low serum Mg^{2+} concentrations, and these horses had a significantly greater prevalence of postoperative ileus than normomagnesemic equine surgical colic patients.[44] Low Mg^{2+} was documented recently in 78% of horses with enterocolitis at the Ohio State University.[27]

18.6.2.3 OUTCOME IN HYPOMAGNESEMIC PATIENTS

Hypomagnesemia is a common observation in the critically ill patient, but whether the condition contributes to mortality or whether it is merely an association in patients with severe disease is unknown.[53] One study of 115 critically ill human patients found a lack of association with clinical outcome, suggesting hypomagnesemia to be an epiphenomenon.[42] In critically ill human pediatric patients, hypomagnesemia and hypocalcemia were predictors of high mortality, with 62% of nonsurvivors having abnormal Mg concentrations.[39] Human beings with endotoxemia and concurrent hypomagnesemia were predisposed to a poorer outcome.[31] In human and canine intensive care unit populations, hypomagnesemic patients had a longer length of hospitalization.[40,54]

In a hospitalized equine population in which 48.7% (401 of 823) were hypomagnesemic, no association with mortality was found, but the length of hospitalization was longer for horses with hypomagnesemia.[52] In a study of equine surgical patients with colic, horses that were euthanatized at the time of surgery (7 of 35) had significantly lower preoperative serum concentrations of Mg^{2+} compared with horses that survived, but serum Mg concentration did not predict hospitalization time or survival.[44] Cats with abnormalities of serum tMg had a longer length of hospitalization compared with normomagnesemic cats (5 verses 4 days: $P = 0.03$) 1368
and a lower survival rate than normomagnesemic cats (54% verses 77%: $P = 0.05$).[51] 1369

18.6.2.4 ASSOCIATION OF HYPOMAGNESEMIA WITH HYPOKALEMIA

Hypomagnesemia frequently is associated with hypokalemia and kaliuresis in human beings and dogs.[37, 40, 54–56] Magnesium deficiency has been associated with loss of cellular potassium stores, and as is the case in hypocalcemic patients, restoring normokalemia until the concurrent Mg deficiency is corrected may be difficult.[57,58] Associations between low serum Mg and K concentrations have been reported in critically ill dogs and human beings.[59] Hypomagnesemia occurred in 36% to 61% of hospitalized human patients with hypokalemia,[37,41,55,60,61] and 31% of dogs with hypomagnesemia concurrently had hypokalemia.[54]

Hypomagnesemia affects the ability of Mg to act as a coenzyme for the Na^+,K^+-ATPase pump. Hypomagnesemia leads to decreased intracellular K and increased intracellular Na concentrations that lower the resting membrane potential, predisposing cells to spontaneous depolarization and impairment of transmission of electric impulses.[62] Hypomagnesemia can result in the blockade of voltage-gated K channels,[63] which interferes with electric repolarization and the propagation of the action potential. Hypomagnesemia also can lead to increased Purkinje fiber excitability, which predisposes to arrhythmia generation.[64]

18.6.2.5 ASSOCIATION OF HYPOMAGNESEMIA WITH HYPOCALCEMIA

Hypocalcemia is a common finding in human patients with hypomagnesemia. Although the mechanism of action is not understood completely, serum Mg may influence serum Ca concentrations.[65,66] Hypocalcemic patients with concurrent hypomagnesemia are often refractory to Ca therapy unless the low serum Mg concentrations are identified and corrected.[67–70] Most human beings with hypocalcemia and concurrent hypomagnesemia have inappropriately low serum PTH concentrations based on their degree of

hypocalcemia, suggesting impairment of PTH synthesis or secretion from the parathyroid gland.[65,69,71–73] Administration of Mg to these patients results in elevation of their serum PTH concentration and normalization of serum Ca concentrations. This response contrasts to normal human beings, in whom administration of Mg results in a decrease in PTH concentrations.[74] Low Mg concentrations increase peripheral organ (renal and skeletal) resistance to PTH,[74–77] with resulting decreases in serum concentration of $1,25(OH)_2D_3$. In a dietary-induced Mg deficiency model in human volunteers, in addition to the induced decrease in serum Mg concentrations were concurrent reductions in serum Ca and $1,25(OH)_2D_3$ concentrations and an inappropriate fall or lack of elevation of PTH in 20 of 25 subjects who had low serum Ca and Mg concentrations. The significant decrease in $1,25(OH)_2D_3$ concentration was suggested to be caused by hypomagnesemic-induced decreases in PTH secretion and renal resistance to PTH.[68] Mild hypocalcemia and hypomagnesemia stimulate PTH release, but severe Mg depletion and acute hypermagnesemia decrease PTH release.[75,78–82] Consequently, parallel determination of Ca and PTH concentrations is important in the investigation of Mg homeostasis.

Magnesium is considered the physiologic calcium blocker of nature because it reduces the release of calcium from and into the sarcoplasmic reticulum and protects the cell against calcium overload under conditions of ischemia.[83] The calcium channel–blocking effect of Mg appears to be decreased in the hypomagnesemic state with a subsequent increase in intracellular Ca concentration leading to enhanced cellular sensitivity to cardiotoxic drugs or ischemic events. In human beings, these physiologic processes support the associations made between hypomagnesemia and various cardiac arrhythmias and organic myocardial diseases.[34,41,63,84–91]

Sepsis-induced hypocalcemia and hypomagnesemia may be associated with intracellular ionic shift, hemodilution, or sequestration. In human beings, inflammation causes elevations in calcitonin and procalcitonin concentrations and may help to explain the hypocalcemia frequently observed in cases of sepsis and trauma.[92,93] Magnesium may function as a Ca antagonist, and low Mg may enhance intracellular entry of Ca in sepsis and endotoxemia.[31] Acute hypomagnesemia following experimental endotoxin administration has been observed in horses (personal communication with Ramiro Toribio and Joanne Hardy, 2002). Whether Mg administration to acutely hypomagnesemic patients is beneficial in reducing mortality or length of hospitalization is undetermined, but to maintain therapeutic serum concentrations within reference range during times of severe illness when homeostatic mechanisms are overwhelmed seems reasonable.

18.6.2.6 AMINOGLYCOSIDE-INDUCED RENAL MAGNESIUM WASTING

Gentamicin administered at standard clinical doses to healthy human subjects results in immediate and transient renal Ca and Mg wasting.[94] Although the mechanism is not defined fully, the phenomenon does not appear to be caused by aminoglycoside tubular injury as previously theorized.[95,96] Magnesium is absorbed primarily in the thick ascending limb of the loop of Henle, but the distal convoluted tubule is the major site 1369
of hormonal regulation of Mg absorption and therefore the final determinant of urinary Mg excretion. 1370
Gentamicin therapy results in Mg loss by its effect on the distal convoluted tubule.[95] Aminoglycosides inhibit PTH-mediated cyclic adenosine monophosphate formation and reduce PTH-stimulated renal tubular cell entry of Mg. The hypothesis is that the positively charged aminoglycosides act via a polyvalent cation–sensing receptor on the extracellular surface of the distal convoluted tubule cells, thereby inhibiting hormone-stimulated renal tubular absorption of Mg.[97] This proposed mechanism helps explain the clinically observed Mg wasting. Gentamicin is a common antimicrobial used to treat gram-negative infections in the

horse, but the effects of gentamicin on renal Mg absorption have not been investigated in the domestic species.

18.6.2.7

MAGNESIUM REQUIREMENTS IN THE HORSE

Obligatory urinary and fecal Mg loss in the horse was estimated at 2.8 mg/kg body mass per day and 1.8 mg/kg body mass per day, respectively, by the use of regression analysis of 72 metabolic balance studies. The horse therefore must absorb a total of 4.6 mg of Mg per kilogram of body mass to replace daily obligatory losses. With an average of 49.5% absorption, the dietary requirement to replace obligatory losses was estimated at 9.3 mg/kg body mass per day. However, the same study determined the regression analysis of intake versus retention to predict Mg balance to occur with ingestion of 13.1 mg Mg per kilogram of body mass per day.[10] The maintenance Mg requirement of 13 mg/kg body mass per day can be provided by a diet containing approximately 0.16% Mg (1600 ppm, 1600 mg/kg, or 1.6 g/kg of feed), which is considered the low-level maintenance requirements for adult horses.[15] Growing, lactating, and exercising animals have a higher requirement of dietary Mg. Mare's milk contains approximately 90 mg/kg of Mg in early lactation and 45 mg/kg in late lactation. Substantial amounts of Mg also can be lost in sweat. During early lactation and for horses undergoing moderate to intense exercise, Mg intake should be increased between 1.5 to 2 times the maintenance level.

Roughage in the form of alfalfa hay had an increased digestibility of Mg (51%) compared with a pelleted complete feed (31%), with a similar Mg content of 1700 ppm, when fed to ponies. In ponies fed alfalfa hay, postprandial plasma concentrations of Mg rose rapidly in the first hour after feeding, peaking after 2 hours at 0.84 mmol/L and returning to 0.75 mmol/L after 12 hours, whereas ponies fed a concentrate pelleted diet had two plasma peaks of 0.67 mmol/L after 2 and 6 hours and then returned to a baseline of 0.6 mmol/L after 12 hours. Therefore the concentration of Mg in the plasma was higher in the group fed roughage and was consistent with the increased Mg absorption from roughage-based feeds. The alfalfa diet resulted in a greater renal excretion of Ca and Mg within 12 hours of feeding (56% and 57% of intake, respectively) than the concentrate diet (19% and 33% of intake, respectively), which reflects increased Mg availability and hence greater excess than with concentrate feeding.[98]

18.6.2.8

EXPERIMENTAL DIETARY MANIPULATION OF MAGNESIUM IN THE HORSE

Hypomagnesemia was induced in mature ponies by feeding Mg at 5 to 6 mg/kg body mass per day (using a 370-ppm diet), whereas 20 mg/kg/day met Mg requirements.[99] A deficiency state is more readily inducible in growing animals because of their higher dietary requirement of Mg. Foals fed a diet extremely deficient in Mg (7 to 8 ppm or 0.0007%) developed severe mineralization of the aorta with severe clinical signs of hypomagnesemia becoming apparent after 90 days in 2 of 11 foals.[100]

Urinary excretion of electrolytes is useful for assessing dietary supply of minerals. The urinary Mg concentration decreased from a baseline of 30 mg/dl to 4 mg/dl after 6 days on a Mg-deficient diet (370 ppm) and increased to more than 300 mg/dl on a high-Mg diet supplemented with 36 g of MgO per day.[99] Increasing the Mg content of a diet from 3100 to 8600 ppm increased Mg digestibility, retention, and excretion in urine and feces and increased serum concentrations from 2.21 mg/dl to 3.39 mg/dl.[15] In foals fed a diet severely deficient in Mg (7 to 8 ppm), serum Mg concentration decreased rapidly from a baseline of 0.78 mmol/L to 0.53 mmol/L after 7 days and then decreased steadily to 0.26 mmol/L after 150 days. The slower rate of reduction in serum Mg concentrations was presumed to be because of mobilization of Mg from

bone. Bone magnesium content decreased in response to Mg depletion, but surprisingly no effect on tissue (brain, liver, kidney, spleen, lung, and cardiac or skeletal muscle) concentrations of Mg, Ca, or P was found after 71 to 180 days.[101]

18.6.2.9 CLINICAL SIGNS AND CONSEQUENCES OF MAGNESIUM DEFICIENCY

Magnesium deficiency may cause muscle weakness, tremors, seizures, cardiac arrhythmias, hypokalemia, and hypocalcemia and may be associated with increased mortality. Hypomagnesemia results from reduced Mg intake (poor nutrition, low Mg content of the diet, or intravenous fluids deficient in Mg), reduced absorption (chronic diarrhea, malabsorption, or bypass/resection of bowel), redistribution (exchange transfusion, third space sequestration), and increased excretion (medication [gentamicin or furosemide], 1370
alcoholism, diabetes mellitus, renal tubular disorders, hypercalcemia [from medication and other causes of 1371
hypercalcemia], hyperthyroidism, aldosteronism, stress, or heavy lactation).

Severe hypomagnesemia can lead to ventricular arrhythmias, supraventricular tachycardia, or atrial fibrillation. Characteristic findings on electrocardiogram include prolongation of the P-R interval, widening of the QRS complex, ST segment depression, and peaked T waves.[102]

18.6.2.10 CLINICAL SIGNS AND CONSEQUENCES OF MAGNESIUM DEFICIENCY IN THE HORSE

Grass tetany, hypomagnesemia associated with grazing lush green winter pastures, is a source of substantial economic loss in lactating beef cattle. However, clinical signs of hypomagnesemia are rarely reported in horses grazing similar pastures. Clinical manifestations of hypomagnesemia include muscle weakness, muscle fasciculations, ventricular arrhythmias, seizures, ataxia, and coma. Hypocalcemic tetany complicated by hypomagnesemia was reported in Welsh mountain ponies.[103,104] Similar signs were induced experimentally after 90 days in 2 of 11 foals fed a diet extremely deficient in Mg (7 to 8 ppm or 0.0007%). The signs of hypomagnesemic tetany were precipitated by loud noises, with foals initially exhibiting nervousness, muscular tremors, and ataxia, followed by collapse, profuse sweating, hyperpnea, and convulsions. One foal died during its third seizure on day 150 of the deficiency trial. Total serum magnesium concentrations decreased from 1.9 ± 0.1 mg/dl to 0.7 ± 0.4 mg/dl. Severe mineralization of the elastic fibers of the aorta and pulmonary artery occurred in all 11 foals fed the Mg-deficient ration for between 30 and 180 days.[100]

Concurrent hypocalcemic and hypomagnesemic tetany was reported in two Thoroughbred broodmares that had been transported for breeding. The mares were nursing foals that were 4 and 7 weeks old. The serum total Ca (tCa) was 4.0 mg/dl and 5.4 mg/dl, whereas the tMg was 1.0 mg/dl and 1.9 mg/dl, respectively. The mares responded to intravenously administered calcium borogluconate and magnesium chloride.[105]

Hypomagnesemia and hypocalcemia are common perioperatively in horses requiring exploratory celiotomy for colic, particularly in horses with strangulating intestinal lesions and ileus. In 35 equine surgical colic cases, preoperative serum tMg and Mg^{2+} concentrations were less than the reference range in 17% (6 of 35) and 54% (19 of 35), respectively. Serum concentrations of tCa and Ca^{2+} were below reference range in 57% (20 of 35) and 86% (30 of 35) of horses before surgery. Serum concentrations of tMg and tCa were less sensitive than Mg^{2+} and Ca^{2+} in detecting horses with hypomagnesemia and hypocalcemia. Significantly lower serum concentrations of Mg^{2+} occurred in horses that developed postoperative ileus. Serum

concentrations of Mg and Ca (total and ionized) correlated significantly with the P-R, QRS, QT, and QT corrected for heart rate (QTc) intervals. Horses that were euthanized at the time of surgery ($n = 7$) had significantly lower preoperative serum concentrations of Mg^{2+} compared with horses that survived, but neither serum Mg nor Ca concentrations were predictors of hospitalization time or survival. Horses with strangulating lesions were more likely to be hypomagnesemic and hypocalcemic and also had significantly shorter PR, QRS and QTc intervals compared with horses with nonstrangulating lesions. Horses with strangulating lesions were more likely to be hypomagnesemic and hypocalcemic and have electrocardiogram changes than horses with nonstrangulating lesions.[44] Multiple factors probably contribute to the observed electrocardiogram disturbances, but the routine detection and correction of the electrolyte abnormalities (including Mg^{2+} and Ca^{2+}) are recommended.

Serum Mg^{2+} is significantly lower in horses with enterocolitis and hypocalcemia compared with healthy horses. Most horses (48 of 64; 75%) with enterocolitis had decreased serum tCa, Ca^{2+}, and Mg^{2+} concentrations and increased phosphorus concentrations. Differential diagnoses for the mechanism of the enterocolitis-induced hypomagnesemia include sequestration of Mg within cells, in the peritoneal fluid, or in the lumen of gastrointestinal tract (increased gastrointestinal secretion or impaired absorption from inflamed bowel) or decreased renal reabsorption of Mg resulting in excessive urinary losses. Fractional clearances of Mg were not calculated in this group of horses. Fractional clearances of Ca were appropriately low in hypocalcemic enterocolitis patients compared with healthy horses, and thus urinary loss of Ca could not explain the observed hypocalcemia. In this group of horses, serum PTH varied. Of the horses with hypocalcemic/hypomagnesemic enterocolitis, 20% (10 of 51) had high PTH, which may be explained by hypomagnesemia-induced end organ resistance to PTH. Some horses (15 of 51; 29%) had inappropriately low serum PTH concentrations in the face of hypocalcemia. One explanation involves hypomagnesemia-induced intracellular accumulation of Ca and reduced cyclic adenosine monophosphate production by the parathyroid gland, resulting in low PTH synthesis and release.[27] The exact mechanisms of the interdependence of Ca and Mg on PTH secretion are unknown.

18.6.2.11 MAGNESIUM AND BRAIN INJURY

Based on evidence from human medicine, Mg infusions recently have gained popularity in the empirical treatment of hypoxic ischemic encephalopathy in neonatal foals.[106] Although such therapy appears safe, results of clinical trials in foals have not yet been published. 1371

1372

Perinatal brain damage may result from asphyxia after reduction of uterine or umbilical blood flow.[107] The resultant cerebral hypoxia decreases oxidative phosphorylation and energy production, resulting in failure to maintain ionic gradients across cell membranes. With the loss of membrane potential, calcium influxes into neuronal cells down its large extra- and intracellular gradient through voltage-gated ion channels. Hypoxic conditions also lead to the release of glutamate sequestered within neurons. The excitatory neurotransmitter glutamate is itself neurotoxic but also allows further influx of calcium into neurons by glutamate-regulated ion channels. Calcium overload results in neuronal cell death by damage resulting from activation of calcium-dependent proteases, endonucleases, and lipases.

Apoptosis (programmed cell death) is thought to occur because of the neurotoxicity of accumulated glutamate and aspartate and the associated increase in intracellular calcium concentrations. Traumatic brain injury induces the activation of the *N*-methyl-d-aspartate (NMDA) subtype of the glutamate receptor[108] and has been implicated in the pathophysiology of hypoxic ischemic encephalopathy.[109] Magnesium is important

in the voltage-dependent blockade of NMDA channels. In the normal resting state, without glutamate-receptor interaction, Mg blocks the NMDA calcium channel, preventing calcium entry into the cell and decreasing neurotransmitter release. Magnesium also blocks the entry of calcium through the voltage-gated calcium channels in the presynaptic membrane.[110] Normal blood-brain vessel vasodilation also depends on Mg. Magnesium can block calcium channels in vascular smooth muscle, thereby decreasing vascular smooth muscle contraction, resulting in vasodilation.[111]

In brain injury, increased glutamate receptor interaction results in phospholipase C activation. A subsequent release of phosphate groups occurs after the cleavage of phospholipid glycerophosphate that binds free Mg. These magnesium-phosphate complexes are removed from the site of injury, resulting in the tissue loss of Mg. Lower Mg concentrations increase vascular smooth muscle tone, potentiating vasospasm with reduction of oxygen and substrate delivery to tissues. Focal traumatic brain and spinal cord injury in rats can reduce free brain Mg concentrations by as much as 60%, with the reduction proportional to the extent of the injury.[110] Therefore brain injury reduces brain Mg concentration and results in the loss of the protective role of Mg and potentiation of further brain injury.

As the excitotoxic cascade occurs over a period of several days, a window for therapeutic intervention exists to prevent secondary brain injury.[112] The reduction in the voltage-dependant Mg^{2+} blockage of NMDA current in mechanically injured neurons can be restored by increasing extracellular Mg concentration. Magnesium sulfate has been shown greatly to improve the immediate recovery of rats from hypoxia[113] and to improve the motor outcome in rats treated after severe traumatic axonal brain injury.[114] Magnesium sulfate also has been shown to protect the fetal brain during severe maternal hypoxia.[115] The available experimental literature and reasoning suggests that in most cases Mg therapy may be advantageous in protecting against and in treating hypoxic ischemic encephalopathy in foals, but further evidence still is required before the benefits, if any, can be proved.

18.6.2.12 DIAGNOSTIC TESTING

The clinical laboratory evaluation of Mg status is limited primarily to measurement of serum Mg concentration, 24-hour urinary excretion, and percent retention following parenteral Mg loading. However, results for these tests do not necessarily correlate with intracellular ionized concentrations. No universally accepted, validated, and readily available test exists to determine intracellular and total body magnesium status.

The diagnosis of Mg deficiency can be a challenge. Only 1% of body stores are located in serum as protein-bound, chelated, or ionized forms. The lack of representative value of serum Mg concentrations, the influence of other constituents on serum Mg concentration, and the slow equilibrium of Mg between tissue pools limits the value of serum Mg determination as an index of total body Mg content.[1,116] Determination of tMg content in blood monocytes or erythrocytes also has been shown to be unreliable for estimation of total body status.[1,116–118] The protein-bound and chelated Mg are unavailable for biochemical processes, and only Mg^{2+} has biologic activity. Because the Mg^{2+} concentration represents the functional pool of serum Mg, determination of Mg^{2+} may provide a better assessment of physiologic Mg status as opposed to measuring tMg.[7,43,45–48]

Even though Mg^{2+} concentrations may not reflect total body stores, an association exists between changes in Mg^{2+} concentrations and acute disease processes.[1,27,44,54] The recent advent of a commercially available ion-selective electrode for determining Mg^{2+} concentrations has allowed quantification of Mg^{2+}, and this test is performed routinely in hospitalized critical equine patients in the author's hospital. Although not specifically proven in the horse, in human beings, one cannot predict Mg^{2+} concentration from concentrations of tMg, albumin, Ca^{2+}, or pH.[43] Hypoalbuminemia results in a low measured serum tMg concentration (pseudohypomagnesemia) and does not require Mg supplementation if the serum Mg^{2+} concentration is normal. One must recognize this association, but formulae to correct Mg concentration based 1372
on adjustment for protein concentrations are not accurate and should not be used (Dennis Chew, personal 1373
communication, 2002). If possible, one should measure Mg^{2+} concentration whenever one finds the total Mg concentration to be abnormal. Similar to calcium, Mg binds to anionic (negatively charged) protein binding sites, with the binding affinity dependent on pH. During acidosis, the increased hydrogen ion concentration displaces Ca^{2+} and Mg^{2+} from their protein binding sites, increasing the percent of these cations in their ionized form, resulting in increased serum Ca^{2+} and Mg^{2+} concentrations. In animals with respiratory or metabolic alkalosis (often observed after prolonged strenuous endurance exercise), Ca^{2+} and Mg^{2+} concentrations may be low because of increased protein binding. Because Mg^{2+} is the physiologically active component, ionized hypomagnesemia supplementation is recommended, especially if one observes clinical signs of synchronous diaphragmatic flutter (thumps), ileus, or (rarely) muscle fasciculations, ataxia, or tetany. Although not likely to be of consequence in an animal with adequate renal function, resolution of the alkalosis may result in elevations of the serum Mg^{2+} concentration. In contrast, animals with metabolic acidosis following sepsis, systemic inflammatory response syndrome, and severe gastrointestinal disease rarely have serum ionized hypermagnesemia, rather their serum Mg^{2+} concentration tends to be low from altered Mg homeostasis, cellular or third space redistribution, gastrointestinal loss of Mg, or diuresis following aggressive fluid therapy with intravenous fluids unsupplemented with Mg.

One may use renal excretion of Mg to evaluate Mg balance. When Mg intake is deficient, urinary Mg excretion falls to negligible levels, whereas serum Mg remains within the normal range.[16,119] Renal Mg excretion is measured in urine collected over 24 hours and expressed as total amount excreted (milligrams per kilogram per day). Renal clearance, also measured by 24-hour urine collection, estimates the amount of blood cleared of Mg daily and uses concurrent serum and urine Mg concentrations for calculations. One can determine renal electrolyte clearance, without quantitative urine collection, by expressing the renal electrolyte clearance relative to the endogenous creatinine clearance, which clinically is referred to as fractional clearance. Fractional clearance relates the amount of substance excreted to the amount filtered by the glomerulus. Reference values for the fractional clearance of Na, K, Cl, and P have been reported in horses.[120–123] The use of spot urine and serum collection as estimates of 24-hour clearance has been validated in horses for Na, K, Cl and P.[122] Spot sample fractional clearance of Mg has been determined in normo- and hypomagnesemic human beings and was found to be useful in the diagnosis of hypomagnesemia.[124,125] Currently, little information has been published on renal handling of Mg in horses. The reference range for the fractional clearance of Mg in normal horses fed grass hay was found to be 29% ± 8%. Fractional clearance of less than 6% would indicate inadequate dietary intake.[4]

Tissue Mg content has been used as an estimate of total body stores. In one study in horses, muscle was found to contain 1.29 ± 0.09 mg/g dry matter of Mg, accounting for 32.3% of the body Mg, whereas the skeleton accounted for 62.5%.[126] Skeletal muscle is therefore important in the assessment of Mg status. The

skeleton buffers the majority of acute Mg loss, and in periods of chronic Mg deficiency, skeletal Mg depletion may be significant.[127]

Investigation of the role of hypomagnesemia in human patients with cardiac disease found that cardiac muscle biopsy Mg concentrations correlated well with Mg status.[128] In human patients undergoing surgery for acute myocardial infarction, a good correlation between intracellular Mg concentration within cardiac cells and that in sublingual epithelial cells was observed. These patients had significantly lower sublingual intracellular Mg concentrations than healthy control subjects and acutely ill patients without myocardial ischemia. Intravenous administration of $MgSO_4$ raised sublingual intracellular Mg concentrations within 24 hours. Intracellular Mg was measured using energy-dispersive x-ray microanalysis using a specially configured scanning electron microscope to irradiate cells with a focused electron beam. Sublingual cells were chosen because they are noncornified and aerobic, have a turnover time of less than 3 days, are readily accessible, and therefore provide a noninvasive measurement of intracellular Mg stores.[129]

Estimation of total body Mg status has been evaluated recently in human beings using an intravenous Mg retention test, which now provides the gold standard for identification of Mg deficiency in human beings.[130,131] One calculates the percentage of Mg retained after an intravenous load after measuring the amount of Mg excreted in urine during a 24-hour period. Magnesium sulfate solution ($MgSO_4 \cdot 7H_2O$) is used commonly and contains 10% elemental Mg. For example, one can provide a dose of 10 mg/kg of elemental Mg using 100 mg/kg of $MgSO_4$ solution. Magnesium sulfate is commercially available as a 50% solution, which should be diluted to 10% before administration. Percent retention (%Ret) is calculated as follows[132]:

$$\%\text{Ret} = \frac{1-(\text{Mg excretion in 24 hours})}{\text{Mg infused}} \times 100$$

In human beings, retention of 40% to 50% of the administered Mg load indicates hypomagnesemia, whereas retention of less than 20% indicates that Mg deficiency is less likely.[133] In one clinical study, 1373
normomagnesemic human beings retained a mean of 14%, whereas patients suspected of having Mg 1374
deficiency retained up to 85%.[134] Development of a Mg retention test for diagnosis of hypomagnesemic states in horses has been investigated using a reduced Mg diet. The Mg retention test is labor intensive. Spot sample fractional clearance was determined to reflect 6- and 24-hour Mg excretions adequately and was more sensitive in detecting reduced Mg intake than the Mg loading test. In states of extreme and prolonged dietary Mg deficiency, the Mg loading test may provide additional information when urinary excretions have dropped to negligible amounts, but such situations are not considered likely to occur clinically. Reference ranges for urinary Mg excretion, clearance, and fractional clearance in normal horses fed grass hay containing 0.24% Mg, were 9.5 ± 4.8 mg/kg/day, 0.43 ± 0.18 ml/kg/min, and 29% ± 8%, respectively. In horses fed a reduced Mg diet of 0.06% Mg for 4 weeks, the urinary Mg excretion, clearance, and fractional clearance were 2.0 ± 1.3 mg/kg/day, 0.09 ± 0.05 ml/kg/min, and 6% ± 3%, respectively. The conditions investigated in this study were not severe enough to induce serum hypomagnesemia but indicate that one can use urinary indexes to reflect Mg intake and determine the necessity of dietary supplementation.[4]

18.6.2.13 TREATMENT FOR HYPOMAGNESEMIA

When supplementing Mg, one carefully must determine whether the dose reported is for elemental Mg or for the compound $MgSO_4$. For example, a dose of 100 mg/kg of $MgSO_4$ solution provides 9.7 mg/kg of elemental Mg. Confusion and subsequent overdose may be fatal.

Recommended dose rates for $MgSO_4$ in adult horses are 25 to 150 mg/kg/day (0.05 to 0.3 ml/kg of a 50% solution) diluted to a 5% solution in normal saline, dextrose, or a polyionic isotonic solution and given by slow intravenous infusion. A constant rate infusion of 150 mg/kg/day intravenously of $MgSO_4$ solution (0.3 ml/kg/day of the 50% solution) would provide the daily requirements of the horse.[135]

Of the commonly available replacement crystalloid fluids for intravenous administration, only Plasmalyte-A (Baxter Healthcare, Deerfield, Ill.) and Normosol-R (Abbott Laboratories, North Chicago, Ill.) contain any Mg. These fluids contain 3 mEq/L (3.6 mg/dl) of elemental Mg. If a horse received 60 ml/kg/day of the replacement fluid, it would receive 2.16 mg/kg/day of elemental Mg, which is equivalent to the amount of Mg from 20 mg/kg of $MgSO_4$. A horse receiving 120 ml/kg/day would receive the same amount of Mg as if it had been given 40mg/kg of $MgSO_4$. Therefore if long-term fluid therapy is required to support an inappetent animal, the horse still may require additional Mg. Based on the available knowledge, one should make an effort to determine and correct serum Mg^{2+} concentrations as is performed routinely for other electrolytes.

Magnesium sulfate also is used to treat refractory ventricular arrhythmias including those caused by idiosyncratic quinidine reactions (especially torsades de pointes) in hypomagnesemic and normomagnesemic horses.

Emergency therapy for ventricular arrhythmias under anesthesia or in response to quinidine-induced ventricular arrhythmias is a dose of 2 to 6 mg/kg/min of $MgSO_4$ intravenously (1.8 to 5.4 ml of 50% $MgSO_4$ per 450-kg horse per minute) to effect. Some authors recommend a maximum dose of 25g (56 mg/kg) of $MgSO_4$,[102,136] but the author's studies in normal horses indicate that at least 100 mg/kg of $MgSO_4$ can be administered safely over 30 minutes, with mild sedation occasionally being noted. Therefore one could exceed the 25 g total if necessary at a reduced infusion rate.

Studies in a canine model of cardiopulmonary arrest found that 100 mg/kg of $MgSO_4$ over 5 to 15 minutes raised the ventricular fibrillation threshold and prevented cerebral hypoperfusion following resuscitation without any adverse effects.[137,138]

Magnesium sulfate also has been recommended as a muscle relaxant as an adjunct treatment for tetanus.

For the treatment of hypoxic ischemic encephalopathy in neonatal foals, Wilkins[106] suggests a constant rate infusion of $MgSO_4$ at an initial dose of 50 mg/kg/hr intravenously for 1 hour, followed by 25 mg/kg/hr constant rate infusion for 24 hours. This dose provides 600 mg/kg/day of $MgSO_4$ and is therefore much higher than that required for maintenance. Therapy has been continued for up to 3 days without visible detrimental effects other than possible trembling.

Magnesium sulfate can be infused with a high therapeutic safety index, with the safety depending on the dose and the infusion rate, but is contraindicated with undiagnosed disturbances in cardiac conduction, renal failure, or elevated serum Mg concentration. In human beings with moderate hypomagnesemia (serum tMg <1.2 mg/dl), the recommendation is that 6 g of $MgSO_4$ solution (86 mg/kg; dose divided for average 70-kg person) be infused over 3 hours in 500 ml of isotonic saline, followed by 5 g over the next 6 hours, and then 5 g every 12 hours by continuous infusion for the next 5 days. In cases of hypomagnesemia associated with life-threatening arrhythmia, one can infuse 2 g of $MgSO_4$ (29 mg/kg) over 2 minutes in 500 ml of isotonic

saline, followed by the second two steps of the protocol for moderate hypomagnesemia.[139] Similar doses have been extrapolated for dogs.[140]

The typical equine diet contains sufficient Mg for maintenance, with supplementation rarely required. If necessary, one can provide Mg orally MgO, $MgCO_3$, or $MgSO_4$, which have equivalent digestibilities of 1374
approximately 70%. One could provide the maintenance requirement of 13 mg/kg/day of elemental Mg by 31 1375
mg/kg/day of MgO, 64 mg/kg/day of $MgCO_3$, or 93 mg/kg/day of $MgSO_4$. This may be important when one formulates oral replacement fluids for inappetent horses.

Magnesium sulfate (Epsom salts) commonly is used as an osmotic cathartic to treat large colon impactions. One can administer a dose of 0.5 to 1.0 g/kg of $MgSO_4$ in 6 to 8 L of water by stomach tube when the horse is metabolically stable. One can administer a second dose 24 to 36 hours later in severe cases only if serum Mg concentrations have returned to normal. Diarrhea may result with clearance of the impaction after the aggressive oral and intravenous fluid therapy often required to resolve large colon impactions. Hypermagnesemic neuromuscular paralysis has been reported after administration of 1.5 to 2 g/kg of $MgSO_4$. Freeman, Ferrante, and Palmer did not observe clinical signs of hypermagnesemia or diarrhea on adminstration of 1.0 g/kg of $MgSO_4$ orally to normal horses.[141]

18.6.3 Hypermagnesemia

Hypermagnesemia is rare in all species and most commonly results from iatrogenic Mg overdose or excessive supplementation to a patient in renal failure. Serum hypermagesemia also occurs after severe rhabdomyolysis or in a patient suffering from systemic inflammatory response syndrome in which cellular breakdown releases Mg into the extracellular fluid. Hyperkalemia and hyperphosphatemia also may occur in cases of severe cellular damage.

The cardiac effects of excessive Mg doses were examined in a canine model in which infusion of 0.12 mEq/kg/min of elemental Mg (15 mg/kg/min of $MgSO_4$ solution) was given safely for 16 minutes. After 16 minutes of infusion a total of 233 mg/kg of $MgSO_4$ solution had elevated the serum tMg concentration to 12.2 mEq/L (14.8 mg/dl) without changing hemodynamic parameters. With continued infusion the heart rate accelerated. Extreme doses of intravenous $MgSO_4$ can be toxic. Dogs given a cumulative infusion dosage of 2.0 mEq/kg of elemental Mg (243 mg/kg of $MgSO_4$ solution) became hypotensive, and dangerous arrhythmias were provoked at a total dosage of 3.9 mEq/kg of elemental Mg (474 mg/kg of $MgSO_4$ solution). A cumulative dose of between 5.9 mEq/kg and 10.9 mEq/kg of Mg, when infused at 0.12 mEq/kg/min, caused ventricular fibrillation or cardiac arrest.[142]

Hypermagnesemia was reported in two horses given excessive Epsom salts ($MgSO_4$) in addition to dioctyl sodium sulfosuccinate for the treatment of large colon impaction. The 450-kg and 500-kg horses were given 750 g and 1000 g of $MgSO_4$, respectively. Four to 6 hours after the $MgSO_4$ overdose the horses showed signs of agitation, sweating, and muscle tremors followed by recumbency and flaccid paralysis. Tachycardia and tachypnea developed, peripheral pulses were undetectable, and capillary refill time was prolonged at 4 seconds. Serum tMg concentrations rose to 5 times the reported reference range. The horses were treated with 250 ml of a 23% solution of calcium gluconate (diluted in 1 L of 0.9% NaCl) administered slowly intravenously. One horse was able to stand 10 minutes after the completion of the infusion. Intravenous fluids were given to induce diuresis. A second calcium infusion was required when muscle tremors reoccurred 1 hour later in this horse. The second horse remained weak for several hours, being only able to stand for short periods. These two horses

were given $MgSO_4$ at 1.5 to 2 times the recommended maximum dose, but this dose of Epsom salts alone normally would not likely be able to induce such severe clinical signs. The authors suggested that the concurrently administered dioctyl sodium sulfosuccinate may have increased intestinal permeability and increased the Mg absorption, with exacerbation of the signs of hypermagnesemia caused by the concurrent low serum calcium concentration. The most severely affected horse also showed signs of endotoxemia, which may have contributed to the observed hypotension and delayed recovery. One should give Epsom salts only to treat large colon impactions after correction of dehydration and metabolic imbalances. One should avoid simultaneous administration of excessive doses of Epsom salts with dioctyl sodium sulfosuccinate.[143]

19 CHAPTER 19 DISORDERS OF FOALS

Pamela A. Wilkins

19.1 Neonatal and Perinatal Diseases

Before the 1980s, intensive management of the compromised neonate was unusual and little was known regarding many of the problems of this special patient population. Although some specific conditions had been described by astute clinician-researchers, most notably the "dummy" foal syndrome[1] and respiratory distress syndrome caused by primary surfactant deficiency,[2] little information regarding the diagnosis and management of conditions of the foal during the neonatal period was available, although at least one active group was investigating fetal and neonatal physiology of the horse in Great Britain.[1–14] When treatment of compromised foals was undertaken, the approach most commonly resembled treating them as small adults with little understanding of the different physiology of the equine neonate. The advent of improved management of reproductive efficiency of mares led naturally to increased interest in preservation of the conceptus to parturition and the foal thereafter. Interested clinicians, taking their lessons from the field of human perinatology/neonatology and sometimes working hand-in-hand with their counterparts in the human field, pioneered investigations into these small patients and created the fields of equine perinatology and equine neonatal intensive care.[1–19] Because of the foresight and energy of these early investigators, the field of veterinary perinatology/neonatology exploded in the 1980s, leading to the creation of equine neonatal intensive care units throughout the United Sates and the world. From these units information about the normal and abnormal physiology of foals, the medical conditions affecting them, and methods for treatment and management of these problems has been developed through observational, retrospective, and prospective studies. This veritable explosion of information over the last 20 years has improved greatly the ability of all practitioners to provide appropriate care for these patients, whether in the field or at an equine neonatal intensive care unit. The ability not only to save the lives of these patients but also to treat them in such a manner as to allow them to fulfill their purposes, whether as pleasure animals or racing athletes, has improved almost exponentially from those early days.[20–23] This chapter aims to provide the clinician with some of the most current information regarding the management of these patients, recognizing that much still remains unknown and that advances will continue to be made in this dynamic field. The reader is cautioned that much of this chapter is flavored by the experiences of the author and that variation in approach and treatment of specific problems exists between neonatal intensive care units (NICUs) and between clinicians in the same NICU and that each year results in change. In some cases, information that is presented has been gleaned from human NICU studies, essentially using the critically ill infant as the experimental model.

Many of the problems of the newborn foal have their genesis in utero. Identification of high-risk pregnancies is an important component of prenatal care of the foal, and some of the most commonly encountered problems of the dam resulting in abnormal foals include previous or concurrent disease, poor reproductive history, poor perineal or pelvic conformation, poor general health, poor nutritional condition, prolonged transport, history of previous abnormal foals, placental abnormalities, and twins.[24]

Some of the more common causes of abortion can result in the birth of severely compromised foals of variable gestation lengths (Box 19-1). These include infectious causes such as equine herpesvirus (EHV) types 1 (most commonly) and 4 (rarely), equine infectious anemia, equine arteritis virus, bacterial and fungal placentitis, leptospirosis, equine ehrlichiosis, and gram-negative septicemia/endotoxemia.[25–27] Noninfectious causes of

abortion include twinning and noninfectious placental abnormalities such as extensive endometrial fibrosis, body pregnancy, and abnormal length (long or short) of the umbilical cord.[24,28]

19.1.1 BOX 19-1 CONDITIONS ASSOCIATED WITH HIGH-RISK PREGNANCY

19.1.1.1 Maternal Conditions

Colic/endotoxemia

Abdominal hernia

Pelvic anatomic abnormalities

Malnutrition

Any debilitating disease

Uterine torsion

Uterine abnormalities

Mare reproductive loss syndrome

Hyperlipemia

Hypogalactia

History of previous abnormal foals

19.1.1.2 Conceptional Conditions

Placentitis

Twins

Hydrops

Prolonged gestation

Fetal abnormalities

Dystocia

Fescue toxicosis

Umbilical abnormalities

Congenital deformity

To the equine neonatologist opportunities for intervention may appear limited, and in the case of many of the aforementioned causes of fetal loss, this is true. However, one can do much in an attempt to preserve the

pregnancy and in effect treat the fetus. When one is faced with a threatened pregnancy, one has various ways of evaluating the fetus and its environment and may use many potential therapies.

19.2 Prepartum Evaluation Of The Fetus And Placenta

Once one identifies a pregnancy as high risk, one should evaluate the fetus for viability. Evaluation should include as thorough an evaluation as possible of the reproductive tract, placenta, and fetal fluids. Prepartum disorders in the mare usually are readily recognizable, but disorders of the fetus and placenta can be more subtle and difficult to determine. The first step is to take a thorough history of the mare. Of particular interest is any history of previous abnormal foals, but the history taking should include questions regarding transportation; establishment of an accurate breeding date (sometimes more difficult than one would suspect); any pertinent medical history including any diagnostic testing performed for this pregnancy such as culture, endometrial biopsy, and cytologic results; and any rectal and ultrasound examination results. Additionally, one should obtain information regarding possible ingestion of endophyte-infected fescue or exposure to potential infectious causes of abortion.[29,30] A complete vaccination and deworming history is requisite, as is a complete history of any medications and supplements administered during pregnancy.

After obtaining a history, one examines the mare per rectum. This examination should include palpation of the cervix, uterus, fetus, and all palpable abdominal contents. One should note any abnormalities. The cervix should be tight throughout gestation; the late gestation uterus will be large and distended with fluid and usually pulled craniad in the abdomen. Palpation of the fetus frequently results in some fetal movement; however, one should interpret lack of movement with caution, for some normal fetuses do not respond. Ultrasonographic evaluation of the uterus and conceptus per rectum can provide valuable information, particularly regarding placental thickness if placentitis is a concern. One may evaluate fetal fluids and estimate fetal size from the size of the eye later in gestation.[31] In the author's hospital the practitioners choose not to perform vaginal examinations or speculum examinations because of an association between these examinations and the subsequent development of placentitis. Unless placentitis is recognized with ultrasonograhic evaluation per rectum and culture is desirable, these types of examinations are generally not necessary.

Following examination per rectum, one performs transabdominal ultrasonographic evaluation of the uterus and conceptus.[28] One can generate a biophysical profile of the fetus from this examination in the late-term fetus and readily determine viability.[32,33] One also readily can determine the presence or absence of twins in the late pregnant mare in this manner. One performs the sonogram through the acoustic window from the udder to the xiphoid ventrally and laterally to the skinfolds of the flank. Imaging of the fetus usually requires a low-frequency (3.5-MHz) probe, whereas examination of the placenta and endometrium requires a higher-frequency (7.5-MHz) 1382
probe. A complete description of this examination is beyond the scope of this chapter, but the reader will find 1383
several complete descriptions of the technique and normal values for specific gestation lengths within the relevant veterinary literature.[33] The utility of this examination lies in its repeatability and low risk to the dam and fetus. Sequential examinations over time allow the clinician to follow the pregnancy and to identify changes as they occur.

A companion to transabdominal ultrasongraphy is evaluation of the fetal electrocardiogram (ECG). One can measure fetal ECGs continuously using telemetry or can obtain them using more conventional techniques several times throughout the day.[24,28,34] One places electrodes on the skin of the mare in locations aimed at maximizing the magnitude of the fetal ECG. Because the fetus frequently changes position, multiple sites may be needed in any 24-hour period. To begin, one places an electrode dorsally in the area of the sacral prominence with two electrodes placed bilaterally in a transverse plane in the region of the flank. The fetal ECG maximal amplitude is

low, usually 0.05 to 0.1 mV, and can be lost in artifact or background noise, so one commonly must move electrodes to new positions to maximize the appearance of the fetal ECG. The normal fetal heart rate during the last months of gestation ranges from 65 to 115 beats/min, a fairly wide distribution. The range of heart rate of an individual fetus can be narrow, however. Bradycardia in the fetus is an adaptation to in utero stress, most commonly thought to be hypoxia. By slowing the heart rate, the fetus prolongs exposure of fetal blood to maternal blood, increasing the time for equilibration of dissolved gas across the placenta and improving the oxygen content of the fetal blood. The fetus also has altered the distribution of its cardiac output in response to hypoxia, centralizing blood distribution.[35,36] Tachycardia in the fetus can be associated with fetal movement, and brief periods of tachycardia should occur in the fetus in any 24-hour period. Persistent tachycardia is a sign of fetal distress and represents more severe fetal compromise than bradycardia. The author has recognized dysrhythmias in the challenged fetus, most commonly as atrial fibrillation but also apparent runs of ventricular tachycardia.

The ability to monitor the fetus in a high-risk pregnancy inevitably has led to questions of whether, how, and when to intervene. Most equine neonatologists would agree that removal of the fetus from the uterus before its attainment of readiness for birth is not desirable. One of the difficulties in determining fetal preparedness for birth is that prediction of parturition is difficult in these mares. Many of the parameters used in normal mares are unreliable in the high-risk pregnant mare. One must have an accurate history of any previous gestation length in terms of days for the specific mare in question to allow a more accurate estimate of her usual gestational length. Evaluation of the usual mammary gland parameters, including size, the presence of “wax,” and alteration of electrolyte concentrations, is not generally predictive in the high-risk mare, for in the author's experience many of these mares have changes predictive of parturition for weeks before actual parturition.[37,38] This circumstance may be related to the observation that many high-risk pregnant mares, particularly those with placentitis, are presented for a primary complaint of early onset lactation. Although pulmonary system maturity in human beings can be assessed with some degree of accuracy using measurement of lecithin/sphingomyelin ratios, this measurement—along with sphingomyelin, cortisol, and creatinine concentrations in the amnionic fluid—has proved to be of no benefit in the horse.[39–41] Amniocentesis carries a high risk of abortion in the horse, even with ultrasound guidance, and is not a clinically useful technique at this time.[41] Currently, no clear-cut guidelines are available as to when to intervene, but the presence of persistent fetal tachycardia or prolonged absence of fetal movements, including breathing movements, as determined by transabdominal ultrasound evaluation, should initiate discussion regarding the appropriateness of induction of parturition or elective cesarean section. The goal of induction or cesarean section is to remove a pregnancy that is threatening the survival of the dam with no thought to fetal survival or to remove the fetus from a threatening environment to improve its likelihood for survival. Preterm induction is ill advised if fetal survival is desirable because of the limited ability to treat severely immature neonates. Timing of intervention in these circumstances remains an art, not a science.

The approach to management of the high-risk pregnancy is dictated to some degree by the exact cause for concern, but for many mares therapy is similar. Many high-risk mares have placentitis, primarily caused by ascending bacterial or fungal infections originating in the region of the cervix. These infections can cause in utero sepsis or compromise the fetus by local elucidation of inflammatory mediators or altered placental function.[42,43] Premature udder development and vaginal discharge are common clinical signs. Treatment consists of administration of broad-spectrum antimicrobial agents and nonsteroidal antiinflammatory drugs (Table 19-1). In the author's clinic, trimethoprim-sulfonamide drugs have been the antimicrobial of choice based on unpublished studies performed at the facility demonstrating increased concentration of these agents in the fetal fluids compared with penicillin and gentamicin. However, if culture and sensitivity results are available, one should institute directed therapy. Nonsteroidal antiinflammatory agents such as flunixin meglumine are useful to combat alterations in prostaglandin balance that may be associated with infection and inflammation. Although the efficacy 1383
of these agents is best when administered before the development of clinical signs, to date no detrimental effects 1384

have been reported in the fetus or dam when chronically used at low doses in well-hydrated patients. Tocolytic agents and agents that promote uterine quiescence have been used and include altrenogest, isoxuprine, and clenbuterol.[44–48] Altrenogest usually is administered, although its need in late gestation has been challenged. The efficacy of isoxuprine as a tocolytic in the horse is unproven, and bioavailability of orally administered isoxuprine appears to be highly variable.[48] The long-term use of clenbuterol is inadvisable because of receptor population changes associated with chronic use and its unknown effects on the fetus at this time. Clenbuterol may be indicated during management of dystocia in preparation for assisted delivery or cesarean section.[46] The intravenous form of clenbuterol is not currently available in the United States.

TABLE 19-1 Drugs Used to Treat High-Risk Pregnancy

DRUG	DOSE/FREQUENCY/ROUTE	REASON
Trimethoprim-sulfonamide	25 mg/kg b.i.d. p.o.	Antimicrobial
Flunixin meglumine	0.25 mg/kg t.i.d. p.o. or IV[*]	Antiinflammatory
Altrenogest	0.44 mg/kg s.i.d. p.o.	Tocolytic
Isoxuprine	0.4–0.6 mg/kg b.i.d. IM or p.o.	Tocolytic
Clenbuterol	0.8 μg/kg as needed p.o.[†]	Tocolytic
Vitamin E	6000–10,000 IU s.i.d. p.o.	Antioxidant

* *IV,* Intravenously; *IM,* intramuscularly.

† Intravenous form currently not available in the United States.

One can use three additional strategies in managing high-risk pregnancy patients. In mares with evidence of placental dysfunction, with or without signs of fetal distress, the author provides intranasal oxygen supplementation in the hope of improving oxygen delivery to the fetus. Intranasal oxygen insufflation of 10 to 15 L/min to the mare significantly increases PaO_2 and percent oxygen saturation of hemoglobin.[49] Because of the placental vessel arrangement of the horse, improvement of these two arterial blood gas parameters should result in improved oxygen delivery to the fetus. Blood gas transport is largely independent of diffusion distance in the equine placenta, particularly in late gestation, and depends more on blood flow. Information from other species cannot be extrapolated to the equine placenta because of its diffuse epitheliochorial nature and the arrangement of the maternal and fetal blood vessels within the microcotyledons.[50,51] Umbilical venous pO_2 is 50 to 54 mm Hg in the horse fetus, compared with 30 to 34 mm Hg in the sheep, whereas the maternal uterine vein to umbilical vein pO_2 difference is near 0. Also unlike the sheep, the umbilical venous pO_2 values decrease 5 to 10 mm Hg in response to maternal hypoxemia and increase in response to maternal hyperoxia.[52–54]

Vitamin E (tocopherol) is administered orally to some high-risk mares as an antioxidant. Administration of large doses of vitamin E before traumatic brain injury improves neurologic outcome in experimental models and has been examined as possible prophylaxis for human neonatal encephalopathy.[55–57] Extrapolation of that information to the compromised equine fetus suggests that increased antioxidant concentrations in the fetus may mitigate some of the consequences of uterine and birth hypoxia, but no evidence is available to date demonstrating that protection occurs or that vitamin E accumulates in the fetus in response to supplementation of the mare. Finally, many high-risk mares are anorectic or held off feed because of their medical condition. These mares are at particularly great risk for fetal loss because of their lack of feed intake, which alters prostaglandin metabolism.[58]

Therefore one should administer 2.5% to 5% dextrose in 0.45% saline or water (5% dextrose) intravenously at maintenance fluid rates to these patients.

Perhaps the most important aspect of managing high-risk pregnancy mares is frequent observation and development of a plan. One should observe mares at least hourly for evidence of early-stage labor and should put them under constant video surveillance if possible. Depending on the primary problem, the team managing the mare should develop a plan for handling the parturition once labor begins and for fetal resuscitation following delivery. Any equipment that might be needed should be readily available stallside, and a call sheet, listing contact numbers for all involved, should be posted on or near the stall. The plan should include a decision as to how to handle a complicated dystocia, should it occur, with permission for general anesthesia and cesarean section obtained before the event so that time is not wasted. An important question to be posed to the owner at the outset is which is most important to the owner, the mare or the foal, for the answer may dictate the direction of the decision tree once labor begins.[59]

19.3 Evaluation Of The Newborn Foal

Early recognition of abnormalities is of utmost importance for successful management of critically ill foals. To recognize the abnormal, one must know the normal. Immediately following birth, foals effect several important physiologic and behavioral changes. Chief among these changes is the adaptation of the cardiovascular and respiratory systems to extrauterine life. The normal transition of the respiratory tract involves opening closed 1384
alveoli and absorption of fluid from the airway, accomplished by a combination of breathing efforts, expiration 1385
against a closed glottis (grunting), and a change in sodium flux across the respiratory membrane from net secretion to net absorption.[60–64] The transition from fetal to neonatal circulatory patterns requires resolution of the pulmonary hypertension present in the fetus, normally shunting blood flow through the lower resistance ductus arteriosus in the fetal state, to direct cardiac output to the pulmonary vasculature for participation in gas exchange. This change is achieved by the opening of alveoli, decreasing airway resistance and providing radial support for pulmonary vessels, functional closure of the ductus arteriosus, and increasing the oxygen tension in the lung, reversing pulmonary vasoconstriction mediated by hypoxia.[65,66] Pulmonary tree vasodilators (prostacyclin, nitric oxide [NO]) and vasoconstrictors (endothelin-1, leukotrienes) play apparently well-coordinated, but as yet not fully elucidated, roles. In the normal newborn this change is smooth and rapid. These critical events are undermined by factors such as inadequate lung development, surfactant deficiency (primary or secondary), viral or bacterial infection, placental abnormalities, in utero hypoxia, and meconium aspiration.

Spontaneous breathing should begin in the neonate within 1 minute of birth, many foals attempt to breathe as their thorax clears the pelvic canal. During the first hour of life, the respiratory rate of a healthy foal can be as high as 80 breaths per minute but should decrease to 30 to 40 breaths per minute within a few hours. Similarly, the heart rate of a healthy newborn foal has a regular rhythm and should be at least 60 beats/min at the first minute.[67,68] One usually can auscultate a continuous murmur over the left side of the heart, although its loudness may vary with position. This murmur is thought to be associated with some shunting through the ductus arteriosus. One may auscultate variable systolic murmurs, thought to be flow murmurs, during the first week of life.[69] One should investigate more thoroughly murmurs that persist beyond the first week of life in an otherwise healthy foal, along with any murmur associated with persistent hypoxia. Auscultation of the thorax shortly after birth reveals a cacophony of sounds as airways open and fluid is cleared. End-expiratory crackles are consistently audible in the dependent lung during and following lateral recumbency. For a normal newborn foal to appear slightly cyanotic during this initial adaptation period is not unusual, but this should resolve within minutes of birth. The equine fetus, as do all fetuses, exists in a moderately hypoxic environment, but the equine fetus has a greater partial pressure of oxygen, around 50 mm Hg.[70] Because the fetus is well adapted to low oxygen tensions, cyanosis is

rarely present in newborn foals once adaption occurs, even those with low oxygen tensions. Although in many species the fetal blood oxygen affinity is greater than the maternal blood, in the equine fetus the oxygen affinity of its hemoglobin is only about 2 mm Hg greater than the maternal blood because of decreased levels of 2,3-diphosphoglycerate compared with other species.[71] The result is enhanced oxygen unloading in the equine fetus compared with others. 2,3-Diphosphoglycerate concentration increases after birth in the foal and reaches mature levels by 3 to 5 days of age. The major blood adaptation of the equine fetus to chronic hypoxia is an increase in packed cell volume of up to 20%, increasing the oxygen content of the blood as compensation for decreased oxygen delivery at the placenta.[72] A larger than expected packed cell volume in any newborn foal should alert the clinician for possible sequelae from chronic hypoxia. The presence of significant cyanosis that persists should prompt the clinician to evaluate the foal thoroughly for cardiac anomalies resulting in significant right-to-left shunting or separated circulations, such as transposition of the great vessels.

The chest wall of the foal is compliant, facilitating passage through the pelvic canal during parturition. This compliance requires that the foal actively participate in inspiration and expiration with several potential consequences. First, restriction of the thorax or the abdomen can result in impaired ventilation, which can occur easily when one restrains a foal and may result in spuriously abnormal arterial blood gas values (see the discussion on arterial blood gas evaluation, Respiratory Diseases Associated with Hypoxemia in the Neonate). Second, foals with primary pulmonary parenchymal disease resulting in poorly compliant lungs develop paradoxical chest wall motion, with the thorax moving inward during inspiration.[73–76] The work of breathing can increase greatly, resulting in respiratory failure because of respiratory muscle fatigue. A foal that appears suddenly to improve a previously abnormal respiratory rate and pattern may in fact be in greater respiratory difficulty because of fatigue. One can observe a reduction in respiratory rate or abnormal breathing pattern in premature/dysmature foals or foals subjected to peripartum hypoxia/asphxia. Although the genesis of these patterns is not understood fully, Cheyne-Stokes (lengthy periods of apnea interrupted by short breaths that wax and wane in depth), cluster (short periods of apnea interspersed with long periods of breathing), and Biot's breathing (periods of apnea and breathing with no discernible pattern) may occur in these cases. Foals attempting to maintain an adequate lung volume expire against a partially closed glottis, called Valsalva's maneuver, producing an audible grunt.

Foals are normally nonresponsive while in the birth canal but should respond to stimulation immediately after
birth.[67] The lack of responsiveness while in the birth canal has lead to presumption of fetal death during dystocia. 1385
Because of this, one should attempt other tests before determining that a foal is dead intrapartum. One possibly 1386
may detect pulses in the tongue, neck, or any presented limbs or palpate the thorax for a heartbeat. In the author's facility, nasotracheal intubation of the foal combined with measurement of CO_2 tensions in the exhaled gas aids practitioners in cases where they can reach the nose. Nasotracheal intubation of foals under these circumstances actually can be performed readily with minimal practice. Having long endotracheal tubes available of several different diameters (7 to 12 mm outer diameter) with an inflatable cuff is important. One can pass the tube blindly using a finger in one nostril for guidance and can check the position frequently by palpation of the throatlatch region. One inflates the cuff and begins manual ventilation with 100% oxygen or room air using an Ambu-bag or equivalent. One can obtain continuous measurement of CO_2 tension using a capnograph or single-use disposable end-tidal CO_2 monitor attached to the Ambu-bag or the nasotracheal tube. In a dead foal the end-tidal CO_2 measurement will be negligible after the first 10 to 20 breaths. One must ensure tube placement and seal integrity and allow for multiple breaths. Some CO_2 will “wash out” with the first few breaths and can result in false hope initially. End-tidal CO_2 varies in living intrapartum foals, depending on cardiac output and ventilation frequency, but should be consistently greater than 20 mm Hg and is usually closer to 30 mm Hg. Once one establishes manual ventilation of a living foal, one must continue ventilation until the foal is delivered satisfactorily. The

author has resuscitated and maintained many foals successfully in this manner throughout induction of general anesthesia in the mare and cesarean section delivery of the foal. The nasotracheal tube also provides a convenient site for administration of intratracheal medications such as epinephrine used for extrauterine intrapartum resuscitation of the foal. The reader is cautioned that intratracheal epinephrine increases end-tidal CO_2 measurements transiently, even in a dead foal, because of local actions on tissues. One should allow a washout period after intratracheal administration of epinephrine.

The righting reflex is present as the foal exits the birth canal, as is the withdrawal reflex. Cranial nerve responses are intact at birth, but the menace response may take as long as 2 weeks to develop fully. One should not consider lack of a menace reflex diagnostic of visual deficits in the newborn foal. Within an hour of birth the normal foal will demonstrate auditory orientation with unilateral pinna control. The normal pupillary angle is ventromedial in the newborn foal; this angle gradually becomes dorsomedial over the first month of life. Foals should begin attempting to stand shortly after birth and should be able to achieve this on their own within 2 hours of birth.[67] The normal newborn foal has a suck reflex shortly after birth and should be searching for an udder even before it stands. The expectation is that a normal foal will be sucking from the dam unaided by 3 hours post partum; many foals are overachievers and will be sucking well before this time. The normal foal may defecate shortly after standing but may not attempt defecation until after it first successfully sucks from the dam. Urination varies more, with filly foals usually urinating before colt foals, but both usually do not urinate for several hours following birth, up to 12 hours for some colts.[67] For colt foals to fail to drop their penises when urinating over the first few days of life is not unusual.

The gait of the newborn foal is hypermetric and the stance is base wide. Extreme hypermetria of the forelimbs, usually bilateral but occasionally unilateral, has been observed in some foals and is associated with perinatal hypoxic/ischemic insults, but this gait abnormality usually resolves without specific therapy within a few days. Spinal reflexes tend to be exaggerated, whereas the crossed extensor reflex may not be fully present until 3 weeks of age.[77] Foals also exhibit an exaggerated response to external stimuli (noise, sudden visual changes, touch) for the first few weeks of life. Foals are not bonded strongly to their mother for the first few weeks of life and will follow any large moving object, including other horses and human beings. Orphan foals bond with surrogate mothers until they are several months of age; their primary motivation appears to be appetite. Conversely, mares strongly bond with their foals shortly after parturition; the process begins once the chorioallantois ruptures and is driven more by olfaction and taste than by vision or hearing. Interference with this process, by medical intervention or excessive owner manipulation of the foal, can disrupt normal bonding and result in foal rejection by the dam.[78]

19.4 Evaluation Of The Weak Or Depressed Foal

19.4.1 NEONATAL RESUSCITATION

Most newborn foals make the transition to extrauterine life easily. However, for those in difficulty, recognition of the condition immediately and institution of appropriate resuscitation is of utmost importance. A modified Apgar scoring system has been developed as a guide for initiating resuscitation and assessing probable level of fetal compromise (Table 19-2).[79] One also must at least perform a cursory physical examination before initiating resuscitation, for issues of humaneness are associated with with serious problems such as severe limb contracture, microophthalmia, and hydrocephalus, among others.

The initial assessment begins during presentation of the fetus. Although the following applies primarily to 1386
attending the birth of a foal from a high-risk pregnancy, one can perform quiet and rapid evaluation during any 1387
attended birth. The goal in a normal birth with a normal foal is to disturb the bonding process minimally. This goal also applies to high-risk parturitions, but some disruption of normal bonding is inevitable. The lead clinician should control tightly the number of persons attending, and the degree of activity surrounding, the birth.

TABLE 19-2 Apgar Score in the Foal

	ASSIGNED VALUE		
PARAMETER	0	1	2
Heart/pulse rate	Undetectable	<60 beats/min irregular	>60 beats/min regular
Respiratory rate/pattern	Undetectable	Slow, irregular	40–60 beats/min regular
Muscle tone	Limp/absent	Lateral, some tone	Sternal
Nasal mucosal stimulation	Unresponsive	Grimace, mild rejection	Cough or sneeze

From Martens RJ: Pediatrics. In Mansmann RA, McAllister ES, Pratt PW, editors: *Equine medicine and surgery,* ed 3, vol 1, Santa Barbara, Calif, 1982, American Veterinary Publications.

One should determine the score at 1 and 5 minutes after birth. Scores of 7 to 8 generally indicate a normal foal; 4 to 6, mild to moderate asphyxia; and 0 to 3, severe asphyxia. A score of 4 to 6 should prompt stimulation, intranasal oxygen, or mechanical ventilation. For a score of 0 to 3, one should begin cardiopulmonary resuscitation.

One should evaluate the strength and rate of any palpable peripheral pulse and should evaluate the apical pulse as soon as the chest clears the birth canal. Bradycardia (pulse <40 beats/min) is expected during forceful contractions, and the pulse rate should increase rapidly once the chest clears the birth canal. Persistent bradycardia is an indication for rapid intervention.

The fetus is normally hypoxemic compared with the newborn foal, and this hypoxemia is largely responsible for the maintenance of fetal circulation by generation of pulmonary hypertension. The fetus responds to conditions producing more severe in utero hypoxia by strengthening the fetal circulatory pattern, and the neonate responds to hypoxia by reverting to the fetal circulatory pattern.[80] During a normal parturition, mild asphyxia occurs and results in fetal responses that pave the way for a successful transition to extrauterine life. If more than mild transient asphyxia occurs, the fetus is stimulated to breathe in utero; this is known as *primary asphyxia*.[81] If the initial breathing effort resulting from the primary asphyxia does not correct the asphyxia, a second gasping period occurs in several minutes, known as the *secondary asphyxia* response. If no improvement in asphyxia occurs during this period, the foal enters *secondary apnea,* a state that is irreversible except with resuscitation.

Therefore the first priority of neonatal resuscitation is establishing an airway and breathing pattern. One should assume that foals not spontaneously breathing are in secondary apnea and should clear the airway of membranes as soon as the nose is presented. If meconium staining is present, one should suction the airway before delivery of the foal is completed and before the foal breathes spontaneously. One should continue to the

trachea if aspiration of the nasopharynx is productive. Overzealous suctioning worsens bradycardia as it worsens hypoxia. One should stop suctioning once the foal begins breathing spontaneously, as hypoxia will worsen with continued suction. If the foal does not breathe or move spontaneously within seconds of birth, one should begin tactile stimulation. If tactile stimulation fails to result in spontaneous breathing, one immediately should intubate the foal and manually ventilate the foal using an Ambu-bag or equivalent. One can use mouth-to-nose ventilation if nasotracheal tubes and an Ambu-bag are not available. The goal of this therapy is to reverse fetal circulation, and hyperventilation with 100% oxygen is the best choice for this purpose. However, recent evidence suggests that no clinical disadvantages are apparent in using room air for ventilation of asphyxiated human neonates rather than 100% oxygen.[82,83] Human infants resuscitated with room air recovered more quickly than those resuscitated with 100% oxygen in one study as assessed by Apgar scores, time to the first cry, and the sustained pattern of breathing.[84] In addition, neonates resuscitated with 100% oxygen exhibited biochemical findings reflecting prolonged oxidative stress, present even after 4 weeks of postnatal life, which did not appear in the group resuscitated with room air. Thus the current accepted recommendations for using 100% oxygen in the resuscitation of asphyxiated neonates needs further discussion and investigation.[85,86] Almost 90% of foals requiring resuscitation respond to hyperventilation alone and require no additional therapy. One can initiate nasotracheal intubation while the foal is in the birth canal if the foal will not be delivered rapidly, such as with a difficult dystocia. This technique is “blind” and requires some practice but 1387
may be beneficial and lifesaving. Once spontaneous breathing is present, one should provide humidified oxygen 1388
via nasal insufflation at 8 to 10 L/min.

One should initiate cardiovascular support in the form of chest compression if the foal remains bradycardic despite ventilation and a nonperfusing rhythm is present. One should make sure the foal is on a hard surface in right lateral recumbency with the topline against a wall or other support. Approximately 5% of foals are born with fractured ribs and an assessment for the presence of rib fractures is in order before initiating chest compressions.[87] Palpation of the ribs identifies many of these fractures, which usually are multiple and consecutive on one side of the thorax and located in a relatively straight line along the part of the rib with the greatest curvature dorsal to the costochondral junction. Unfortunately, ribs 3 to 5 frequently are involved, and their location over the heart can make chest compression a potentially fatal exercise. Auscultation over the ribs during breathing results in a recognizable click, identifying rib fractures that may have escaped detection by palpation.

One should initiate drug therapy if a nonperfusing rhythm persists for more than 30 to 60 seconds in the face of chest compression. Epinephrine is the first drug of choice (Table 19-3). Practitioners pose various arguments regarding the best dose and the best frequency of administration for resuscitation. However, most of the data are acquired from human cardiac arrest studies and are not strictly applicable to the equine neonate because the genesis of the cardiovascular failure is different.[88,89] Vasopressin is gaining attention as a cardiovascular resuscitation drug, and although the author has used this drug in resuscitation and as a pressor, experience is limited at this time.[90] The author does not use atropine in bradycardic newborn foals because the bradycardia usually is caused by hypoxia, and if the hypoxia is not corrected, atropine can increase myocardial oxygen debt.[89] The author also does not use doxapram because it does not reverse secondary apnea, the most common apnea in newborns.

TABLE 19-3 Resuscitation Drugs Used for Cardiopulmonary Resuscitation of Foals*

DRUG	HOW SUPPLIED	DOSE PER kg	ml/kg	ml/30 kg	ml/40 kg	ml/50 kg
Epinephrine (low dose)	1 mg/ml (1:1000)	0.01–0.02 mg	0.01–0.02	0.3–0.6 3–5 minutes	0.4–0.8	0.5–1
Epinephrine (high dose)	1 mg/ml (1:1000)	0.1–0.2 mg	0.1–0.2	3–6 3–5 minutes	4–8	5–10
Lidocaine	2% (20 mg/ml)	1.5 mg	0.075	2.25 Every 5 minutes for a maximum of 3 mg/kg	3	3.75
Bretylium	50 mg/ml	5–10 mg (30–35 mg/kg maximum dose)	0.1–0.2	3–6 10 minutes	4–8	5–10
Atropine	0.54 mg/ml	0.02 mg	0.037	1.1 Maximum of 2 times	1.5	1.8
CaCl	10% solution	0.5–1.0 mEq	0.2	6	8	10
$NaHCO_3$	1 mEq/ml	0.5–1 mEq	0.5–1	15–30	20–40	25–50
$MgSO_4$	50% (500 mg/ml)	14–28 mg	0.028–0.056	0.8–1.7	1.1–2.2	1.4–2.8

* Epinephrine is the most commonly used of the drugs.

Because birthing areas are generally cold, one should dry the foal and place it on dry bedding once resuscitation is complete. The fetus has some homeothermic mechanisms, but its size in relation to its mother and its position within her body means that it is in effect a poikilotherm. The body temperature of the foal generally reflects that of its environment, namely its mother, although the human fetal temperature directly measured at cesarean section, induction of labor, or during labor is approximately 0.5° C higher than the mothers.[91,92] Adaptation from poikilothermy to homeothermy normally takes place rapidly following birth. The fetus is capable of nonshivering thermogenesis, primarily through the oxidation of brown fat reserves, but this type of thermogenesis is inhibited in utero, probably by placental prostaglandin E_2 and adenosine.[93,94] Immediately after birth the foal must adapt to independent thermoregulation. Local physical factors, including ambient temperature and humidity, act to induce cold stress, and the newborn must produce heat by metabolic activity. In response to the catecholamine surge associated with birth, uncoupling of oxidative phosphorylation occurs

within mitochondria, releasing energy as heat. This nonshivering thermogenesis is impaired in newborns undergoing hypoxia or asphyxiation and in those that are ill at birth. Infants born to mothers sedated with benzodiazepines are affected similarly, a consideration in the choice of sedative and preanesthetic medications 1388
in mares suffering dystocia or undergoing cesarean section.[95–97] Heat losses by convection, radiation, and 1389
evaporation are high in most areas where foals are delivered, resuscitated, and managed, and one must take care to minimize cold stress in the newborn and the critically ill foal. Supplementary heat, in the form of radiant heat lamps or warm air circulating blankets, may be required.

One should use fluid therapy conservatively during postpartum resuscitation, for the neonate is not volume depleted unless excessive bleeding has occurred. Some compromised newborn foals are actually hypervolemic. Fluid therapy of the neonate is discussed in more detail later in this chapter. Because the renal function of the equine neonate is substantially different from the adult, one cannot simply scale down fluid therapy from adult therapy.[98–100] If intravenous fluids are required for resuscitation and blood loss is identified, administration of 20 ml/kg of a non–glucose-containing polyionic isotonic fluid over 20 minutes (about 1 L for a 50-kg foal) once intravenous access is established can be effective. The author stresses non–glucose-containing polyionic intravenous fluids because hyperglycemia, but not hypoglycemia, immediately after fetal or neonatal asphyxia interfered with the recovery of brain cell membrane function and energy metabolism in neonatal piglets in one recent study.[101] These findings suggest that post–hypoxic-ischemic hyperglycemia is not beneficial and might even be harmful in neonatal hypoxic-ischemic encephalopathy. Indications for this shock bolus therapy include poor mentation, poorly palpable peripheral pulses, and the development of cold distal extremities, compatible with hemorrhagic shock. One should reassess the patient after the initial bolus and administer additional boluses as necessary. Ideally, one should follow up on blood pressures and ECG readings and initiate appropriate pressor therapy if needed. Again, these procedures are discussed in detail later in the chapter.

One can administer glucose-containing fluids after resuscitation at a rate of 4 to 8 mg/kg/min (about 250 ml/hr of 5% dextrose or 125 ml/hr of 10% dextrose) to the average 50-kg foal, particularly in the obviously compromised foal. This therapy is indicated to help resolve metabolic acidosis, to support cardiac output because myocardial glycogen stores likely have been depleted, and to prevent postasphyxial hypoglycemia. Under normal conditions, the fetal-to-maternal blood glucose concentration gradient is 50% to 60% in the horse, and glucose is the predominant source of energy during fetal development.[102,103] Glucose transport across the placenta is facilitated by carrier receptors (glucose transporter [GLUT] receptors), and a direct relationship exists between maternal and fetal blood glucose concentration when maternal glucose is in the normal range.[102] The GLUT receptors in the placenta are stereospecific, saturable, and energy independent.[104] Although the enzyme kinetics for GLUT isoform 1 suggest that they are not saturable under conditions of euglycemia, equine maternal hyperglycemia results in increased fetal glucose concentration to a plateau point, likely caused by GLUT saturation.

At term, the net umbilical uptake of glucose is 4 to 7 mg/kg/min, with most of the glucose being used by the brain and skeletal muscle.[105–107] The fetus only develops gluconeogenesis under conditions of severe maternal starvation. A certain percentage of the delivered glucose is used to develop large glycogen stores in the fetal liver and cardiac muscle in preparation for birth, and at birth the foal liver produces glucose at a rate of 4 to 8 mg/kg/min by using these stores. Fetal glycogen stores also are built using the substrates lactate, pyruvate, and alanine; fetal uptake of lactate across the placenta is about half that of glucose.[102,108] The transition to gluconeogenesis, stimulated by increased circulating catecholamine concentration from birth and by stimulation of glucagon release at the time the umbilical cord breaks takes 2 to 4 hours in the normal foal, and glycogenolysis supplies needed glucose until feeding and glucose production are accomplished.[109] In the

challenged foal, glycogen stores may have been depleted and gluconeogenesis delayed, so provision of glucose at rates similar to what the liver would normally produce during this period is requisite.

19.4.2 PERSISTENT PULMONARY HYPERTENSION

Persistent pulmonary hypertension (PPH) also is known as reversion to fetal circulation or persistent fetal circulation, and its genesis lies in the failure of the fetus to make the respiratory and cardiac transition to extrauterine life successfully or reversion of the newborn to fetal circulatory patterns in response to hypoxia or acidosis. Differentiating this problem from other causes of hypoxemia in the newborn requires some investigation, and multiple serial arterial blood gas analyses are necessary to confirm suspicion of this problem (see the section on arterial blood gas analysis, Respiratory Diseases Associated with Hypoxemia in the Neonate). However, one should suspect the condition in any neonate with hypercapnic hypoxemia that persists and worsens; these foals are in hypoxemic respiratory failure. The fetal circulatory pattern, with pulmonary hypertension and right-to-left shunting of blood through the patent foramen ovale and ductus arteriosus, is maintained in these cases.

Pulmonary vascular resistance falls at delivery to about 10% of fetal values, while pulmonary blood flow increases accordingly.[110] Early in the postnatal period these two changes balance each other, and mean pulmonary and systolic pressures remain increased for several hours. Systolic pulmonary pressures can remain 1389
equivalent to systemic pressure for up to 6 hours of age in human infants, although diastolic pulmonary 1390
pressures are well below systemic diastolic pressures by 1 hour.[111] Mean pulmonary artery pressures fall gradually over the first 48 hours.[112] The direct effects of lung expansion and increasing alveolar oxygen tension probably provide the initial stimulus for pulmonary arteriolar dilation and partly result from direct physical effects, but vasoactive substances are released in response to physical forces associated with ventilation, for example prostacyclin.[110] Other vasoactive mediators thought to play a role in regulating pulmonary arteriolar tone include NO, prostaglandins D_2 and E_2, bradykinin, histamine, endothelin-1, angiotensin II, and atrial natriuretic peptide. The increase in alveolar and arterial oxygen tensions at birth is required for completion of resolution of pulmonary hypertension. Much of this increase is thought to be mediated by NO, evidence for this being the parallel increase during gestation of the pulmonary vasodilation response to hyperoxia and the increase in NO synthesis.[113] However, inhibition of NO synthesis does not eliminate the initial decrease in pulmonary artery resistance occurring because of opening of the airways.[114]

When these mechanisms fail, one can recognize PPH. Right-to-left shunting within the lungs and through patent fetal conduits occurs and can result from many factors, including asphyxia and meconium aspiration, but in many cases the precipitating trigger is unknown. Inappropriately decreased levels of vasodilators (NO) and inappropriately increased levels of vasoconstrictors (endothelin-1) currently are being examined as potential mechanisms. Chronic in utero hypoxia and acidosis may result in hypertrophy of the pulmonary arteriolar smooth muscle.[115] In these cases, reversal of PPH can be difficult and cannot be achieved rapidly.

Treatment of PPH is twofold: abolishment of hypoxia and correction of the acidosis, for both abnormalities only bolster the fetal circulatory pattern. Initial therapy is provision of oxygen intranasally at 8 to 10 L/min. Some foals respond to this therapy and establish neonatal circulatory patterns within a few hours. Failure to improve or worsening of hypoxemic respiratory failure following intranasal oxygen administration should prompt intubation and mechanical ventilation with 100% oxygen. This serves two purposes, one diagnostic and one therapeutic. Ventilation with 100% oxygen may resolve PPH and, if intrapulmonary shunt and altered ventilation-perfusion relationships are causing the hypoxic respiratory failure, arterial oxygen tension (PaO_2)

should exceed 100 mm Hg under these conditions. Failure to improve PaO_2 suggests PPH or large right-to-left extrapulmonary shunt caused by congenital cardiac anomaly. The vasodilators prostacyclin and telazoline (an α-blocking vasodilator) cause pulmonary vasodilation in human infants with PPH, but the effects on oxygenation vary and the side-effects (tachycardia, severe systemic hypotension) are unacceptable.[116] Recognition of NO as a potent dilator of pulmonary vessels has created a significant step forward in the treatment of these patients, for inhaled NO dilates vessels in ventilated portions of the lung while having minimal effects on the systemic circulation.[117] Based on evidence presently available, use of inhaled NO in an initial concentration of about 20 ppm in the ventilatory gas seems reasonable for term and near-term foals with hypoxic respiratory failure and PPH that fails to respond to mechanical ventilation using 100% oxygen alone.[117,118] The author has used this approach in the clinic, administering a range of 5 to 40 ppm NO with success.

19.4.3 PERINATAL ASPHYXIA SYNDROME

Hypoxic ischemic encephalopathy (HIE), currently referred to as neonatal encephalopathy in the human literature, is one systemic manifestation of a broader syndrome of perinatal asphyxia syndrome (PAS), and management of foals with signs consistent with a diagnosis of HIE requires the clinician to examine other body systems fully and to provide therapy directed at treating other involved systems.[119] Although PAS primarily manifests as HIE, the gastrointestinal tract and kidneys frequently are affected by peripartum hypoxia/ischemia/asphyxia, and one should expect complications associated with these systems. Hypoxic ischemic encephalopathy also may affect the cardiovascular and respiratory systems, and one also may encounter endocrine disorders in these patients.

Hypoxic ischemic encephalopathy has been recognized as one of the most common diseases of the equine neonate for generations.[1,10,12] In the past HIE has been known as dummy foal syndrome and as neonatal maladjustment syndrome. The designation HIE, although not perfect, attempts to describe the syndrome in terms of the suspected underlying pathophysiology.

A wide spectrum of clinical signs is associated with HIE and can range from mild depression with loss of the suck reflex to grand mal seizure activity. Typically, affected foals are normal at birth but show signs of central nervous system abnormalities within a few hours after birth. Some foals are obviously abnormal at birth, and some do not show signs until 24 hours of age. Hypoxic ischemic encephalopathy commonly is associated with adverse peripartum events, including dystocia and premature placental separation, but a fair number of foals have no known peripartum period of hypoxia, suggesting that these foals result from unrecognized in utero hypoxia (Box 19-2). Severe maternal illness also may result in foals born with PAS. In human beings, 1390
ascending placental infection now is suspected of being a major contributor to neonatal encephalopathy in 1391
infants, and the incidence of neonatal encephalopathy increases with the presence of maternal fever, suggesting a role for maternal inflammatory mediators.[120]

19.4.3.1 BOX 19-2 CAUSES OF HYPOXIA IN THE FETUS AND NEONATE

19.4.3.1.1 Maternal Causes

Reduced maternal oxygen delivery

Maternal anemia

- Maternal pulmonary disease with hypoxemia
- Maternal cardiovascular disease

Reduced uterine blood flow

- Maternal hypotension (endotoxemia/colic)
- Maternal hypertension (laminitis/painful conditions)
- Abnormal uterine contractions
- Anything that increases uterine vascular resistance

19.4.3.1.2
Placental Causes

Premature placental separation

Placental insufficiency; for example, twins

Placental dysfunction

- Fescue toxicity
- Postmaturity
- Placentitis
- Placenta edema

Reduced umbilical blood flow

- General anesthesia of the dam
- Congenital cardiovascular disease
- Inappropriate fetal blood distribution
- Fetal hypovolemia

- Excessive length of umbilical cord

19.4.3.1.3 ### Intrapartum Causes

Dystocia

Premature placental separation

Uterine inertia

Oxytocin induction of labor

Cesarean section

- General anesthesia
- Poor uterine blood flow because of maternal positioning
- Decreased maternal cardiac output
- Reduced umbilical blood flow
- Effects of anesthetic drugs on fetus

Anything that prolongs stage 2 labor

19.4.3.1.4 ### Neonatal Period Causes

Prematurity

Recumbency

- Musculoskeletal disease
- Sepsis
- Prematurity
- Mild hypoxic ischemic encephalopathy

Pulmonary disease

  - Meconium aspiration
  - Milk aspiration
  - Persistent pulmonary hypertension
  - Septic pneumonia
  - Acute respiratory distress syndrome or acute lung injury
- Severe disturbance in breathing pattern
- Septic shock
- Anemia
  - Neonatal isoerythrolysis
  - Excessive umbilical bleeding
  - Fractured ribs (hemothorax) or long bone fracture
- Congenital cardiovascular disease

Adapted from Palmer JE: Perinatal hypoxic-ischemic disease. Proceedings of the International Veterinary Emergency Critical Care Symposium, San Antonio, Tex., 1998. p 717-718.

The underlying pathophysiologic details of HIE in the foal are unknown, and to date accurate experimental models of HIE and PAS in the foal have not been described. However, a great deal of attention has been paid to peripartum hypoxia/asphyxia by human counterparts because the effects of adverse peripartum events in the human neonate have far ranging implications for the affected human neonate and for society. Therefore equine neonatologists have long looked to human studies and models of the human disease for understanding of the syndrome in the equine neonate.

Perinatal brain damage in the mature fetus usually results from severe uterine asphyxia caused by an acute reduction of uterine or umbilical circulation. The fetus responds to this challenge by activation of the sympathetic adrenergic nervous system, causing a redistribution of cardiac output that favors the central organs: brain, heart, and adrenal glands.[121,122] If the hypoxic insult continues, the fetus reaches a point beyond which it cannot maintain this centralization of circulation, cardiac output falls, and cerebral circulation diminishes.[122] The loss of oxygen results in a substantial decrease in oxidative phosphorylation in the brain with concomitant decreased energy production. The Na^+/K^+ pump at the cell membrane cannot maintain the ionic gradients, and the membrane potential is lost in the brain cells. In the absence of the membrane potential, calcium flows down

its large extracellular/intracellular concentration gradient through voltage-dependent ion channels into the cell. 1391
This calcium overload of the neuron leads to cell damage by activation of calcium-dependent proteases, lipases, 1392
and endonucleases. Protein biosynthesis is halted. Calcium also enters the cells by glutamate-regulated ion channels as glutamate, an excitatory neurotransmitter, is released from presynaptic vesicles following anoxic cellular depolarization. Once the anoxic event is over, protein synthesis remains inhibited in specific areas of the brain and returns to normal in less vulnerable areas of the brain. Loss of protein synthesis appears to be an early indicator of cell death caused by the primary hypoxic/anoxic event.[123]

A second wave of neuronal cell death occurs during the reperfusion phase and is thought to be similar to classically described postischemic reperfusion injury in that damage is caused by production of and release of oxygen radicals, synthesis of NO, and inflammatory reactions.[124] Additionally, an imbalance between excitatory and inhibitory neurotransmitters occurs.[123] Part of the secondary cell death that occurs is thought to be caused by apoptosis, a type of programmed cell death termed *cellular suicide*. Secondary cell death also is thought be caused by the neurotoxicity of glutamate and aspartate resulting again from increased intracellular calcium levels.[125,126] In human infants the distribution of lesions with hypoxic-ischemic brain damage following prenatal, perinatal, or postnatal asphyxia falls into distinct patterns depending on the type of hypoxia-ischemia rather than on postconceptual age at which the asphyxial event occurs.[126] Periventricular leukomalacia was associated with chronic hypoxia-ischemia, whereas the basal ganglia and thalamus were affected primarily in patients experiencing acute profound asphyxia, providing direct evidence that the nature of the event determines the severity and distribution of neurologic damage in human beings. These remarkably selective patterns of injury in children, with differential variability in the damage caused to regions anatomically located within millimeters of each other, resulted in the hypothesis that location within neurotransmitter-specific circuitry loops is important. This hypothesis has important implications in the design of neuroprotective strategies and therapies for neonates experiencing hypoxic-ischemic-asphyxial events. Now the evidence is overwhelming that the excitotoxic cascade that evolves during HIE extends over several days from the time of insult and is modifiable.[125,126]

In brain injury, traumatic or hypoxic, the mechanisms underlying delayed tissue injury still are understood poorly. Many believe that neurochemical changes, including excessive neurotransmitter release, are pivotal in the pathophysiology of secondary neuronal death. Excitatory amino acid neurotransmitters and magnesium are known to play at least a minimal role in secondary cell death following brain injury; a fair body of literature regarding these factors has been generated over the last 10 years. The activation of the *N*-methyl-D-aspartate (NMDA) subtype of glutamate receptors is implicated in the pathophysiology of traumatic brain injury and is suspected to play a role in HIE.[125–127] Mechanically injured neurons demonstrate a reduction of voltage-dependent Mg^{2+} blockade of NMDA current that can be restored partially by increasing extracellular Mg^{2+} concentration or by pretreatment with calphostin C, a protein kinase C inhibitor.[128] This finding suggested that administration of Mg^{2+} to patients with brain injury could lead to improved outcome. Subsequently, magnesium sulfate solution was shown to improve dramatically the immediate recovery of rats from hypoxia.[129] However, although pretreatment with magnesium sulfate protected against hypoxic ischemic brain injury, postasphyxial treatment worsened brain damage in 7-day-old rats, suggesting an age-related response in the rat.[130] Delayed magnesium treatment of mature rats following severe traumatic axonal brain injury improved motor outcome when administered up to 24 hours after injury, with early treatments providing the most benefit.[131]

Maternal seizure in rats is associated with fetal histopathologic changes that are abolished by administration of magnesium sulfate to the mother, and magnesium sulfate has been demonstrated to protect the fetal brain from

severe maternal hypoxia.[132] Clinical trials investigating the efficacy of magnesium treatment following hypoxia in infants are under way, with few reports currently in the medical literature. Magnesium sulfate was used to treat nine infants after perinatal asphyxia in one study (no control group), and all children were neurologically normal at 1 year of age. Seizures did not occur in any of these children, nor were any adverse side effects noted.[133] Magnesium sulfate administration failed to delay the global impairment in energy metabolism after hypoxia ischemia, characteristic of severe brain damage, in newborn piglets; at 48 hours after hypoxia ischemia, no difference could be found in the severity of injury in piglets treated with magnesium compared with piglets treated with placebo, suggesting magnesium may not be protective with severe acute injury.[134]

In developing countries, birth hypoxia frequently is associated with HIE, and although this finding is attributed most frequently to inadequate obstetric care, poor nutrition also may play a role. Red blood cell magnesium levels were measured in more than 500 women in labor at a teaching hospital in South Africa.[135] Fifty five of the women delivered infants with HIE and had significantly lower levels of magnesium than controls; the infants with HIE also had significantly lower magnesium levels than controls. The large majority (54 of 55) of the women giving birth to HIE infants were from poor social circumstances, suggesting nutrition might play a 1392
role in some cases of HIE, with maternal magnesium levels affecting outcome in the infants. The authors 1393
suggested an early pregnancy intervention study may help determine the role of magnesium in the pathogenesis of HIE in human infants born to at-risk mothers.

Therapy for the various manifestations of hypoxia-ischemia involves control of seizures, general cerebral support, correction of metabolic abnormalities, maintenance of normal arterial blood gas values, maintenance of tissue perfusion, maintenance of renal function, treatment of gastrointestinal dysfunction, prevention and recognition and early treatment of secondary infections, and general supportive care. Control of seizures is important because cerebral oxygen consumption increases fivefold during seizures. One can use diazepam for emergency control of seizures (Table 19-4). If diazepam does not stop seizures readily or one recognizes more than two seizures, then one should replace diazepam with phenobarbital given to effect. The half-life of phenobarbital can be long in the foal (100 hours), and one should keep this in mind when monitoring neurologic function in these cases after phenobarbital administration (J.E. Palmer, personal communication, 1998).[136] Early-stage, preseizure administration of phenobarbital has been advocated by some investigators for prevention of neonatal encephalopathy. However, one recent study in asphyxiated human infants demonstrated that early phenobarbital treatment was associated with a threefold increase in the incidence of subsequent seizures and consequently a trend toward increased mortality. Seizures per se were associated with almost a twentyfold increase in mortality. Their findings suggest that early phenobarbital administration may produce adverse rather than beneficial effects following asphyxia. Because this was an observational study; the results need to be confirmed by appropriate randomized trials in similar clinical settings.[137] If phenobarbital fails to control seizures, one may attempt phenytoin therapy. In cases of HIE, one should avoid ketamine and xylazine because of their association with increased intracranial pressure. One must protect the foal from injury during a seizure and also ensure the patency of the airway to prevent the onset of negative pressure pulmonary edema[138] or aspiration pneumonia.

TABLE 19-4 Drugs Used to Control or Prevent Seizures in Foals

DRUG	DOSE	ROUTE	FREQUENCY	COMMENT
Diazepam	5–10 mg per foal	IV*	As needed	Short-term seizure control
Phenobarbital	2–3 mg/kg	IV	Bolus to effect	Bolus over 15–20 minutes. Half-life can be prolonged; decreases thermoregulatory control, respiratory drive, and blood pressure
Phenytoin	5–10 mg/kg loading; 5 mg/kg maintenance	IV	q4h for first 24 hours; then b.i.d. (?)	Seizure control
Magnesium sulfate†	0.05 mg/kg/hr loading dose; 0.025 mg/kg/hr maintenance‡	IV	Constant rate infusion for first hour and for maintenance	Discontinue if muscle tremors or hypotension occur. Treat for 24–48 hours after hypoxic insult
Gabapentin	8 mg/kg	p.o.	b.i.d. to t.i.d.	Seizure control

* *IV,* Intravenous.

† To make 0.1 gm/ml solution, add 20 ml 50% $MgSO_4$ to 80 ml 0.9% NaCl.

‡ Loading dose = 25 ml/hr of 0.1 gm/ml solution for 1 hour. Maintenance dose = 12 ml/hr of 0.1 gm/ml solution.

Probably the most important therapeutic interventions are aimed at maintaining cerebral perfusion, which is achieved by careful titration of intravenous fluid support, neither too much nor too little (see Fluid Therapy in Neonates) and judicious administration of inotropes and pressors to maintain adequate perfusion pressures (see Pressor and Inotrope Therapy in Neonates). Cerebral interstitial edema is only truly present in the most severe cases[139,140]; in most cases the lesion is intracellular edema and most of the classic agents used to treat cerebral interstitial edema (e.g., mannitol) are minimally effective treating cellular edema. Occasionally the author uses thiamine supplementation in the intravenous fluids to support metabolic processes, specifically mitochondrial metabolism and membrane Na^+,K^+-ATPases, involved in maintaining cellular fluid balance.[141,142] This therapy is rational and inexpensive but unproven in efficacy. Only if cellular necrosis and vasogenic edema are present are drugs such as mannitol and dimethyl sulfoxide indicated, and again these cases are usually the most severely affected. In the author's clinic, practitioners rarely have used dimethyl sulfoxide in neonates for the last several years and have recognized no change in outcome by discontinuing its use. When the practitioners use intravenously administered dimethyl sulfoxide, they do so within the first hour after an acute asphyxial insult and use it primarily for its hydroxyl radical scavenging effects and its theoretical modulation of postischemic reperfusion injury.[143]

1393

1394

Naloxone has been advocated for treating HIE in human beings and in foals,[144–146] perhaps based on a study suggesting that postasphyxia blood-brain barrier disruption was related causally to poor neurologic outcome in a lamb model of HIE and that naloxone prevented disruption and neurologic dysfunction among those survivors with an intact blood-brain barrier.[145] However, other studies have demonstrated that naloxone exacerbates hypoxic-ischemic brain injury in 7-day-old rats subjected to unilateral common carotid artery ligation and

hypoxia. Moreover, systemic acidosis and cellular edema were no different in naloxone-treated animals compared with animals treated with saline solution. The authors concluded that high doses of naloxone in fact may reduce the resistance of the fetus to hypoxic stress.[146] The use of naloxone in human neonatal resuscitation remains controversial, for whether the contradictory effects are related to a reduction in acute neuronal swelling by osmotic effects or by a more direct receptor-mediated mechanism is currently unknown.[147] Naloxone is most effective in resuscitation of compromised human infants born to mothers addicted to drugs. Some practitioners are using γ-aminobutyric acid adrenergic agonists to manage HIE in foals, based on evidence showing neuroprotection when used in ischemia alone and combined with NMDA antagonists.[148–150] The author currently has no experience with these compounds and cannot comment regarding their efficacy in foals. Regional hypothermia also is being investigated as a potential therapy for global hypoxia/ischemia; published data are consistent with the theory that cooling must be continued throughout the entire secondary phase of injury (about 3 days) to be effective.[151] Experimentally, this approach has resulted in dramatic decreases in cellular edema and neuronal loss; its practical application remains to be demonstrated.

Despite a lack of consensus regarding the use of magnesium to treat infants with HIE, the author has used magnesium sulfate infusion as part of the therapy for selected foals with HIE for the past several years. The rationale is based primarily on the evidence demonstrating protection in some studies and a failure of any one study to demonstrate significant detrimental effects. The clinical impressions of the author to date suggest that the therapy is safe and may decrease the incidence of seizure in patients. The author administers magnesium sulfate as a constant rate infusion over 1 hour after giving a loading dose. The author has continued the infusion for up to 3 days without demonstrable negative effect beyond some possible trembling. Given the current evidence, a 24-hour course of treatment may be effective and all that is necessary. Postasphyxial treatment certainly may be beneficial in foals with HIE, and maternal magnesium therapy may be beneficial in certain high-risk pregnancy patients.

Foals with PAS often have a variety of metabolic problems including hypo- or hyperglycemia, hypo- or hypercalcemia, hypo- or hyperkalemia, hypo- or hyperchloremia, and varying degrees of metabolic acidosis. Although one needs to address these problems, one should not forget the normal period of hypoglycemia that occurs postpartum and should not treat aggressively so as to avoid worsening the neurologic injury. Foals suffering from PAS also have frequent recurrent bouts of hypoxemia and occasional bouts of hypercapnia. Intranasally administered oxygen is generally needed in these cases as a preventative therapy and as direct treatment, for the appearance of the abnormalities can be sporadic and unpredictable. Additional respiratory support, particularly in those foals with centrally mediated hypoventilation and periods of apnea or abnormal breathing patterns, include caffeine (per os or per rectum) and positive pressure ventilation. Caffeine is a central respiratory stimulant and has minimal side effects at the dosages used (10 mg/kg loading dose; 2.5 mg/kg as needed).[152] The author purchases whatever oral form of caffeine is available at the local convenience store or drug store and administers it dissolved in warm water per rectum. Foals treated with caffeine have an increased level of arousal and are more reactive to the environment. Adverse effects generally are limited to restlessness, hyperactivity, and mild to moderate tachycardia. Mechanical ventilation of these patients can be rewarding and generally is required for less than 48 hours. One must monitor and maintain blood pH within the normal range. Metabolic alkalosis can develop in some of these foals and requires clinician tolerance of some degree of hypercapnia. pH is important in evaluation and consideration of alternatives for treatment. If the respiratory acidosis is not so severe as to affect the patient adversely (generally >70 mm Hg), and the pH is within normal limits, the foal may tolerate hypercapnia.[153] The goal is to normalize pH. Foals with respiratory acidosis as compensation for metabolic alkalosis do not respond to caffeine. Metabolic alkalosis in critically ill foals frequently is associated with electrolyte abnormalities, creating differences in strong ion balance. One handles this pH perturbation best by correcting the underlying electrolyte problem.

Maintaining tissue perfusion and oxygen delivery to tissues is a cornerstone of therapy for PAS to avoid additional injury. One should maintain the oxygen-carrying capacity of the blood; some foals require transfusions to maintain a packed cell volume greater than 20%. Adequate vascular volume is important, but one should take care to avoid fluid overload in the foal. Early evidence of fluid overload is subtle accumulation of ventral edema between the front legs and over the distal limbs. Fluid overload can result in cerebral edema, pulmonary edema, and edema of other tissues, including the gastrointestinal tract. This edema interferes with 1394
normal organ function and worsens the condition of the patient. One maintains perfusion by supporting cardiac 1395
output and blood pressure by judicious use of intravenous fluid support and inotrope/pressor support. The author does not target therapy to a specific systolic, mean, or diastolic pressure but monitors urine output, mentation, limb perfusion, gastrointestinal function, and respiratory function as indicators that perfusion is acceptable. For these patients to require pressor therapy is not unusual, but in some cases the hypoxic damage is sufficiently severe to blunt the response of the patient to the drugs.

The kidney is a target for injury in patients with PPH, and for renal compromise to play a significant role in the demise of these foals is not unusual. Clinical signs of renal disease are generally referable to disruption of normal control of renal blood flow and tubular edema leading to tubular necrosis and renal failure. These foals have signs of fluid overload and generalized edema. One must balance urine output and fluid therapy in these cases to prevent additional organ dysfunction associated with edema. Although evidence has accumulated that neither dopamine nor furosemide play a role in protecting the kidney or reversing acute renal failure, these agents can be useful in managing volume overload in these cases.[154–156] The aim is not to drive oliguric renal failure into a high-output condition but rather to enhance urine output.

Overzealous use of diuretics and pressors in these cases can result in diuresis requiring increased intravenous fluid support and can be counterproductive. The author's approach is more conservative. Low doses of dopamine administered as a constant rate infusion of 2 to 5 μg/kg/min are usually effective in establishing diuresis by natriuresis. One should avoid large doses of dopamine (>20 μg/kg/min) because high doses can produce systemic and pulmonary vasoconstriction, potentially exacerbating PPH.[157] One can administer a bolus (0.25 to 1.0 mg/kg) or constant rate infusion (0.25 to 2.0 mg/kg/hr) of furosemide, but once furosemide diuresis is established, one must evaluate electrolyte concentrations and blood gas tensions frequently because potassium, chloride, and calcium losses can be considerable and because significant metabolic alkalosis can develop from strong ion imbalances. The author does not aim for urine production rates of 300 ml/hr, as has been presented by other authors as a urine output goal for critically ill equine neonates.[158] Rather the author looks for urine output that is appropriate for fluid intake and does not attempt to drive urine output to an arbitrary goal by excessive fluid administration or pressor use. Although the average urine output for a normal equine neonate is about 6 ml/kg/hr (~300 ml/hr for a 50-kg foal), these values were obtained from normal foals drinking a milk diet with a large free water component.[98–100] The urine of normal newborn foals is dilute, reflecting the large free water load they incur by their diet. Expecting critically ill foals to produce such large volumes of urine, particularly those on restricted diets or receiving total parenteral nutrition, is an exercise in futility, and manipulating fluid, pressor, or diuretic therapy in attempt to meet an artificial goal is inappropriate. Fluid therapy in the critically ill neonate is discussed later in this chapter.

One final caveat regarding renal dysfunction in PAS is that one should perform therapeutic drug monitoring when it is available. Many antimicrobial agents used to manage these cases, most notably the aminoglycosides, depend on renal clearance. Aminoglycoside toxicity occurs in the equine neonate and exacerbates or complicates the management of renal failure originally resulting from primary hemodynamic causes. The author monitors aminoglycoside concentrations for 30-minute peak and 23- to 24-hour trough values in these

cases and adjusts dosage and frequency of drug administration based on these results. The author considers a trough value of less than 2 µg/dl as desirable for gentamicin and amikacin.

Foals with PAS suffer from a variety of problems associated with abnormalities within the gastrointestinal tract.[159] Commonly they have ileus, recurrent excessive gastric reflux, and gas distention. These problems are exacerbated by constant feeding in the face of continued dysfunction and continued hypoxia. Frequently, enteral feeding cannot meet their nutritional requirements, and partial or total parenteral nutrition is required. One must give special attention to passive transfer of immunity (see Failure of Passive Transfer) and glucose homeostasis in these cases. Although some practitioners use prokinetic agents as therapy for ileus in these cases, the author's approach is again more conservative. Appearance of damage to the gastrointestinal tract can be subtle and lag behind other clinical abnormalities for days to weeks. Low-grade colic, decreased gastrointestinal motility, decreased fecal output, and low weight gain are among the most common clinical signs of gastrointestinal dysfunction in these case, but more severe problems, including necrotizing enterocolitis and intussusception, have been associated with these cases. The return to enteral feeding must be slow in many of these cases. A currently debated topic is constant versus pulsed enteral feeding.[160–162] The author uses pulsed feeding through an indwelling small-gauge feeding tube. In many foals these tubes stay in place for weeks and cause no problems as the foals are returned to their dams for sucking or are trained to drink from a bottle or bucket.

Foals with PAS are also susceptible to secondary infection. Treatment of recognized infection is covered under sepsis in this chapter. If infection is recognized in these patients after hospitalization, one should give attention to the likelihood of nosocomial infection and should direct antimicrobial therapy based on known nosocomial 1395
pathogens in the NICU and their susceptibility patterns until culture and sensitivity results become available. 1396
One should make repeat determinations of immunoglobulin G (IgG) concentration; additional intravenous plasma therapy may be required. Nosocomial infections are often rapidly overwhelming, and acute deterioration in the condition of a foal with PAS should prompt a search for nosocomial infection.

The prognosis for foals with PAS is good to excellent when the condition is recognized early and aggressively treated in term foals. Up to 80% of these neonates survive and go on to lead productive and useful athletic lives.[20–23] The prognosis decreases with delayed or insufficient treatment and concurrent problems such as prematurity and sepsis.

19.4.4 PREMATURITY/DYSMATURITY/POSTMATURITY

In human NICUs the survival rates of low-gestation-length infants has increased dramatically since the 1980s concurrent with improvements in obstetric and neonatal care. The now routine, well-validated use of antenatal steroid and artificial surfactant therapies has contributed greatly to the enhanced survival of this patient population, although the use of these particular therapies is not common or frequently indicated in the equine NICU.[163,164] However, with improved care, outcomes in the equine NICU population have improved also, with survival of premature patients in many NICUs exceeding 80%.[21] In the equine population, gestation length is much more flexible than in the human population; however, the definition of the term *prematurity* needs reexamination. Traditionally, *prematurity* is defined as a preterm birth of less than 320 days of gestation in the horse. Given the variability of gestation length in the horse, ranging from 310 days to more than 370 days in some mares, a mare with a usual gestation length of 315 days possibly could have a term foal at 313 days, whereas a mare with a usual gestation length of 365 days may have a premature foal at 340 days, considered the normal gestation length. Foals that are born postterm but are small are termed *dysmature;* a postmature foal is a postterm foal that has a normal axial skeletal size but is thin to emaciated. Dysmature foals may have been

classified in the past as small for gestational age and are thought to have suffered placental insufficiency, whereas postmature foals are usually normal foals that have been retained too long in utero, perhaps because of an abnormal signaling of readiness for birth, and have outgrown their somewhat aged placenta. Postmature foals become more abnormal the longer they are maintained, also may suffer from placental insufficiency, and are represented best by the classic foal born to a mare ingesting endophyte-infested fescue.[165] Box 19-3 compares the characteristics of premature/dysmature foals with those of postmature foals.

The causes of prematurity/dysmaturity/postmaturity include the causes of high-risk pregnancy presented in Box 19-1. Additional causes include iatrogenic causes such as early elective induction of labor based on inaccurate breeding dates or misinterpretation of late-term colic or uterine bleeding as ineffective labor. Most causes remain in the category of idiopathic, with no discernible precipitating factor. Despite lack of an obvious cause, 1396

premature labor and delivery does not just happen, and even if undetermined, the cause may continue to affect 1397 the foal in the postparturient period. All body systems may be affected by prematurity, dysmaturity, and postmaturity, and thorough evaluation of all body systems is necessary.

19.4.4.1

BOX 19-3 CLINICAL CHARACTERISTICS OF PREMATURE/DYSMATURE AND POSTMATURE FOALS

19.4.4.1.1

Premature/Dysmature

Low birth weight

Small frame; thin

Poor muscle development possible

Flexor laxity common

Periarticular laxity

Hypotonia more common

High chest wall compliance

Low lung compliance

Short, silky hair coat

Domed forehead

Floppy ears; poor cartilage development

Weak suck reflex

Poor thermoregulation

Gastrointestinal tract dysfunction

Delayed maturation of renal function: low urine output

Entropion with secondary corneal ulcers

Poor glucose regulation

19.4.4.1.2 Postmature

Normal to high birth weight

Large frame; thin

Poor muscle development possible

Flexor contraction common

Hypertonia more common

Long hair coat

Fully erupted incisors

Weak suck reflex

Poor thermoregulation

Gastrointestinal tract dysfunction

Delayed maturation of renal function: low urine output

Poor glucose regulation

Delayed time to standing

- Hyperreactive
- Poor postural reflexes

Adapted from Palmer JE: Prematurity, dysmaturity, postmaturity. Proceedings of the International Veterinary Emergency Critical Care Symposium, San Antonio, Tex., 1998. pp 722-723.

Respiratory failure is common in these foals, although the cause usually is not surfactant deficiency. Immaturity of the respiratory tract, poor control of respiratory vessel tone, and weak respiratory muscles combined with poorly compliant lungs and a greatly compliant chest wall contribute to respiratory failure in these cases. Most require oxygen supplementation and positional support for optimal oxygenation and ventilation. One must extend effort to maintain these “floppy foals” in sternal recumbency. Some foals may require mechanical ventilation. These foals also require cardiovascular support but are frequently unresponsive to commonly used pressors and inotropes: dopamine, dobutamine, epinephrine, and vasopressin. Careful use of these drugs and judicious intravenous fluid therapy are necessary. The goal should not be one of achieving specific pressure values (e.g., mean arterial pressure of 60 mm Hg) but of adequate perfusion. Renal function, reflected in low

urine output, is frequently poor initially in these cases because of delay in making the transition from fetal to neonatal glomerular filtration rates.[166] The delay can result from true failure of transition or from hypoxic/ischemic insult. One should approach fluid therapy cautiously in these cases; initial fluid restriction may be in order to avoid fluid overload. Many premature/dysmature/postmature foals have suffered a hypoxic insult and have all of the disorders associated with PAS, including HIE. Treatment is similar to that of term foals with these problems. These foals also are predisposed to secondary bacterial infection and must be examined frequently for signs consistent with early sepsis or nosocomial infection.

The gastrointestinal system of these foals is not usually functionally mature, which may result from a primary lack of maturity or from hypoxia. Dysmotility and varying degrees of necrotizing enterocolitis are common. One commonly encounters hyperglycemia and hypoglycemia. Hyperglycemia generally is related to stress, increased levels of circulating catecholamines, and rapid progression to gluconeogenesis, whereas hypoglycemia is associated with diminished glycogen stores, inability to engage gluconeongenesis, sepsis, and hypoxic damage.[167] Immature endocrine function is present in many of these foals, particularly regarding the hypothalamic-pituitary-adrenal axis, and contributes to metabolic derangements.[168,169] One should delay enteral feeding when possible until the foal is stable regarding metabolic and cardiorespiratory parameters. On intiating enteral feeding, one should provide small volumes initially and slowly increase the volume over several days.

One frequently encounters musculoskeletal problems, particularly in premature foals, that include significant flexor laxity and decreased muscle tone. Postmature foals frequently are affected by flexure contracture deformities, most likely because of decreased intrauterine movement as they increase in size. Premature foals frequently exhibit decreased cuboidal bone ossification that predisposes them to crush injury of the carpal and tarsal bones if weight bearing is not strictly controlled. Physical therapy in the form of standing and exercise is indicated in the management of all these problems, but one should take care to ensure that the patient does not fatigue or stand in abnormal positions. Bandaging of the limbs is contraindicated because this only increases laxity, although light bandages over the fetlock may be necessary to prevent injury to that area if flexor laxity is severe. The foals are predisposed to angular limb deformity and must be observed closely and frequently for this problem as they mature.[170]

The overall prognosis for premature/dysmature/postmature foals remains good with intensive care and good attention to detail. Many of these foals (up to 80%) survive and become productive athletes.[21] Complications associated with sepsis and musculoskeletal abnormalities are the most significant indicators of poor athletic outcome.

19.4.5 SEPSIS

The last 20 years have seen an explosion of new therapeutic agents purportedly useful for treating sepsis. Unfortunately, clinical trials investigating these new therapies have failed to demonstrate a positive effect, have shown negative results, or have resulted in diametrically opposed study results, one showing a benefit and another showing no benefit or a detrimental effect. On a positive note, the survival rate of foals being treated for sepsis has improved. Work was done regarding foal diseases and their treatment in the 1960s, but the field did not attract much serious attention until the 1980s. Since that time almost every major veterinary college and many large private referral practices have constructed NICUs or their equivalent. Next to hypoxic ischemic asphyxial syndromes, sepsis is the number one reason for presentation and treatment at these facilities. Neonatal septicemia of the horse has been the subject of three international workshops,[171–173] and a

perinatology lecture covering some aspect of neonatal sepsis has been presented at almost every large continuing education meeting attended by equine veterinarians.

Concensus criteria conferences[1] in the early 1990s defined sepsis and septic shock for human beings.[174,175] *Sepsis* was defined as the systemic response to infection manifested by two or more of the following conditions as a result of infection: a) temperature >38° C or <36°; b) heart rate >90 beats/min; c) respiratory rate >20 breaths per minute or Pa_{CO_2} <32 torr; and d) white blood cell count >12,000 cell/μl, <4,000 cell/μl, or >10% immature (band) forms. *Septic shock* was defined as sepsis induced hypotension or the requirement for vasopressors/ionotropes to maintain blood pressure despite adequate fluid resuscitation along with the presence of perfusion abnormalities that may include lactic acidosis, oliguria, or acute alteration in mental status. These definitions are broadly acceptable and applicable to neonatal sepsis in foals, and many of the treatment modalities in human medicine have been applied in some manner to the equine neonatal patient. Additional definitions that have come into vogue that are actually useful at times, include the following: SIRS, the systemic inflammatory response system; MODS, multiple organ system dysfuction; and MOFS, multiple organ failure syndrome. (SIRS is sick, MODS is sicker, and MOFS is dying.) The compensatory response syndrome (CARS) ideally balances SIRS and keeps it from becoming detrimental. If balance is achieved, recovery is possible. Imbalance progresses to septic shock, MODS, and MOFS. In horses, MODS is manifested most commonly as renal failure, hepatic failure, central nervous system dysfunction, and disseminated intravascular coagulation. Managing the septic patient involves early recognition of all the potential alphabet combinations and supporting the patient or intervening in the face of multiple clinical consequences, termed *CHAOS* (*C*ardiovacular compromise; *H*omeostasis; *A*poptosis; *O*rgan dysfunction; *S*uppression of the immune system).[176] Inflammatory mediators are involved in all these processes and can be beneficial or detrimental, depending on timing and opposing responses. Neutrophils, platelets, lymphocytes, macrophages, and endothelial cells are involved, and the implicated inflammatory molecules grow daily in numbers.

1397

1398

Sepsis in the foal initially can be subtle, and the onset of clinical signs varies depending on the pathogen involved and the immune status of the foal. For the purposes here, the discussion is limited to bacterial sepsis, but the foal also is susceptible to viral and fungal sepsis, which can appear similar to bacterial sepsis. Failure of passive transfer (FPT) of immunity can contribute to the development of sepsis in a foal at risk.[177,178] Testing for and treating FPT has received attention in the veterinary literature. It remains true, however, that foals presented to NICUs that have an ultimate diagnosis of sepsis have FPT.[16,19] The current recommendation is that foals have IgG levels greater than or equal to 800 mg/dl for passive transfer to be considered adequate. Other risk factors for the development of sepsis include any adverse advents at the time of birth, maternal illness, or any abnormalities in the foal. Although the umbilicus frequently is implicated as a major portal of entry for infectious organisms in the foal, the gastrointestinal tract may be the primary site of entry.[179] Other possible portals of entry include the respiratory tract and wounds.

Early signs of sepsis include depression, decreased suck reflex, increased recumbency, fever, hypothermia, weakness, dysphagia, failure to gain weight, increased respiratory rate, tachycardia, bradycardia, injected mucous membranes, decreased capillary refill time, shivering, lameness, aural petechia, and coronitis. If sepsis is recognized early, patients with sepsis may have a good outcome, depending on the pathogen involved. Gram-negative sepsis remains the most commonly diagnosed, but increasingly gram-positive septicemia is being recognized.[180] Foals in intensive care units and at referral hospitals have an additional risk of nosocomial infection. An attempt to isolate the organim involved early in the course of the disease becomes important. If possible, one should obtain blood cultures, and if localizing signs are present, one should obtain samples as deemed appropriate.

Cultures should be aerobic and anaerobic. Recently, work has been done evaluating real-time polymerase chain reaction technology in sepsis in the foal as a means of identifying causative organisms.[181,182] Until one obtains antimicrobial sensitivity patterns for the pathogen involved, one should initiate broad-spectrum antimicrobial therapy (Table 19-5). Intravenously administered amikacin and penicillin are good first-line choices, but one should monitor renal function closely. Other first-line antimicrobial choices might include high-dose ceftiofur sodium or ticarcillin/clavulanic acid. One should treat failure of passive transfer if present. One should provide intranasal oxygen insufflation at 5 to 10 L/min even if hypoxemia is not present to decrease the work of breathing and provide support for the increased oxygen demands associated with sepsis.[183] Should arterial blood gas analysis reveal significant hypoventilation, one may administer caffeine orally or per rectum to increase central respiratory drive. Mechanical ventilation may be necessary in cases of severe respiratory involvement such as with acute lung injury or acute respiratory distress syndrome. If the foal is hypotensive, one may administer pressor agents or inotropes by constant rate infusion (Table 19-6). Inotrope and pressor therapy generally is restricted to referral centers where these drugs can be given as constant rate infusions and blood pressure can be monitored closely. Some practitioners use nonsteroidal antiinflammatory agents and, in specific circumstances, corticosteroids. Use of these drugs should be judicious because they may have several negative consequences for the foal including renal failure and gastric/dunodenal ulceration.[184–186]

Nursing care is one of the most important aspects of treating septic foals. Foals should be kept warm and dry. 1398
They should be turned at 2-hour intervals if they are recumbent. Feeding septic foals can be a challenge if 1399
gastrointestinal function is abnormal, and total parenteral nutrition may be needed. If at all possible, foals should be weighed daily and blood glucose levels monitored frequently. Some foals become persistently hyperglycemic on small glucose infusion rates. These foals may benefit from constant rate low-dose insulin infusions (Table 19-7). Recumbent foals must be examined frequently for decubital sore development, the appearance of corneal ulcers, and for heat and swelling associated with joints and physis.

TABLE 19-5 Antimicrobial Drugs Dosages Used in Foals in the Neonatal Intensive Care Unit

DRUG	DOSE	ROUTE	FREQUENCY	COMMENTS
Amikacin sulfate	25–30 mg/kg	IV*	s.i.d.	Requires therapeutic drug monitoring: peak >60; trough <2
Ampicillin trihydrate	20 mg/kg	p.o.	t.i.d.	Poor absorption noted in foals >2–3 weeks of age.
Sodium ampicillin	50–100 mg/kg	IV	q.i.d.	—
Amoxicillin trihydrate	20–30 mg/kg	p.o.	t.i.d.	Poor absorption noted in foals >2–3 weeks of age.
Cefotaxime	50–100 mg/kg	IV	q.i.d.	—
Cefuroxime (Ceftin)	30 mg/kg/day	p.o.	b.i.d., t.i.d.	Total daily dose is divided into 10 mg/kg t.i.d. or 15 mg/kg b.i.d.
Cephalexin	10 mg/kg	p.o.	q.i.d.	—
Ceftiofur (Naxcel)	10 mg/kg	IV	q.i.d.	Give slowly over 20 minutes as double-diluted volume in 0.9% saline.
Chloramphenicol palmitate	50 mg/kg	p.o.	q.i.d.	Public health concerns
Chloramphenicol succinate	10–25 mg/kg	IV	q.i.d.	Public health concerns
Enrofloxacin	2.5–10 mg/kg	IV, p.o.	s.i.d.	Chondropathy and arthropathy reported in foals.
Erythromycin stearate	20–30 mg/kg	p.o.	t.i.d. to q.i.d.	Avoid warm temperatures and high humidity. Colitis reported in dams of foals receiving this drug.
Erythromycin lactiobionate	~5 mg/kg	IV	Every 4–6 hours	—
Gentamicin sulfate	8.8 mg/kg	IV	s.i.d.	Requires therapeutic drug monitoring: peak >40; trough <2
Imipenem	10–20 mg/kg	IV	q.i.d.	Seizures reported as adverse reaction.
Metronidazole	15 mg/kg 25 mg/kg	p.o., as needed	q.i.d. b.i.d.	Anorexia can occur.
Potassium penicillin Sodium penicillin	20,000–50,000 U/kg	IV	q.i.d.	Give potassium penicillin slowly over 5 to 10 minutes.
Rifampin	5 mg/kg	p.o.	b.i.d.	Always administer with second antimicrobial because of rapid development of resistance.

Ticarcillin	50–100 mg/kg	IV	q.i.d.	—
Ticarcillin and clavulonic acid (Timentin)	50–100 mg/kg	IV	q.i.d.	—
Trimethoprim-sulfonamide	30 mg/kg	p.o.	b.i.d.	—
Fluconazole	8 mg/kg loading; 4 mg/kg	p.o.	b.i.d.	—
Adapted from Palmer JE: *Neonatal drug doses*. Proceedings of the sixth International Veterinary Emergency Critical Care Symposium, San Antonio, Tex., 2000.				

* *IV,* Intravenous.

TABLE 19-6 Inotrope and Pressor Medications Used in the Neonatal Intensive Care Unit[*]

DRUG	DOSE	ROUTE	COMMENT
Dopamine	3–20 μg/kg/min	IV-CRI[†]	Follow the rule of 6: 6 × mass of foal (kg) = number of milligrams to add to 100 ml saline (1 ml/hr = 1 g/kg/min)
Dobutamine	3–40 μg/kg/min	IV-CRI	
Epinephrine[‡]	0.2–2 μg/kg/min	IV-CRI	
Norepinephrine[‡]	0.2–3 μg/kg/min	IV-CRI	
Data fom Connoly Neonatal Intensive Care Unit, Kennet Square, Penn.			

* One should use these medications to effect and should monitor blood pressure during their use.

† *IV-CRI,* Intravenously at constant rate infusion.

‡ For epinephrine and norepinephrine, apply a “rule of 0.6” where 0.6 × mass of foal (kg) = number of mg drug to add to 100 ml saline so 1 ml/hr = 0.1 μg/kg/min.

The prognosis for foals in the early stages of sepsis is fair to good. Once the disease has progressed to septic 1399
shock the prognosis decreases, although short-term survival rates are as good as those in human critical care 1400
units. Long-term survival and athletic outcomes are fair. Racing breed foals that make it to the track perform similarly to their age-matched siblings.[21]

TABLE 19-7 Miscellaneous Drugs Used in the Neonatal Intensive Care Unit

DRUG	DOSE	ROUTE	FREQUENCY	COMMENTS
Aminophylline	2–3 mg/kg	IV[*]	b.i.d. to q.i.d.	Monitor theophylline levels. Therapeutic: 6–12 μg/l Toxic: >20 μg/l
Caffeine	10 mg/kg loading dose 2.5 mg/kg maintenance	Orally as needed	s.i.d., b.i.d.	Steady state level: 5–20 μg/l Toxic: >50–75 μg/l
Dimethyl sulfoxide	1 g/kg	IV	Once	Administer as 5% to 10% solution; dimethyl sulfoxide is hypertonic.
Heparin	40–100 U/kg	SQ/IV	b.i.d.	—
Insulin (protamine zinc)	0.15 U/kg	IM/SQ	b.i.d.	—
Insulin (regular)	0.00125–0.2 U/kg/hr	IV	Constant rate Infusion	Pretreat lines: insulin adsorbs to lines.

* *IV,* Intravenous; *SQ,* subcutaneous; *IM,* intramuscular.

19.5 Other Diseases Causing Weakness In Foals

19.5.1 BOTULISM

Botulism is a neuromuscular disease of foals characterized by flaccid paralysis.[187] Although the disease is discussed in detail elsewhere in this text, the form most commonly observed in foals, the toxicoinfectious form, deserves some specific comments. The causative organism is *Clostridium botulinum,* an anaerobic organism. Although affected adults usually acquire the disease by ingestion of preformed toxin elucidated from the organism, in the foal less than 8 months of age the organism can survive and multiply in the gastointestinal tract and produce necrotic foci within the liver, giving the foal constant exposure to newly formed toxin. The horse is exquisitely sensitive to the toxin, and only small quantities of toxin are required to produce clinical signs and death in affected animals. The ε-toxin of *C. botulinum* binds to the presynaptic membrane of motor neurons and prevents transmission of impulses by blocking the release of acetylcholine from the presynaptic vessicles. This block produces the clinical signs of muscle weakness, manifested in foals as trembling (shaker foals) or acute recumbency.[188] Pupillary dilation, dysphagia, tremors, recumbency, and terminal respiratory distress caused by respiratory muscle paralysis occur. Foals can be found acutely dead. In endemic areas (the Northeast and mid-Atlantic regions of United States), for these foals to be evaluated first as having colic is not unusual.

Treatment aims to neutralize the toxin by administration of botulinum antitoxin and to provide antimicrobial treatment of the infection with penicillin, metronidazole, and/or oxytetracycline.[189,190] At a minimum, feeding of milk replacer via indwelling nasogastric tube at 20% of the body weight of the foal per day divided into

every 2-hour meals is required. Many of these foals require respiratory support (in the form of intranasal oxygen insufflation), because of respiratory muscle paralysis. Respiratory acidosis is present on arterial blood gas analysis in most of these foals because of hypoventilation and lateral recumbency, but they can tolerate some degree of hypercapnia ($Pa{CO_2}$ ~70 mm Hg) if the pH is normal and oxygenation ($Pa{O_2}$ >70 mm Hg; percent oxygen saturation of hemoglobin, >90%) is adequate. Metabolic alkalosis can accompany the respiratory acidosis, but this is a compensatory change and resolves once gas exchange is normalized. Some of these patients require mechanical ventilation, which may be lifesaving. One may discontinue mechanical ventilation as clinical signs resolve and the respiratory muscles gain strength. Nursing care is important, and these foals should be turned every 2 hours. They should be maintained in sternal recumbency if possible and kept warm and dry. With good nursing care, good nutritional support, and adequate respiratory support, the prognosis for these foals is good. The limiting factor in the prognosis for life is often financial.[190] Foals that recover from the acute stage of this disease eventually fully recover.

Botulism is an expensive disease to treat and is also an entirely preventable disease.[189,190] All pregnant mares in endemic areas should be vaccinated against *C. botulinum*. Vaccination does not prevent all cases of botulism, particularly if the foal has failure of passive transfer or acquires the disease after maternal immunity wanes and before its own vaccination. 1400

1401

19.5.2 NUTRITIONAL MUSCULAR DYSTROPHY (WHITE MUSCLE DISEASE)

Nutritional muscular dystrophy or white muscle disease is a vitamin E/selenium–responsive muscle disease of horses of all ages probably caused by a dietary deficiency of selenium and vitamin E.[191] The condition occurs most commonly in geographic areas with low selenium levels in the soil, generally the northeastern, northwestern, Great Lakes and mid-Atlantic regions of the United States.

Two forms of the disease are described in foals: the fulminant form, in which the foal is found acutely dead, and the subacute form. In the fulminant form, death usually is attributed to myocardial lesions resulting in cardiovascular collapse. The subacute form is characterized by dysphagia and gait abnormalities primarily caused by stiffness of the muscles of locomotion. Paralysis, if present, is not flaccid as in botulism. Abnormal function of respiratory muscles may complicate the clinical situation. Aspiration pneumonia may be present following problems associated with swallowing; the tongue and pharyngeal muscles frequently are affected in the early stages of disease.[191] Foals with severe disease may have widespread muscle necrosis leading to hyperkalemia, which can be severe and result in death of the foal. Serum activities of the muscle enzymes creatine kinase and aspartate aminotransferase may be greatly increased. Diagnosis is confirmed at necropsy or ante mortem by determination of decreased vitamin E, selenium, and glutathione peroxidase concentrations in the blood of the foal before supplementation. Myoglobinuria and acute renal failure are not uncommon in these foals.

Treatment of foals with nutritional muscular dystrophy is primarily supportive. One should address all metabolic abnormalities. Some foals require intranasal oxygen insufflation. Affected foals are unable to suck effectively, and one should provide enteral (via an indwelling nasogastric tube) or parenteral nutritional support. Because of the high likelihood of aspiration pneumonia, one should administer broad-spectrum antimicrobial therapy parenterally. The patient should be kept quiet and should be stimulated minimally. Affected foals should receive parenteral (intramuscular) vitamin E and selenium supplementation. Selenium is toxic in large doses. The prognosis for severely affected foals is guarded. For less severely affected foals the prognosis is good with appropriate treatment. The disease is preventable by ensuring that mares receive sufficient vitamin E and selenium while pregnant and by supplementing foals with parenteral injections of

vitamin E and selenium at birth in endemic areas. A more complete discussion of the pathophysiology of this disease and the nutritional management is presented elsewhere in this text.

19.6 Diseases Causing Abnormal Mentation Or Other Neurologic Signs In Foals (Other Than Perinatal Asphyxia Syndrome)

19.6.1 HEPATIC ENCEPHALOPATHY

Primary liver disease is uncommon in the foal and occurs primarily as a sequela to sepsis. Clinical signs of severe liver disease may include depression, ataxia, and seizures. In affected foals, increases in serum liver enzyme activities and concentrations of ammonia and bile acids frequently can be identified. The mechanism(s) underlying hepatoencephalopathy are not delineated clearly, although increased excitatory neurotransmitters, or compounds that mimic their activity, are implicated. Hepatoencephalopathy is discussed in more detail elsewhere in this text.

Tyzzer's disease (*Clostridium piliformis* infection) rarely causes primary liver disease in foals from 4 to about 40 days of age. This disease is almost uniformly fatal. The incubation period is short, and the mare is thought to be the carrier.[192–196] Clinical signs range from acute death to depression, fever, and pronounced icterus. The feces of affected foals may appear white to grey because of the lack of bile. Clinicopathologic abnormalities include leukopenia, hyperfibrinogenemia, metabolic acidosis, and hypoglycemia.[197,198] Liver lesions at postmortem are characterized microscopically by multiple foci of necrosis. One usually can demonstrate variable numbers of elongated, slender intracytoplasmic bacilli within hepatocytes bordering the necrotic foci. Infiltration of the portal triads with inflammatory cells and biliary duct hyperplasia and degeneration are observable. The bacillus also occurs in association with myocardial lesions. Lesions in the intestine are characterised by mucosal necrosis with inflammatory cell infiltration, increased mucus production, submucosal lymphoid hyperplasia, and submucosal hemorrhage. Necrosis of lymphoid follicles, congestion, and hemorrhage can be present in the spleen and mesenteric lymph nodes.[196] Affected foals may have a profound metabolic acidosis that is unresponsive to treatment. The clinical course is short, and most affected foals die within a few hours of developing neurologic signs.

Primary liver disease has been reported in association with ferrous sulfate administration in a probiotic compound.[199] The lesion was massive hepatocellular necrosis and liver failure. The product is no longer commercially available. Portosystemic shunt is rare in the foal but has been reported in foals as young as 3 months of age.[200–202] 1401

1402

19.6.2 INFECTIOUS CAUSES

Most infectious causes of neurologic abnormalities in foals are associated with sepsis. Although rarely reported, *Halicephalobus gingivalis (deletrix)* infection has been reported in three foals; in one case the foal was 3 weeks of age.[203,204] Possibly transmission in these cases was transmammary; the dam in one case died 1 year later with confirmed *H. deletrix* infestation of her udder. *Listeria monocytogenes* has been reported as a cause of neurologic disease in foals.[205] Recently, *Sarcocystis neurona* was identified as the causative agent of central nervous system disease in a foal, and equine herpes myeloencephalitis has been diagnosed in individual foals and in herd outbreaks involving foals.[206,207] *Neospora* also was reported in one foal recently.[208] *Rhodococcus*

equi abscesses can form in the central nervous system or cause neurologic signs associated with compression, as with vertebral body abscesses.[209–211]

19.6.3 OTHER DISEASES

Cerebellar hypolasia, occipitoatlantoaxial malformation, and agenesis of the corpus callosum with cerebellar vermian hypoplasia have been reported in foals.[212–217] Ivermectin toxicity and moxidectin toxicity have been reported.[218,219] Electrolyte abnormalities such as extreme hypo- or hypernatremia may result in neurologic manifestations of disease.[220,221] Cervical stenotic myelopathy and degenerative myelopathy also have been reported in foals, although the age at onset is usually more than 4 months.[222] Idiopathic epilepsy of Arabian foals usually is associated with another infectious disease and is thought to be temporary and self-limiting.

19.7 Immunologic Diseases Of Foals

19.7.1 FAILURE OF PASSIVE TRANSFER

Causes, diagnosis, and treatment of FPT of immunity are covered in detail elsewhere in this text. Failure of passive transfer occurs when a foal fails to ingest a significant quantity of good-quality colostrum. Failure of passive transfer may occur by several mechanisms: failure of the foal to suck from the dam for any reason and failure of the dam to produce sufficient quantity of quality colostrum. Box 19-4 presents causes of FPT. Several methods are available for measuring IgG concentration in blood; the most reliable are enzyme-linked immunosorbent assay and single radial immunodiffusion technology-based tests.[223–229] Foals usually are tested at 24 hours of age, but one may test the foal earlier if colostrum ingestion has occurred and a concern exists regarding the passive transfer of immunity status of the foal, recognizing that additional increases in IgG concentration may occur with additional time.[230,231] The concentration of IgG in the blood of the foal has been used as an indicator of the adequacy of passive transfer, but the actual blood concentration at which FPT is diagnosed has been challenged in recent years.[232–234] Foals with sepsis commonly have a serum IgG concentration of less than 800 mg/dl.[16,19] Foals with FPT are more likely to die from sepsis.[177,178,235–237] One should consider the IgG concentration only as a marker for adequacy of colostral absorption. All the measured IgG is unlikely to be directed against the specific pathogen affecting any particular neonate, and IgG is not the only immune protection afforded the foal by colostrum. Many factors that confer local and more general immunity to the newborn are present in colostrum; these include growth factors, cytokines, lactoferrins, CD14, leukocytes, and other yet to be described proteins.[240–244] By considering IgG a marker of adequacy for passive transfer, similar to γ-glutamyltransferase in calves, the clinician can make choices for replacement that are more beneficial to the patient.[245] After one identifies FPT in a foal, treatment depends on the current condition of the foal and its local environment. Foals not presently ill and on well-managed farms with low population density and low prevalence of disease may not require treatment if their IgG concentration is between 400 and 800 mg/dl. Critically ill neonates with FPT in an equine NICU are by definition ill and in an environment with high 1402
disease prevalence. These patients require immediate treatment of FPT and frequent reassessment of their 1403
passive immunity status. Critically ill foals often fail to demonstrate the expected increase in blood IgG concentration based on grams of IgG administered per kilogram of body mass compared with healthy, colostrum-deprived foals.[235,246,247] Sick foals also demonstrate a more rapid decline in IgG concentration than do healthy foals because they use and catabolize available protein.

19.7.1.1 BOX 19-4 CAUSES OF FAILURE OF PASSIVE TRANSFER

19.7.1.1.1 Maternal Causes

Premature lactation

- Placentitis
- Twins
- Premature placental separation

Poor colostral quality

- Maiden mares
- Older mares

Failure of lactation

- Aglactia
- Fescue toxicosis

19.7.1.1.2 Foal Causes

Failure to ingest colostrum

- Weakness
- Prematurity
- Musculoskeletal deformity
- Perinatal asphyxia syndrome

Failure to absorb colostrum

- Prematurity

Necrotizing enterocolitis

One may treat foals with FPT by oral or intravenous administration of various products containing IgG. One can attempt oral administration of additional colostrum or IgG-containing products such as plasma, serum, or lyophilized colostrum in foals less than 12 to 24 hours of age.[248–250] Depending on the age of the foal and the maturity and function of the gastrointestinal tract, this treatment may be effective. Many NICUs and large breeding farms maintain colostrum banks for this purpose. One should administer plasma intravenously if the foal is not expected to absorb additional colostrum or if the enteral route is unavailable. Commercially available hyperimmune plasma products designed for use in foals are available and can be stored frozen. Plasma and banked colostrum should be stored in a non–frost-free freezer to minimize protein loss associated with freeze-thaw cycling.[251] One should administer plasma through special tubing with an in-line filter and should monitor patients closely for transfusion reactions.[252] One may use serum and concentrated IgG products, but the practitioner should be aware that many of these products focus on IgG retention and not on other factors associated with passive transfer of immunity. One should measure IgG concentration after transfusion and provide additional plasma as necessary. Administration of plasma to critically ill foals without FPT may be beneficial through provision of other factors present in the plasma. In these situations, fresh frozen plasma or fresh plasma may be best, particularly if transfusion of clotting proteins is desired.

19.7.2 NEONATAL ISOERYTHROLYSIS

Neonatal isoerythrolysis is a hemolytic syndrome in newborn foals caused by a blood group incompatibility between the foal and dam and is mediated by maternal antibodies against foal erythrocytes (alloantibodies) absorbed from the colostrum. The disease most often affects foals born to multiparous mares and should be suspected in foals less than 7 days of age with clinical signs of icterus, weakness, and tachycardia. A primiparous mare can produce a foal with neonatal isoerythrolysis if she has received a prior sensitizing blood transfusion or has developed placental abnormalities in early gestation that allowed leakage of fetal red blood cells into her circulation. Many are the causes of jaundice in newborn foals, including sepsis, meconium impaction, and liver failure, but these usually can be differentiated readily from neonatal isoerythrolysis by measuring the packed cell volume, which is usually less than 20% in foals with neonatal isoerythrolysis.

Foals with neonatal isoerythrolysis are born clinically normal then become depressed and weak and have a reduced suckle response within 12 to 72 hours of birth. The rapidity of onset and severity of disease are determined by the quantity and activity of absorbed alloantibodies. Affected foals have tachycardia, tachypnea, and dyspnea. The oral mucosa is initially pale and then becomes icteric in foals that survive 24 to 48 hours. Hemoglobinuria may occur. Seizures caused by cerebral hypoxia are a preterminal event.

The salient laboratory findings are anemia and hyperbilirubinemia. Most of the increased bilirubin is unconjugated, although the absolute concentration of conjugated bilirubin generally is increased well above normal. Urine may be red to brown and is positive for occult blood.

19.7.2.1 Cause and Pathogenesis

The natural development of neonatal isoerythrolysis has several prerequisites. First, the foal must inherit from the sire and express an erythrocyte antigen (alloantigen) that is not possessed by the mare. Blood group incompatibility between the foal and dam is not particularly uncommon, but most blood group factors are not

strongly antigenic under the conditions of exposure through previous parturition or placental leakage. Factor Aa of the A system and factor Qa of the Q system are highly immunogenic, however, and nearly all cases of neonatal isoerythrolysis are caused by antibodies to these alloantigens. The exception is in the case of mule foals in which a specific donkey factor has been implicated.[253–255] Mares that are negative for Aa or Qa or both are considered to be at risk for producing a foal with neonatal isoerythrolysis. The risk involves approximately 19% and 17% of Thoroughbred and Standardbred mares, respectively. Second, and perhaps most important, the mare must become sensitized to the incompatible alloantigen and produce antibodies to it. The mechanism for this is not known in many instances but generally is believed to result from transplacental hemorrhage during a previous pregnancy involving a foal with the same incompatible blood factor.[255]

Sensitization via transplacental contamination with fetal erythrocytes earlier in the current pregnancy is possible, but an anamnestic response is generally necessary to induce a pathogenic quantity of alloantibodies.[256] Ten percent of Thoroughbred mares and 20% of Standardbred mares have antibodies to the Ca blood 1403
group antigen without known exposure to erythrocytes.[255] Some common environmental antigen is 1404
postulated possibly to lead to production of anti-Ca antibodies. Data suggest that these natural antibodies may suppress an immune response to other blood group antigens because mares negative for Aa that have anti-Ca antibodies often do not produce antibodies to Aa of the erythrocytes in their foals that also contain Ca antigen. This antibody-mediated immunosuppression is thought to result from the destruction of fetal cells before the dam mounts an immune response to other cell surface antigens. Natural alloantibodies have not been associated with neonatal isoerythrolysis in horses.

After the mare becomes sensitized to the erythrocytes of her foal, alloantibodies are concentrated in the colostrum during the last month of gestation. Unlike the human neonate, which acquires alloantibodies in utero and thus is born with hemolytic disease, the foal is protected from these antibodies before birth by the complex epitheliochorial placentation of the mare. Thus the final criterion for foal development of neonatal isoerythrolysis is ingestion in the first 24 hours of life of colostrum-containing alloantibodies specific for foal alloantigens. Immunoglobulin-coated foal erythrocytes are removed prematurely from circulation by the mononuclear phagocyte system or are lysed intravascularly via complement. The rapidity of development and severity of clinical signs are determined by the amount of alloantibodies that was absorbed and their innate activity. Alloantibodies against Aa are potent hemolysins and generally are associated with a more severe clinical syndrome than antibodies against Qa or other alloantigens. The highest alloantibody titers are likely to be produced by mares that were sensitized in a previous pregnancy and then subsequently reexposed to the same erythrocyte antigen during the last trimester of the current pregnancy. Prior sensitization of a mare by blood transfusion or other exposure to equine blood products may predispose to neonatal isoerythrolysis.[256]

19.7.2.2 Diagnosis

One can make a tentative diagnosis of neonatal isoerythrolysis in any foal that has lethargy, anemia, and icterus during the first 4 days of life. Blood loss anemia caused by birth trauma is attended by pallor. Icterus caused by sepsis or liver dysfunction would not be associated with anemia. One must base the definitive diagnosis of neonatal isoerythrolysis on demonstration of alloantibodies in the serum or colostrum of the dam that are directed against foal erythrocytes. The most reliable serodiagnostic test for neonatal isoerythrolysis is the hemolytic cross-match using washed foal erythrocytes, mare serum, and an exogenous source of absorbed complement (usually from rabbits).[5] Although this test is impractical in a practice setting, a number of qualified laboratories routinely perform this diagnostic service. The direct antiglobulin test (Coombs' test)

may demonstrate the presence of antibodies on foal erythrocytes; however, false negatives occur frequently. Most human or veterinary hematology laboratories can perform routine saline agglutination cross-match between mare serum and foal cells. Because some equine alloantibodies act only as hemolysins, agglutination tests may be falsely negative. Most field screening tests of colostrum have not proved to be reliable enough for practical use.

19.7.2.3 Treatment

If one recognizes neonatal isoerythrolysis when the foal is less than 24 hours old, one must withhold the dam's milk and feed the foal an alternative source of milk during the first day of life. One can accomplish this by muzzling the foal and feeding it via nasogastric tube. The minimum necessary amount of milk is 1% of body mass every 2 hours (e.g., a 50-kg foal should receive 500 ml or 1 pint of mare's milk or milk replacer every 2 hours). The udder of the mare should be stripped regularly (at least every 4 hours) and the milk discarded. In most instances, clinical signs are not apparent until after the foal is 24 hours old, when colostral antibodies have been depleted or the absorptive capacity of the foal's intestine for immunoglobulin has diminished. Withholding milk at this point is of minimal benefit.

Supportive care to ensure adequate warmth and hydration is paramount. The foal should not be stressed and exercise must be restricted. Confining the mare and foal to a box stall is a best. Intravenous fluids are indicated to promote and minimize the nephrotoxic effects of hemoglobin and to correct any fluid deficits and electrolyte and acid-base imbalances. Antimicrobials may be necessary to prevent secondary infections.

One should monitor foals carefully for the necessity of blood transfusion, although transfusion should be used only as a lifesaving measure. When the packed cell volume drops below 12%, blood transfusion is warranted to prevent life-threatening cerebral hypoxia. Erythrocytes from the dam are perfect in terms of nonreactivity with the blood of the foal; however, the fluid portion of the blood of the mare has to be removed completely from the cells to prevent administration of additional harmful alloantibodies to the foal. One can pellet the erythrocytes of the dam from blood collected in acid-citrate-dextrose solution by centrifugation or gravity and then aseptically draw off the plasma by suction apparatus or syringe and replace it with sterile isotonic (0.9%) saline. One thoroughly mixes the cells with the saline and then repeats the centrifugation or sedimentation, followed by aspiration and discarding of the saline. One should perform this washing process at least three times. One then can suspend the packed erythrocytes in an equal volume of 1404

1405 isotonic saline for administration. Erythrocyte washing by centrifugation is more desirable than gravity sedimentation because antibody removal is more complete and packed cell preparations can be prepared more quickly (each gravity sedimentation requires 1 to 2 hours). Packed red blood cells are advantageous in overcoming the problem of volume overload.

When equipment or conditions do not allow the safe use of dam erythrocytes, an alternative donor is necessary. Because the alloantibodies absorbed by the foal generally are directed against Aa or Qa and because the latter are highly prevalent among most breeds of horses, a compatible blood donor is difficult to identify. The odds of finding a donor without Aa or Qa are higher in Quarter Horses, Morgans, and Standardbreds than in Thoroughbreds and Arabians. Previously blood-typed individuals negative for Aa and Qa and free of alloantibodies are optimal. One should give 2 to 4 L of blood or 1 to 2 L of packed erythrocytes over 2 to 4 hours. These allogeneic cells have a short life span and represent a large burden to the neonatal mononuclear phagocyte system, which may cause increased susceptibility to infection. In addition, these cells sensitize the foal to future transfusion reactions. One must measure all potential harm against the benefit in each situation.

If a mule foal is the patient, one should not use blood from a female previously bred to a donkey. In cases in which transfusion will be delayed, one cannot identify a compatible donor, or the packed cell volume is so low as to be life-threatening (hemoglobin <5 mg/dl), one may administer polymerized bovine hemoglobin products at a dose of 5 to 15 ml/kg.[257] One may use dexamethasone (0.08 mg/kg) to treat peracute neonatal isoerythrolysis if the packed cell volume is less than 12% and transfusion may be delayed or is not fully compatible, but dexamethasone has detrimental effects on blood glucose regulation in the neonate, and because the antibody in question is of maternal origin, corticosteroid therapy in immunosuppressive doses probably is not indicated. Intranasal oxygen insufflation (5 to 10 L/min) may be beneficial. Most foals with neonatal isoerythrolysis have adequate passive transfer of immunity, but antimicrobial therapy is indicated to protect against secondary sepsis resulting from the compromised condition of the foal. Supportive care and good nursing care, including keeping the foal warm and quiet are essential. One should expect the packed cell volume to decline again 4 to 7 days after transfusion.[258]

19.7.2.4 Client Education

The prognosis for neonatal isoerythrolysis in foals depends on the quantity and activity of absorbed antibodies and is indirectly proportional to the rate of onset of signs. In peracute cases the foal may die before the problem is recognized, whereas foals with slowly progressive signs often live with appropriate supportive care.

Like most diseases, neonatal isoerythrolysis is much more effectively prevented than treated.[259] Any mare that has produced a foal with neonatal isoerythrolysis should be suspect for the production of another affected foal; thus one should provide all subsequent foals with an alternative colostrum source and discard the colostrum of the dam unless she is bred to a stallion with known blood type compatibility. Mares negative for Aa and Qa alloantigens are most at risk of producing affected foals, thus they should be identified by blood-typing. Subsequently, breeding of these mares may be restricted to Aa- and Qa-negative stallions, thus eliminating the possibility of producing an affected foal. In breeds with a high prevalence of Aa or Qa alloantigens (e.g., Thoroughbreds and Arabians), a stallion negative for these and suitable based on other criteria may be difficult to identify. If these “at risk” mares are bred as desired, their serum should be screened in the last month of pregnancy for the presence of erythrocyte alloantibodies. One must test mares with low or equivocal titers closer to the time of parturition. If one detects alloantibodies, the colostrum of the dam should be withheld and the foal then should be provided with an alternative colostrum source. Maternal alloantibodies to Ca do not appear to mediate neonatal isoerythrolysis in foals and actually may be preventive by removing potentially sensitizing cells from the circulation[56]; therefore one should not deprive foals of colostrum from mares possessing anti-Ca antibodies, even when Ca is present on their erythrocytes. Rarely, the antigens De, Ua, Pa, and Ab have been associated with neonatal isoerythrolysis in foals; however, to consider mares without these alloantigens to be at risk for neonatal isoerythrolysis is not practical.

19.7.3 IMMUNE-MEDIATED THROMBOCYTOPENIA AND NEUTROPENIA

These syndromes recently have been recognized and described within the veterinary literature, although they have been recognized widely in human neonatology for many years.[260–263] Affected foals demonstrate these hematologic abnormalities within the first week of life, and the mechanism is similar to neonatal isoerythrolysis following ingestion of maternal antibody directed against the platelet or the neutrophil. In general, affected foals are healthy but may demonstrate bleeding tendencies if thrombocytopenia is severe or they may be more susceptible to sepsis. One confirms the diagnosis by appropriate testing for platelet- and neutrophil-associated

antibody.[264] One must rule out other causes of neonatal thrombocytopenia and neutropenia, particularly sepsis. Foals born to the mare in the future seem likely to be at risk for developing similar problems, and one should 1405

1406 treat future foals as one treats neonatal isoerythrolysis foals: prevent sucking from the dam and provide an alternate source of passive immunity in the form of banked colostrum or intravenous plasma. One should provide an alternative nutritional source, such as foal milk replacer, to the foal for the first 48 hours of life and should muzzle the foal while it is in the company of its dam for that period of time. Treatment is primarily supportive, but in the case of severe thrombocytopenia, transfusion of platelet-enriched fresh plasma may be indicated. Granulocyte colony-stimulating factor has been used in foals with neutropenia, but substantial efficacy has yet to be demonstrated. Broad-spectrum antimicrobial therapy may be prudent in cases of alloantibody-associated neutropenia. Treatment with immunosuppressive doses of corticosteroids is probably unwarranted, given the increased risk of infection, because the antibody in question is of maternal origin.

Other specific diseases of the immune system of foals, severe combined immunodeficiency, selective IgM deficiency, transient hypogammaglobulinemia, agammaglobulinemia, and other unclassified immunodeficincies are covered in detail elsewhere in this text.

19.8 Diseases Of The Respiratory Tract

19.8.1 RESPIRATORY DISTRESS

The neonate can experience respiratory distress immediately after birth because of several congenital respiratory tract or cardiac anomalies. Chief among these causes are bilateral choanal atresia, stenotic nares, dorsal displacement of the soft palate caused by anatomic deformity or neurologic impairment, accessory or ectopic lung lobes, lung lobe hypertrophy, lung lobe dysplasia, cardiac anomalies with right-to-left shunting, and miscellaneous causes such as subepiglotic cysts and severe edema of the larynx.[264–271] One must evaluate and treat these situations immediately and should consider them true emergencies.

One readily can recognize foals with airway occlusion by the lack of airflow through the nostrils despite obvious attempts to breathe and by respiratory stridor. These foals may demonstrate open-mouth breathing and their cheeks may puff outward when they exhale. One foal with congenital bilateral choanal atresia was recognized during extrauterine intrapartum resusucitation because of an inability to pass a nasotrancheal tube. One can establish an effective airway by orotracheal intubation in these cases under most circumstances, but some foals require an emergency tracheostomy. One diagnoses the underlying problem by endoscopy or radiography in most cases. Treatment of choanal atresia and cystic structures is surgical, whereas severe laryngeal edema and laryngeal paralysis frequently respond to medical management. Until the underlying problem is resolved in these cases, one should administer broad-spectrum antimicrobial therapy and feed the foal by intubation or total parenteral nutrition. One can give colostrum, but these foals frequently develop aspiration pneumonia if allowed to suck from their dams, so intravenously administered plasma also may be necessary to provide sufficient passive immunity.

19.8.2 RESPIRATORY DISEASES ASSOCIATED WITH HYPOXEMIA IN THE NEONATE

Arterial blood gas determinations are the most sensitive indicator of respiratory function readily available to the clinician. The most readily available arteries for sampling are the metatarsal arteries and the brachial arteries. Portable arterial/venous blood gas analyzers now are making arterial blood gas analysis more practical in the field, and the technique is no longer reserved for large referral practices. Managing a critically ill equine neonate without knowledge of arterial blood gas parameters is veritably impossible. Pulse oximetry is useful,

but these monitors only measure oxygen saturation of hemoglobin. Desaturation can occur rapidly in critically ill neonates. The utility of these monitors in the foal has yet to be demonstrated clearly, particularly in cases of poor peripheral perfusion.[272] The most common abnormalities recognized with arterial blood gas analysis are hypoxemia with normo- or hypocapnia and hypoxemia with hypercapnia. *Hypoxemia* is defined as decreased oxygen tension of the arterial blood (decrease PaO_2), and *hypoxia* is defined as decreased oxygen concentration at the level of the tissue, with or without hypoxemia. Hypoxia results from hypoxemia, decreased perfusion of the tissue bed in question, or decreased oxygen-carrying capacity of the blood resulting from anemia or hemoglobin alteration.

Five primary means by which hypoxemia may develop are (1) low concentration of oxygen in the inspired air such as in high altitude or in an error mixing ventilator gas; (2) hypoventilation; (3) ventilation/perfusion mismatch; (4) diffusion limitation; and (5) intrapulmonary or intracardiac right-to-left shunting of blood. Hypoxemia is not an uncommon finding in neonates but must be evaluated in terms of the current age of the foal and its position.[15,273–276] One also must consider the difficulty encountered in obtaining the sample because severe struggling can affect the arterial blood gas results. Table 19-8 presents normal arterial blood gas parameters for varying ages of foals. The normal foal has a small shunt fraction (~10%) that persists for the first few days of life and contributes slightly to a blunted response to breathing 100% oxygen compared with the adult. Hypoxemia frequently occurs in foals with prematurity, PAS, and sepsis, although other conditions 1406
also result in hypoxemia in the neonate. In the early stage of sepsis associated hypoxemia, $PaCO_2$ may be within 1407
normal limits or decreased if the foal is hyperventilating for any reason. If the lung is involved significantly in the underlying pathologic condition, such as with severe pneumonia, acute lung injury, or acute respiratory distress syndrome, increased $PaCO_2$ may well be present, representing respiratory failure.[277]

TABLE 19-8 Normal Arterial Blood Gas Values for Foals[*]

GESTATIONAL AGE	POSTNATAL AGE	POSITION	pH	$PaCO_2$ (mm Hg)	PaO_2 (mm Hg)
Term[†]	2 minutes	Lateral	7.31 ± 0.02	54.1 ± 2.0	56.4 ± 2.3
	15 minutes		7.32 ± 0.03	50.4 ± 2.7	57.5 ± 3.6

Hypoxemia usually is treated with intranasal humidified oxygen insufflation at 4 to 10 L/min. Hypercapnia is not a simple matter to treat. One must try to distinguish between acute and chronic hypercapnia. Acute hypercapnia usually is accompanied by a dramatic decrease in blood pH of 0.008 pH units for each 1 mm Hg increase in $PaCO_2$. This acidemia can promote circulatory collapse, particularly in the concurrently hypoxemic and/or hypovolemic patient. The effects of more chronic CO_2 retention are less obvious because the time course allows for adaptation. The pH change is less, about 0.003 pH units per 1 mm Hg increase in $PaCO_2$, because it is balanced by enhanced renal absorption of bicarbonate by the proximal renal tubule. Most foals with acute respiratory distress are in the acute stages of respiratory failure, but chronic adaptation begins to occur within 6 to 12 hours and is maximal in 3 to 5 days. One will note an increase in bicarbonate, particularly if the acidemia is primarily respiratory in origin. Intravenous administration of sodium bicarbonate to correct respiratory acidosis/acidemia should be done cautiously in these foals because CO_2 retention may only be increased. Also, one should remember that 1 mEq of sodium is administered with each mEq of bicarbonate and hypernatremia has been seen in foals treated exuberantly with sodium bicarbonate. Foals with hypercapnia of several days' duration also may develop a blunted respiratory drive to increased CO_2. In these foals, oxygen administration, although essential to treat hypoxemia, may further depress ventilation and further decrease pH. This effect is caused by a loss of hypoxic drive following oxygen therapy. One should consider these foals candidates for mechanical ventilation if the $PaCO_2$ is greater than 70 mm Hg or is contributing to the poor condition of the foal, such as causing significant pH changes. If hypercapnia is caused by central depression of ventilation, as frequently occurs in foals with PAS, one can administer caffeine (10 mg/kg loading dose; then 2.5 mg/kg as needed) per rectum or orally in foals with normal gastrointestinal function. Other clinicians may recommend continuous rate infusions of doxapram hydrochoride (Dopram; 400 mg/total dose at 0.05 mg/kg/min) for these foals. If this therapy fails, one should consider mechanical ventilation. Mechanical ventilation of foals with central respiratory depression is rewarding and may be necessary only for a few hours to days. A special category is the foal with botulism exhibiting respiratory failure caused by respiratory muscle paralysis. These foals do well with mechanical ventilation, although the duration of mechanical ventilation is more prolonged, frequently more than 1 week. Foals with primary metabolic alkalosis usually have compensatory respiratory acidosis. Treatment of hypercapnia is not necessary in these cases because it is in response to the metabolic condition. These foals do not respond to caffeine, and they should not be ventilated mechanically if this is the only disorder present.

19.8.2.1 Bacterial Pneumonia

In the neonate, bacterial pneumonia usually results from sepsis or aspiration during sucking. Foals with sepsis can develop acute lung injury or acute respiratory distress syndrome as part of the systemic response 1407
to sepsis, and this is frequently a contributor to the demise of foals in septic shock. The best way to diagnose 1408
bacterial pneumonia is by cytologic examination and culture of a transtracheal aspirate, but blood culture may aid in early identification of the causative organism and allow for early institution of directed antimicrobial therapy. A second frequent cause of bacterial pneumonia in the neonate is aspiration caused by a poor suck reflex or dysphagia associated with PAS, sepsis, or weakness. One must take care to ensure that aspiration is not iatrogenic in foals being bottle fed. Auscultation over the trachea while the foal is sucking helps identify occult aspiration. One should suspect occult aspiration pneumonia in any critically ill neonate that is being bottle fed or is sucking on its own that has unexplained fever, fails to gain weight, or has a persistently increased fibrinogen level.

Older foals develop bacterial pneumonia, frequently following an earlier viral infection.[278] Bacterial pneumonia is discussed in depth elsewhere in this text, but a few comments specific to the foal are necessary. One should auscultate and percuss the thorax of the foal, but results may not correlate closely with the severity of disease. The most commonly isolated bacterial organism in foal pneumonia is *Streptococcus zooepidemicus,* and one may isolate it alone or as a component of a mixed infection.[278–280] Transtracheal aspirate for culture and cytologic examination is recommended because mixed gram-positive and gram-negative infections are common, and antimicrobial susceptibility patterns can be unpredictable. One should split the obtained aspirate and submit samples for bacterial culture, virus isolation, and cytologic examination. Additional diagnostics include radiography, ultrasonography, and serial determination of white blood cell counts (with differential) and blood fibrinogen concentrations. Treatment includes administration of appropriate antimicrobial therapy. Some foals may benefit from nebulization with saline or other local products. Ascarid larval migration through the lung can mimic bacterial pneumonia.[281] In these cases the foal may not respond to antimicrobial therapy and should be dewormed with ivermectin. Deworming the mare within 1 month of parturition and frequent deworming of the foal prevent ascarid migration pneumonia in most foals.

A special category of bacterial pneumonia in foals is *Rhodococcus equi* bronchopneumonia. This pneumonia of young foals was described first in 1923.[282] The organism originally was known as *Corynebacterium equi* and is a gram-positive pleomorphic coccobacillus usually less than 1 μm in diameter and 2 μm in length. The organisms frequently are associated in L- and V-shaped clusters that have been termed *Chinese character formations. R. equi* has an acid-fast staining characteristic under some growing circumstances because of the presence of mycolic acid in its cell wall, similar to *Mycobacterium* and *Nocardia* species. Mycolic acid promotes granuloma formation. The organism is able to multiply in and destroy macrophages as it prevents phagosome lysosome fusion.[283,284] Much attention has been paid to this organism in recent years, given its propensity to produce enzootic and epizootic outbreaks of disease. The organism is thought to be primarily an opportunistic pathogen, and it lives in the soil of most geographic areas. Foals are affected most frequently between the ages of 1 and 6 months, when maternally derived immunity has begun to wane. The disease is insidious, and foals may have significant pulmonary involvement before developing noticeable clinical signs.

Phagocytosis of *R. equi* by equine macrophages is not associated with a functional respiratory burst and, at least in human beings, the L-arginine–NO pathway is not required for intracellular killing of this organism.[285,286] Optimal binding of *R. equi* to mouse macrophages in vitro requires complement and is mediated by Mac-1, a leukocyte complement receptor type 3 (CR3, CD11b/CD18).[287] Opsonisation of *R. equi* with specific antibody is associated with increased phagosome-lysosome fusion and enhanced killing of *R. equi,* suggesting that the mechanism of cellular entry is important.[283] Neutrophils from foals and adult horses are fully bactericidal, and killing of *R. equi* is enhanced considerably by specific opsonizing antibody.[288]

The ability of *R. equi* to induce disease in foals likely depends on host and microbial factors. Knowledge of the virulence mechanisms of *R. equi* was speculative until the discovery of the virulence plasmid.[289] As opposed to most environmental *R. equi* organisms, isolates from clinically affected foals typically contain 85- to 90-kb plasmids encoding an immunogenic virulence-associated protein (VapA) that is expressed on the bacterial surface in a temperature-regulated manner.[290] Plasmid-cured bacteria lose their ability to replicate and survive in macrophages and are cleared from the lungs within 2 weeks of intrabronchial challenge without producing pneumonia.[291] However, expression of VapA alone is not sufficient to restore the

virulence phenotype. Six other genes have approximately 40% overall amino acid identity with VapA, and the identification of multiple genes with considerable homology suggests these genes constitute a virulence-associated gene family in *R. equi*.[292] Other candidates for virulence factors include capsular polysaccharides and cholesterol oxidase, choline phosphohydrolase, and phospholipase C exoenzymes ("equi factors"), but their roles have not been defined clearly.

The primary manifestation of disease caused by *R. equi* infection is severe bronchopneumonia with granuloma, abscess formation, or both. Up to 50% of foals diagnosed with bronchopneumonia also have 1408
extrapulmonary sites of infection.[293] As the pneumonia progresses, clinical signs may include decreased 1409
appetite, lethargy, fever, tachypnea, and increased effort of breathing characterized by nostril flaring and increased abdominal effort. Cough and bilateral nasal discharge are inconsistent findings. A smaller percentage of affected foals may have a more devastating, subacute form. These foals may be found dead or have acute respiratory distress with a high fever and no previous history of clinical respiratory disease.

Hyperfibrinogenemia is the most consistent laboratory abnormality in foals with *R. equi* pneumonia. Neutrophilic leukocytosis (>12,000 cells/μl), with or without monocytosis, is common.[294] Thoracic radiography is a useful diagnostic aid, frequently revealing a prominent alveolar pattern with poorly defined regional consolidation and/or abscessation. Ultrasonography is a helpful diagnostic tool when the disease involves peripheral lung tissue. Although a number of serologic tests have been described, serologic diagnosis of *R. equi* infections is controversial and difficult because exposure of foals to this organism at a young age leads to production of antibody without necessarily producing clinical disease.[295,296] Serologic tests may be more useful at the farm level to detect overall exposure than at the individual level. Bacteriologic culture combined with cytologic examination of a tracheobronchial aspirate remains the most definitive method for accurate diagnosis of *R. equi* pneumonia. However, foals without clinical disease exposed to contaminated environments may have *R. equi* in their tracheae from inhalation of contaminated dust; therefore one should interpret culture results in the context of the overall case presentation.[297] Culture results in one study were as sensitive as polymerase chain reaction–based assays and offered the advantage of allowing in vitro antimicrobial susceptibility testing.[298] However, polymerase chain reaction is likely to be a useful tool, and results from a second trial suggest the assay is more sensitive and specific than culture of tracheobronchial aspirates for diagnosis.[299]

The combination of erythromycin and rifampin has become the treatment of choice for *R. equi* infections in foals, and the combination reduces the likelihood of resistance to either drug. The recommended dosage regimen for rifampin is 5 mg/kg every 12 hours or 10 mg/kg every 24 hours orally. The recommended dose of estolate or ethylsuccinate esters of erythromycin is 25 mg/kg every 8 or 12 hours orally.[300] Recently, azithromycin has been recommended for treatment of *R. equi* infection at a dosage of 10 mg/kg orally every 24 hours for 5 to 7 days and then every other day.[301] Alternatively, clarithromycin at 7.5 mg/kg every 12 hours orally, in combination with rifampin, may be therapeutically effective. Severely affected foals may require intranasal oxygen insufflation, intravenous fluid support, and nutritional support. Treatment generally continues for 4 to 10 weeks until all clinical and laboratory evidence of infection is resolved. Although well tolerated by most foals, erythromycin can result in soft feces. This diarrhea is generally self-limiting and does not require cessation of therapy, but one should monitor affected foals carefully. An idiosyncratic reaction characterized by severe hyperthermia and tachypnea has been described in foals treated with erythromycin during periods of hot weather.[302] Affected foals should be moved to a colder environment and treated with antipyretic drugs and alcohol baths if necessary. *Clostridium difficile* enterocolitis has been reported in the

dams of nursing foals treated with erythromycin given orally.[303] The dam is exposed to active erythromycin by coprophagy or by drinking from a communal water source where the foal has "rinsed" its mouth.

Prevention of *R. equi* pneumonia on farms with recurrent problems is problematic. The most clearly demonstrated prophylactic measure to date has been the administration of plasma that is hyperimmune to *R. equi* to foals within the first week of life and then again when maternal immunity begins to wane at around 30 days of age.[304–311] No effective vaccination protocols for the dam or foal have been described to date. Farm management is important in preventing disease, and control measures include frequent manure removal, avoidance of overcrowded conditions, and planting of dusty or sandy soils.[304]

The prognosis for *R. equi* bronchopneumonia is fair to good in foals with the more chronic form of the disease. Foals with acute respiratory distress have a more guarded prognosis, as do foals with sites of significant extrapulmonary infection. The long-term prognosis for survival for foals with *R. equi* bronchopneumonia is good, and many foals perform as expected as athletes.[312]

19.8.2.2 Viral Pneumonia

The most commonly identified causes of viral pneumonia in foals are equine herpesviruses 1 and 4 (EHV-1 and EHV-4), equine influenza, and equine arteritis virus (EVA). Equine herpesvirus 1 is probably the most clinically important, but outbreaks of EVA in neonates have occurred and are devastating.[27,313–318] Adenovirus is reported sporadically and as a problem in Arabian foals with severe combined immunodeficiency.[319–321]

In the neonate, infection with EHV-1 or EVA is almost uniformly fatal and antemortem diagnosis is difficult, even once an outbreak on a particular farm is identified. Several factors appear common to foals with EHV-1, including icterus, leukopenia, neutropenia, and petechial hemorrhage, but these problems also are identified in foals with severe sepsis.[315,322,323] The antiviral drug acyclovir (10 to 16 mg/kg orally or per rectum 4 to 5 times per day) has been used in cases of EHV-1 in neonates, with some evidence of efficacy in mildly affected foals or foals affected after birth.[323] If viral pneumonia is a possibility, one should collect 1409
blood and tracheal aspirates at presentation for bacterial and virus isolation. The lungs of foals with EHV-1 1410
or EVA are noncompliant, and pulmonary edema may be present. Mechanical ventilation of these cases may prolong life, but death is generally inevitable because of the magnitude of damage to the lungs. Foals suspected of having EHV-1 or EVA should be isolated because they may be shedding large quantities of virus and pose a threat to other neonates and pregnant mares. Foals with EVA generally are born to seronegative mares, and intravenous treatment with plasma with a high titer against EVA may prove beneficial because passive immunity appears to have a large role in protection against this disease in neonates.[318,324]

Older foals and weanlings may be affected by herpesviruses. Disease is usually mild, although a fatal pulmonary vasculotropic form of the disease has been described recently in young horses.[325,326] The clinical signs of disease are indistinguishable from influenza and include a dry cough, fever, and serous to mucopurulent nasal discharge, particularly if secondary bacterial infection occurs. Rhinitis, pharyngitis, and tracheitis may be present. Treatment of affected foals is primarily supportive. Foals also may become infected with EHV-2. The predominant clinical signs are fever and lymphoid hyperplasia with pharyngitis.[327,328] Diagnosis is by virus isolation.

19.8.3 OTHER CAUSES OF RESPIRATORY SIGNS IN FOALS

Rib fractures have been recognized in 3% to 5% of all neonatal foals and can be associated with respiratory distress.[87] Potential complications of rib fractures include fatal myocardial puncture, hemothorax, and pneumothorax. Rib fractures frequently are found during physical examination by palpation of the ribs or by auscultation over the fracture sites. One can confirm the diagnosis by radiographic and ultrasonographic evaluation. Often multiple ribs are affected on one side of the chest. Specific treatment is generally unnecessary, but direct pressure on the thorax should be avoided in all cases. Some specific patients may benefit from surgical stabilization of some fractures, particularly those fractures overlying the heart.

Pneumothorax can occur spontaneously or following excessive positive pressure ventilation[329] or following tracheostomy surgery or trauma. Any foal being ventilated mechanically that suddenly has respiratory distress and hypoxemia should be evaluated for pneumothorax. Diagnosis is by auscultation and percussion of the thorax, but one can confirm the diagnosis with radiographic and ultrasonographic evaluation of the thorax. Needle aspiration of air from the pleural space also confirms the diagnosis. Treatment is required in cases in which clinical signs are moderate to severe or progressive and involves closed suction of the pleural space. Subcutaneous emphysema can complicate treatment of this problem.

Idiopathic or transient tachypnea has been observed in Clydesdale, Thoroughbred, and Arabian breed foals. In human infants, transient tachypnea can be related to delayed absorption of fluid from the lung, perhaps because of immature sodium channels.[330] In foals, tachypnea generally occurs when conditions are warm and humid and is thought to result from immature or dysfunctional thermoregulatory mechanisms. Clinical signs of increased respiratory rate and rectal temperature develop within a few days of birth and may persist for several weeks. Treatment involves moving the foal to a cooler environment, body clipping, and provision of cool water or alcohol baths. These foals frequently are treated with broad-spectrum antimicrobial drugs until infectious pneumonia can be ruled out.

A syndrome of bronchointerstitial pneumonia and acute respiratory distress has been described in older foals and appears to be a distinct entity from acute respiratory distress syndrome in neonatal foals in association with sepsis.[331] The underlying cause has not been identified, but the genesis is probably multifactorial with several potential pathogens being implicated. Affected foals have acute respiratory distress with significant tachypnea, dyspnea, nostril flare, and increased inspiratory and expiratory effort. Auscultation reveals a cacophony of abnormal sounds including crackles and polyphonic wheezes in all lung fields. Loud bronchial sounds are audible over central airways, and bronchovesicular sounds are lost peripherally. Affected foals are cyanotic, febrile, and unwilling to move or eat. Foals may be found acutely dead. Laboratory abnormalities include leukocytosis, hyperfibrinogenemia, and hypoxemia with hypercapneic acidosis. Foals can be dehydrated severely and have coagulation changes consistent with disseminated intravascular coagulation. Hypoxic injury to other organs, primarily the kidneys and liver, can occur. Chest radiographs reveal a prominent interstitial pattern overlying a bronchoalveolar pattern that is distributed diffusely throughout the lung. This syndrome is a respiratory emergency. Treatment is broad-based and includes administration of oxygen, nonsteroidal antiinflammatory agents, broad-spectrum antimicrobial therapy, nebulization, judicious intravenous fluid therapy, nutritional support, and corticosteroid therapy. One must manage hyperthermia in the foal. Corticosteroid therapy appears to have been lifesaving in most of the reported surviving foals. Because this syndrome is associated with high environmental temperatures in some areas, prevention involves control of ambient temperatures, not transporting foals during hot weather, and keeping foals out of direct sun on hot days, particularly foals being treated with erythromycin for suspected or confirmed *R. equi* infection.[332] 1410

19.9 Diseases Of The Urinary Tract

19.9.1 UROPERITONEUM

Uroperitoneum has been recognized as a syndrome in foals for more than 50 years.[333,334] Classically, affected foals are 24 to 36 hours old at the time clinical signs first are recognized.[334–336] Previous reports had a proportionately larger affected male than female population.[334,335,337] The hypothesis was that colts were more at risk because their long, narrow, high-resistance urethra was less likely to allow bladder emptying, resulting in rupture of a full bladder during parturition when high pressures were applied focally or circumferentially around the bladder.[333] More recent reports suggest that such extreme sex bias may have been an artifact of small case numbers in the early reports.

Rupture or disruption of any structure of the urinary tract can occur. The dorsal wall of the bladder has been reported to be a frequent disruption site, with the ventral wall less likely to be involved.[336] The urachus appears to be the next most commonly affected structure. A few cases of ureteral and urethral defects have been reported.[336,337] Sepsis does not appear to favor one site over the others.[338]

The pathophysiology of uroperitoneum is not yet understood fully. The high pressure exerted on a full bladder during parturition once was thought to be the main cause. Full bladder and obstruction caused by a partial umbilical cord at parturition, strenuous exercise, and external trauma have been reported as causes.[339] A few reports describe smooth and noninflamed edges of torn tissue, suggesting the possibility of congenital bladder wall defects.[338,340,341] Sepsis leading to urinary tract rupture and uroperitoneum may occur in foals hospitalized for a variety of unrelated problems. The onset of clinical signs of uroperitoneum may be insidious in these foals, and diagnosis may be less obvious.[338]

Clinical signs associated with uroperitoneum in the neonatal foal typically include straining to urinate, dribbling urine, and a stretched-out stance. Weakness, tachycardia, tachypnea, and not sucking well are also common. A distended abdomen may be evident, and one may feel a fluid wave on ballottement of the abdomen. Occasionally, urine accumulates in the scrotum and should not be confused with hernia. Foals also may show signs of sepsis, including fever, injected mucous membranes, diarrhea, and disease of other body systems.

Laboratory findings vary depending on the duration of the uroperitoneum and on the presence and severity of sepsis. Classic findings include hyperkalemia, hyponatremia, and hypochloremia arising from equilibration of urine electrolytes and water with blood across the peritoneal membrane.[335–337] The usual foal diet of milk, which is high in potassium and low in sodium, promotes the electrolyte abnormalities. Foals that develop uroperitoneum while receiving intravenous fluids may not have classic electrolyte imbalances at the time clinical signs are recognized.[338] Increased serum creatinine concentration is often present, whereas blood urea nitrogen concentrations occasionally, but not consistently, are increased.[335–337] Metabolic acidosis and hypoxemia may be present. Some patients also have serum hypoosmolality.[335] One should test foals for failure of passive transfer. One of the most sensitive laboratory tests for uroperitoneum is the ratio of peritoneal to serum creatinine. A ratio greater than or equal to 2:1 is considered diagnostic of uroperitoneum. One should collect peritoneal fluid and test it for creatinine concentration, as well as for cytologic findings, culture, and sensitivity. Cytologic evaluation of peritoneal fluid is necessary to identify concurrent peritonitis or other gastrointestinal compromise. One should perform an electrocardiogram on initial evaluation of a foal with

suspected uroperitoneum because hyperkalemia may result in bradycardia, increased duration of the QRS complex, a shortened Q-T interval, increased P-wave duration, prolonged P-R interval, or atrioventricular conduction disturbances. Other possible cardiac sequelae to hyperkalemia include cardiac arrest, third-degree atrioventricular block, ventricular premature contractions, and ventricular fibrillation.[337,340]

For any foal exhibiting signs of dypsnea, tachypnea, or hypoxemia, one should have thoracic radiographs taken *before* induction of anesthesia to rule out pleural effusion, pneumonia, or acute respiratory distress syndrome, which could complicate ventilation and oxygenation during anesthesia and the postoperative period. Ultrasonography has become the tool of choice in the diagnosis of uroperitoneum and is a useful tool available to the practitioner.[342] One can image free peritoneal fluid readily, and tears within the bladder are readily visible. The empty bladder with a significant defect, in a fluid-filled abdomen, will collapse on itself and often have a U shape. One also can visualize urachal and urethral lesions. Six of eight foals in one study had urinary tract lesions identified sonographically, and all 31 foals of another study underwent sonographic evaluation, and a significant correlation between ultrasonographic findings and location of the lesion at surgery existed.[336,338]

Initial treatment aims to stabilize the patient and correct any electrolyte and acid-base abnormalities and provide fluid volume replacement. One should use 0.9% or 0.45% saline with 5% dextrose until laboratory data are available. A potassium concentration of greater than 5.5 mEq/L can be life threatening. One can manage hyperkalemia by peritoneal drainage to decrease whole-body potassium stores using teat cannulae, Foley catheters, large-gauge (16 or 14) intravenous catheters, or human peritoneal dialysis catheters. Fluid 1411
replacement at least should equal the amount of fluid removed from the abdomen to prevent acute hypotension 1412
caused by expansion of previously collapsed capillary beds. Abdominal drainage also helps ventilation and decreases the work of breathing by decreasing pressure on the diaphragm. One may administer calcium gluconate, glucose, sodium bicarbonate, or insulin intravenously to decrease serum potassium concentrations. These maneuvers do not correct the whole-body potassium overload, however, and once therapy is discontinued, hyperkalemia can reappear until the urine is removed from the abdomen. One should correct hyponatremia slowly. Because of the real possibility of concurrent sepsis, one should obtain blood cultures *before* preoperative administration of antimicrobials. Broad-spectrum coverage (penicillin and amikacin or ceftiofur sodium) is recommended until culture results become available. One should perform therapeutic drug monitoring when using aminoglycoside therapy. However, the peak value may be depressed because of the increased volume of distribution represented by the volume of urine in the abdomen, so one should not make dose adjustment based on a low peak until obtaining a new peak after surgical correction of the uroperitoneum. One should treat foals with failure of passive transfer with adequate volumes of intravenously administered plasma.

After one has addressed the metabolic abnormalities, one may consider surgical management. Medical management using an indwelling Foley catheter has been described.[343] Preoperative medical stabilization reduces anesthetic risk. Safer inhalant agents such as isoflurane also have decreased risk. Removal of the internal umbilical remnant at the time of surgery is usual. One should consider culturing any removed umbilical remnant and submitting the remnant for histopathologic evaluation. Recurrence of urinary tract rupture can occur. Sepsis, hypoxemia, pneumonia, peritonitis, and acute respiratory distress syndrome complicate the management of uroperitoneum. Many affected foals are persistently oxygen dependent for several days following surgical correction, and one should perform serial arterial blood gas analyses before discontinuing intranasal oxygen supplementation.

Prognosis is associated closely with concurrent illness, especially septicemia. Uncomplicated uroperitoneum from a defect in the bladder has a good prognosis. If the location of the lesion is other than the bladder, the prognosis is not as favorable.[337] Foals with septicemia have a much poorer prognosis.[338,339]

19.9.2 ACUTE RENAL FAILURE

Acute renal failure most often occurs as a complication of prenatal asphyxial syndrome, sepsis, or aminoglycoside therapy. Acute renal failure also has been reported following oxytetracycline administration in foals.[344] The dose of oxytetracycline commonly used to treat flexural deformities in foals is approximately 10 times the antimicrobial dose. Many foals treated in this manner also have suffered some degree of perinatal asphxia, which also damages the kidney, because of prolonged parturition precipitated in part by the flexural deformity. Evaluation of renal function in these foals *before* the administration of the first dose of oxytetracycline and continued monitoring of serum creatinine concentrations before administering subsequent doses of this nephrotoxic compound would seem reasonable. Hemodialysis has been used as therapy in one of these cases, but prevention is important because these foals may fail to respond to usual therapy for oliguric renal failure and are euthanized.[344]

19.9.3 CONGENITAL RENAL DISEASE

The most commonly reported congenital deformity of the kidney of the foal is renal hypoplasia and dysplasia, which may have a heritable component.[345,346] Renal arteriovenous malformations have been reported also.[347] Ectopic ureters and fenestrated ureters have been described in the foal.[348–350] Congenital renal defects, among others, were reported in three weak, recumbent neonatal foals born to mares being treated for equine protozoal myeloencephalitis.[351] Mares received sulfadiazine or sulfamethoxazole-trimethoprim, pyrimethamine, folic acid, and vitamin E orally. The foals were anemic, leukopenic, azotemic, hyponatremic, and hyperkalemic. Serum folate concentrations were lower than those reported in the literature for clinically normal brood mares. Treatment was unsuccessful. Necropsy revealed lobulated kidneys with thin cortices and a pale medulla. The authors postulated that oral administration of sulfonamides, 2,4-diaminopyrimidines (pyrimethamine with or without trimethoprim), and folic acid to mares during pregnancy is related to congenital defects in newborn foals.

19.10 Umbilical Disorders

The umbilicus serves as the conduit for nutrition and gas exchange between the dam and the fetal foal. The urine from the foal is expelled via this structure into the allantoic cavity. The author has recognized cases of in utero bladder distention in the fetus that were associated with multiple twists decreasing urine flow or focal stenosis creating the same effect. Foals born with this condition did not have bladder rupture associated with parturition but did have other severe abnormalities that eventually resulted in their demise, primarily premature delivery with failure to adapt to extrauterine life (P.A. Wilkins, J.E. Palmer, and F.T. Bain, unpublished data). At birth the umbilicus breaks, leaving a small external remnant and a large internal remnant. The umbilicus long has been regarded as the primary site of entry of pathogens into the neonate, although this has been challenged recently. 1412

1413 Treatment of the umbilicus after birth involves dipping it (preferably just the most distal component) with various caustic compounds. The most current recommendation is to treat the umbilicus with dilute chlorhexidine, povidone-iodine, or dilute iodine solutions for just a few times following birth. Exuberant treatment of the umbilical stump with caustic solutions can lead to scalding of the ventral abdomen and may promote patency of

the urachus. The ultrasonographic appearance and measurements of the umbilical arteries, urachus, and umbilical vein of foals from 6 hours to 4 weeks of age have been described in detail.[342] A 7.5-MHz sector scanner transducer placed across the midline of the ventral portion of the abdominal wall of the foal works best because of the superficial location of these structures. The mean (± SD) diameter of the umbilical vein was 0.61 ± 0.20 cm immediately cranial to the umbilical stalk, 0.52 ± 0.19 cm midway between the umbilicus and liver, and 0.6 ± 0.19 cm at the liver. The urachus and umbilical arteries of normal foals have a mean total diameter of 1.75 ± 0.37 cm at the bladder apex. The umbilical arteries scanned along either side of the bladder have a mean diameter of 0.85 ± 0.21 cm. One can use these measurements and the ultrasonographic appearance of the internal umbilical structures from clinically normal foals as references to diagnose abnormalities of the umbilical structures in neonatal foals.[352,353] The most common abnormalities of these structures are focal abscess formation, hematoma, and urachal tear.

19.10.1 HERNIA

Herniae traditionally have been thought to develop from failure of closure at the umbilical stump after birth. However, the closure of the body wall defect at the umbilicus was studied in relation to the development of umbilical herniae in a large group of normal foals followed from birth until 5 months of age or from birth until 11 months of age.[354] At birth, approximately half of these foals had a defect in the body wall at the umbilicus that was termed a *palpable umbilical ring*. In 18 foals this defect disappeared within 4 days, but in one foal the ring did not close and a hernial sac with abdominal contents was palpable. This foal was considered to be the only foal to have a truly congenital umbilical hernia. Twelve foals developed an umbilical hernia between 5 and 8 weeks of age. The prevalence of umbilical herniae was much higher than in other studies, possibly because of the prospective nature of the study. Based on this study, the large majority of umbilical herniae would appear not to result from failure of closure but rather to be acquired after birth. One should consider the palpable ring structure within the body wall at the umbilicus a variant of normal in the foal and should not call it a hernia until the foal is at least 1 month of age.

In one study of 147 horses treated for umbilical herniae over a 13½-year period, only 8.8% developed complications in association with umbilical defects.[355] Six horses had intestinal incarceration; the incarceration was reduced manually in 3 horses before admission and resolved without treatment in 2 others. The hernia was surgically reduced in 1 horse. Herniorrhaphy was performed on 4 of the 5 horses in which the incarceration did not require surgical reduction, and the fifth was managed conservatively. The study confirmed that complications of umbilical herniae are rare in horses; however, when they do develop, they may be one of various forms, some of which are insidious in onset. The primary differential diagnosis for an external swelling in the umbilical stump region is an external abdominal abscess, which will be firm, variably painful, warm, and nonreducible. Ultrasonographic evaluation readily can confirm either possibility.

19.10.2 OTHER CONGENITAL ABNORMALITIES

One report describes a 3-day-old foal that died from intestinal strangulation caused by a remnant of vitelline vein that extended between the umbilicus and the portal vein.[356]

19.10.3 PATENT URACHUS

Patent urachus frequently is recognized in the abnormal neonate, probably because of the increased recumbency and decreased movement of these patients. Cauterization of a patent urachus is no longer recommended except

in cases that persist for long periods of time (>1 month) after the foal becomes more active. Surgical resection may provide relief in some foals, but most cases resolve without treatment if given enough time. Foals with a patent urachus may posture and strain frequently to urinate, some of this may be associated with irritation or local infection of the urachus. One can alleviate this by administration of broad-spectrum antimicrobial therapy such that the drug has a high concentration in the urine (e.g., trimethoprim-sulfa drug combinations) and by oral administration of phenazopyridine hydrochloride (Pyridium), a dye that anesthetizes the urinary tract epithelial surfaces (see Table 19-7). This dye turns the urine orange and stains everything yellow-orange that it or the urine touches but can provide a great deal of relief to foals with this problem.

19.10.4 UMBILICAL REMNANT INFECTION

The umbilicus has been considered the traditional point of entry of bacteria into the septic neonate, and septic foals have been referred to as having "navel ill" and "joint ill" in the past. Although current thought suggests that the gastrointestinal tract may be the route of entry in most septic neonates, infection of the umbilicus— 1413
1414
termed *omphalitis,* or *omphalophlebitis* if the vessels are involved—still occurs as a single focus of infection or along with more generalized infection. External signs, such as swelling, heat, pain, ventral edema, or purulent discharge may be present in some foals, but more usually external signs are minimal and one suspects infection because of infection in another site (e.g., an infected joint), fever, or otherwise unexplained increased blood fibrinogen concentration. One confirms the diagnosis by ultrasonographic evaluation of the internal umbilical remnant. Any of the umbilical structures may be involved. A complete description of the evaluation is available within the relevant veterinary literature, but the examination is performed best with the foal standing using a 7.5-MHz probe with a standoff.[353] The usual finding is that the affected structure is larger than expected. A fluid-filled core and echogeneic shadows consistent with gas may be apparent in some cases. Interpretation requires some experience, and the examiner should be familiar with variants of normal, such as gas shadows associated with a patent urachus and enlarged vessels caused by hematoma formation, so that treatment is not initiated inappropriately.

Two options for treatment are surgical and medical. Medical treatment is preferable in cases in which the lesion is well localized and small and in foals with a medical condition that is not amenable to anesthesia and surgical intervention. One should institute broad-spectrum antimicrobial therapy, and one may need to continue therapy for 2 to 3 weeks. Most affected foals respond to medical therapy. Frequent reevaluation of the abnormality is necessary, every 5 to 7 days initially, and one should measure blood fibrinogen concentrations at reevaluation because they should stabilize and decrease with effective treatment. Failure to respond to therapy within 10 days to 2 weeks suggests that an empiric change in the antimicrobial used may be necessary. In foals that are refractory to medical management or where the lesion is large, surgical excision of the entire umbilical remnant may be desirable.

19.11 Diseases of The Gastrointestinal Tract

19.11.1 COLIC IN THE NEONATE

Colic in the foal can be difficult to diagnose accurately because one cannot perform an examination per rectum. However, many diagnostic aids, most importantly ultrasonography, are available to help differentiate medical from surgical causes of abdominal discomfort in the foal.

19.11.2 OBSTRUCTION

Intestinal accidents of all types described in adult horses, with the possible exception of enteroliths, occur in foals. Intussusception, volvulus, displacement, diaphragmatic hernia, and intra- and extraluminal obstruction have been reported in foals. Abdominal ultrasonographic and radiographic evaluation greatly aids diagnosis. Treatment is primarily surgical. Foals with PAS and intestinal dysmotility are at increased risk of intussusception and displacement, and Miniature breed foals appear to be at increased risk for fecolith and enterolith formation.

19.11.3 MECONIUM RETENTION/IMPACTION

Meconium retention or impaction is a common cause of abdominal discomfort in newborn foals. Most foals defecate shortly after their first meal. The usual practice for most owners or veterinarians attending the birth of a foal is to administer an enema to aid this process. In the past, phosphate-based commercially available enemata (Fleet) were used frequently, but if used excessively these types of enemata can create problems of their own, including rectal irritation and hyperphosphatemia. The best enema is warm soapy water made with a mild soap such as liquid Ivory soap that can be administered through soft rubber tubing using gravity flow. Foals with significant meconium retention become colicky within the first few hours of life as gas accumulates within their bowel. Frequently, one can palpate the meconium through the abdominal wall. Additional diagnostics can include abdominal ultrasonography and radiography, particularly if one must rule out other, more serious types of colic. These foals assume a classic stance with an arched back. One must differentiate this stance from the stance assumed by foals with uroperitoneum, which is more extended. Foals with meconium retention have had simultaneous ruptured bladder, however, so the clinician must be sure to evaluate the foal fully for both problems. Foals that do not respond rapidly to enema administration need additional treatment, which can include giving mineral oil (2 to 4 ounces) by nasogastric tube. One can treat persistent meconium retention resulting in significant abdominal distention by muzzling the foal to prevent further milk intake and administering intravenous fluids at an appropriate maintenance rate. If continuous rate infusion is possible, 5% to 10% dextrose is the preferred fluid to use to provide calories to the foal. One should not use dextrose as a bolus fluid. More aggressive treatment would include administration of retention enemata made using acetylcysteine, which serves as an irritant and increases secretion. Extreme cases of meconium retention may require surgical intervention, but this is usually not necessary and most cases resolve with medical management alone within 12 to 24 hours. Some foals require pain managment. One should avoid nonsteroidal antiinflammatory drugs in the neonate because of their effects on renal function and gastric mucosal blood flow 1414
(see Gastric Ulcers). Many foals respond well to butorphanol administered intramuscularly at a dose of 3 to 5 1415
mg to an average 50-kg foal. Intranasal oxygen insufflation is beneficial in foals with significant abdominal distention.

One should evaluate foals with meconium impaction/retention for evidence of PAS because intestinal dysmotility is common in PAS. Colostrum is a laxative, and these foals also may suffer from failure of passive transfer, with meconium retention resulting from the lack of adequate colostrum. These foals are also at risk of sepsis because the mucosal intestinal barrier probably has been disrupted and translocation of bacteria can occur. One should obtain blood cultures on these foals and should monitor them closely for signs of sepsis.

19.11.4 CONGENITAL DEFECTS

Atresia within the gastrointestinal system of the foal occurs infrequently, but clinical signs are characteristic.[357] Acute colic occurs within the first few hours and is accompanied by abdominal distention similar to meconium retention. Three primary types of atresia are described in the foal: membrane atresia, cord atresia, and blind-end atresia. Antemortem diagnosis of atresia, short of abdominal exploratory surgery, is aided by the lack of meconium staining of the rectum or any administered enema fluids. Additional diagnostic tests may include administration of a barium enema for a radiographic study, colonoscopy, and abdominal ultrasonography. Abdominocentesis is usually normal until bowel rupture is imminent or has occurred. One can make affected foals more comfortable by muzzling them to prevent further milk intake and by supplying them with fluids and nutrition intravenously. If one attempts surgical correction, one first should initiate broad-spectrum antimicrobial therapy and determine passive transfer status. Frequently, these foals are hypoxemic because of the abdominal distention, and oxygen supplementation is desirable.

19.11.5 LETHAL WHITE SYNDROME

Solid white foals born to overo-overo matings of American Paint Horses may suffer from congential aganglionosis of the ileum, cecum, and colon. These foals present similarly to foals with meconium impaction or atresia in that colic develops shortly after birth and involves progressive abdominal distention with feeding. The inherited defect is in the endothelin receptor gene.[358–361] No effective treatment exists, but the clinician should be aware that not all white foals of this mating are affected, and some simply may have meconium retention, so a short period of treatment may be warranted.

19.11.6 NECROTIZING ENTEROCOLITIS

Necrotizing enterocolitis is considered the most common acquired gastrointestinal emergency of human infants.[362,363] The 1500 to 2000 infants that die every year from this disease in the United States and the large number of infants who develop short gut syndrome from this disease only represent the tip of the iceberg of the problems necrotizing enterocolitis causes. The widespread fear of necrotizing enterocolitis among neonatologists and pediatric surgeons has contributed in large part to the use of the intravenous route rather than the gastrointestinal tract for nourishing these infants for long periods. The pathogenesis of necrotizing enterocolitis is unknown but may result from a disturbance of the delicate balance among gastrointestinal perfusion, enteric organisms, and enteral feeding. Risk factors for necrotizing enterocolitis in human infants include prematurity, hypoxic-ischemic insult, and formula or breast milk feedings. The clinical spectrum of necrotizing enterocolitis is multifactoral and ranges from temperature instability, apnea, lethargy, abdominal distention, bilious residuals, septic shock, disseminated intravascular coagulation, and death. Medical management is usually adequate treatment for necrotizing enterocolitis. In the neonatal foal, necrotizing enterocolitis is probably one of the most underrecognized causes of gastrointestinal dysfunction and in the past has been attributed only to infection with anaerobic organisms including *Clostridium perfringens* type C and *C. difficile*.[364] Although a specific form of enteritis is associated with intestinal infection by these organisms, most necrotizing enterocolitis is associated with prematurity or PAS in the infant and the foal.

One should suspect necrotizing enterocolitis in any foal that is having difficulty tolerating oral feeding, demonstrating signs of ileus, or having episodes of colic and in any foal with occult blood or frank blood in the stool. Foals exhibiting any of these clinical signs should not be fed orally if possible and should receive

parenteral nutrition until gastrointestinal function returns to near normal. The mucosal barrier of the intestine is unlikely to be fully intact, and these foals are at risk for sepsis from bacterial translocation. One should institute broad-spectrum antimicrobial therapy in these foals and, if any evidence of coordinated gastrointestinal motility is apparent, should administer sucralfate orally as a protectant.

19.11.7 GASTRIC ULCERS

Gastric ulcer disease has been recognized in foals, and lesions vary in anatomic distribution, severity, and cause. In clinically normal neonatal foals (<30 days of age), gastric ulcers and mucosal desquamation have been documented.[365–368] Because of these reports and other early reports of death following ruptured clinically silent ulcers in neonatal foals, for years many clinicians felt it necessary to treat critically ill neonates with antiulcer medication prophylactically.[369–371] Recently, this paradigm has been challenged. 1415

1416

The pathophysiology of gastric ulcer disease is described most reasonably as an imbalance in protective and aggressive factors.[372–374] These protective factors are responsible for maintaining a healthy gastrointestinal tract by promoting adequate mucosal blood flow, adequate mucus and bicarbonate production, prostaglandin E_2 production, epithelial growth factor production, gastric afferent innervation, epithelial cell restitution, and gastroduodenal motility. Probably the most important factor is maintenance of mucosal blood flow. Hypoxia, NO, prostaglandins, and gastric afferent innervation influence mucosal blood flow. The aggressive factors include gastric acid, bile salts, pepsin, and enzymes. Few specific causes have been found for gastric ulcer disease in foals. Excessive administration of nonsteroidal antiinflammatory drugs can result in ulceration of the glandular and squamous epithelium because of an inhibition of prostaglandin production, which leads to a decrease in mucosal blood flow and an increase in acid production. Nonsteroidal antiinflammatory drugs also can impair the healing of lesions and rarely are indicated in neonatal equine medicine.[372,373]

In the critically ill neonate the suspected cause of gastric ulcers has shifted away from an excessive amount of intraluminal gastric acid toward gastric mucosal ischemia caused by hypoxia, low blood flow conditions, or both.[375] Perforating gastric ulcers are more likely a manifestation of necrotizing enterocolitis than of excessive gastric acid. Shock, sepsis, or trauma can result in gastric mucosal ischemia, allowing for the disruption of epithelial cell integrity and permitting damage by aggressive factors or providing an environment suitable for the establishment of bacteria colonization.[375,376] Impairment of mucosal blood flow also may result in reperfusion injury, allowing the formation of gastric ulcers. In the sick neonatal foal (<7 days of age) a wide variability in the intragastric pH has been documented depending on the type of disease, severity, and milk intake frequency and volume, suggesting that in the critically ill equine neonate, ulcer prophylaxis using histamine antagonists or proton pump inhibitors is not only unnecessary but unlikely to work.[377]

Clinically significant gastric ulcers can occur in the squamous, glandular, or both portions of the stomach as a primary problem or resulting from another problem. Clinical signs include diarrhea, abdominal pain, restlessness, rolling, lying in dorsal recumbency, excessive salivation, and bruxism. In the neonatal foal the only clinical signs present may be depression or partial anorexia until a more catastrophic event, such as perforation, occurs. Some lesions in the gastric mucosa extend from the pylorus into the proximal duodenum and can result in stricture of the pylorus and proximal duodenum. These foals are usually older (>1 month of age) and have a greater volume of reflux. Bruxism and ptyalism are also more prominent in these older foals.

The most sensitive and specific method for diagnosing gastric ulcers is visualization by endoscopic examination.[365] Unfortunately, the use of gastric endoscopy has led to recognition of relative nonlesions and

ulcers resulting from other problems and of clinically significant disease states. The clinician should not stop simply when ulceration of the stomach is recognized with endoscopy but should examine that patient fully for other potential sources of the clinical signs. Other diagnostic tests may help in determining the severity of the ulcers, including fecal occult blood or gastric blood assessments, contrast radiography, abdominal ultrasound, and abdominocentesis. Endoscopy of the foal stomach carries an additional risk of exacerbating colic in the short term, unless the examiner ensures that as much introduced air as possible is evacuated from the stomach at the end of the procedure.

The presence of a brown gastric reflux fluid may indicate the presence of bleeding ulcers. Blood in the feces of the neonate is more consistent with a diagnosis of necrotizing enterocolitis, which can be associated with gastric ulcers. Contrast radiography is useful if one suspsects delayed gastric emptying or pyloric or duodenal stricture in older foals. If a stricture has occurred, one will note a delay in complete emptying of barium from the stomach (>2 hours).[367] Abdominal ultrasound may be useful to visualize free abdominal fluid and gastric or small intestinal distention if one suspects a perforation. One can visualize portions of the descending duodenum, and a thickened duodenum should increase the index of suspicion for duondenal stricture. Abdominocentesis also may confirm perforation.

Traditional therapy for gastric ulceration includes mucosal adherents, histamine type 2 receptor antagonists, proton pump inhibitors, and antacids.[378] The most widely used mucosal adherent is sucralfate, which is a hydroxy aluminum salt of sucrose. The main therapeutic action of sucralfate is to bind to the negatively charged particles in the ulcer crater.[378,379] At a pH less than 2, sucralfate is converted to a sticky viscous gel, which adheres to the ulcer crater and remains adhered for 6 hours, but at a higher pH, sucralfate remains in a suspension. Sucralfate is still effective because it inhibits pepsin and buffers hydrogen ions. Other important actions of sucralfate include stimulating production of prostaglandin E, which maintains mucosal blood flow; increasing bicarbonate secretion; stimulating mucous secretion; decreasing peptic activity; and binding epidermal growth factor. The histamine type 2 receptor antagonists include cimetidine, ranitidine, and
famotidine. These compounds block the interaction of histamine with the histamine type 2 receptor on the 1416
parietal cell, resulting in inhibition of gastric acid secretion. Clinically normal neonatal foals have a highly 1417
acidic gastric fluid that is influenced by sucking. Intravenous and oral administration of ranitidine increases intragastric pH in normal foals but critically ill neonatal foals have a blunted response to ranitidine administration.[377,380] One possible conclusion reached from these studies is that in critically ill neonatal foals, gastric ulcers may not be caused by an increased intraluminal gastric acidity.

The most commonly used proton pump inhibitor is omeprazole. This drug has not as yet been approved for use in foals under 30 days of age. Omeprazole inhibits the secretion of hydrogen ions at the parietal cell by irreversibly binding to the H^+,K^+-ATPase proton pump of the cell. Most of the lesions in older foals were healed after daily administration of omeprazole for 28 days according to one report.[381] Table 19-9 summarizes the therapeutic agents for treating gastric ulcers in foals.

Prophylactic treatment of critically ill neonates for gastric ulcers has been standard therapy for years because of the evidence of clinically silent ulcers. This approach may not be appropriate for several reasons. An increased incidence of nosocomial pneumonia and systemic sepsis is associated with high gastric pH in human patients in intensive care.[382–384] Patients in intensive care units treated prophylactically with histamine type 2 receptor antagonists are more likely to develop pneumonia during ventilation therapy and gastric colonization with potentially pathogenic bacteria or yeast.[382,385] An acidic environment appears to protect against airway colonization by bacteria of intestinal origin and bacteria translocated across the gastrointestinal tract. Pathogenesis of ulcers in the neonatal foal most likely does not involve increased intraluminal gastric acid but

instead may be caused by decreased mucosal perfusion associated with shock, hypoxia, and hypoxic/ischemic insult to the gastric mucosa. A recent report revealed that gastric ulcer disease in equine NICU patients is independent of pharmacologic prophylaxis.[386] In this study, despite decreased treatment, the incidence of gastric ulcers found in these foals at necropsy had decreased significantly. The decrease was attributed to overall improvement in management of these cases. Similarly, in a human intensive care unit, the incidence of stress ulcers decreased independent of the use of prophylaxis.[375,387] Early treatment of sepsis, sufficient oxygenation, improved monitoring, institution of enteral feedings, and improved nursing care may contribute to the reduction in gastric ulcers in the neonatal patient. Use of histamine type 2 receptor antagonist and proton pump inhibitors apparently may not be necessary; however, in some instances sucralfate may be useful. Sucralfate reduced the rate of bacterial translocation in a rat model during hemorrhagic shock and also may prohibit the generation of acute gastric mucosal injury and progression to ulcer formation induced by ischemia-reperfusion.[388,389] In a human medical intensive care unit, airway colonization by new pathogens occurred more frequently in patients receiving agents that increased gastric pH than in those receiving sucralfate.[382,390] In the critically ill neonatal foal, risk factors for gastric ulceration have not been identified clearly, although foals treated routinely with nonsteroidal antiinflammatory drugs may be at increased risk for gastric lesions. Prophylactic treatment for gastric ulcers in critically ill neonates may not be necessary, and one should consider carefully the pros and cons of their use *before* their administration.

TABLE 19-9 Therapeutic Agents for Treating Gastric Ulcers in Foals

DRUG CATEGORY	DRUG	DOSE	ROUTE	FREQUENCY
Mucosal protectant	Sucralfate	10–20 mg/kg	p.o.	t.i.d. to q.i.d.
Histamine type 2 receptor antagonist	Cimetidine	10–20 mg/kg	p.o.	q4h
	Ranitidine	6.6 mg/kg	IV[*]	q4h
		5–10 mg/kg	p.o.	b.i.d. to q.i.d.
		0.8–2.2 mg/kg	IV	q.i.d.
Proton pump inhibitor	Omeprazole	4 mg/kg	p.o.	s.i.d.
		1–2 mg/kg	p.o.	s.i.d. (prophylaxis)
Antacids	Milk of Magnesia	2–4 oz	p.o.	s.i.d. to b.i.d.
	Maalox	240 ml	p.o.	q4h

19.11.8 DIARRHEAL DISEASES OF FOALS

19.11.8.1 Foal Heat Diarrhea

Foal heat diarrhea is a mild, self-limiting form of diarrhea that occurs in foals between 5 and 14 days of age, about the time of the "foal heat" in the dam. The definitive cause of foal heat diarrhea has yet to be described, 1417

but the condition may be associated with dietary changes or changes in gastrointestinal function that occur around that time. This form of diarrhea is not caused by *Stongyloides westeri* infestation as previously thought.[391] Foals with foal heat diarrhea are not systemically ill and should not require therapy. One should evaluate fully any foals with diarrhea at this time for other possible causes of diarrhea, particularly if they are unwell or exhibit anorexia or dehydration. 1418

19.11.8.2 Viral Diarrhea

Viral diarrhea occurs most commonly in large groups of mares and foals that are housed together. Rotavirus is an isolate from the feces of up to 40% of foals with diarrhea worldwide, alone or with another pathogen.[392,393] The virus infects and denudes the microvilli, resulting in increased secretion combined with decreased absorption. The virus interferes with disaccharidase function and alters the function of the intestinal sodium-glucose cotransport proteins. The initial clinical signs are anorexia and depression, with profuse watery diarrhea occurring shortly thereafter. Severely affected foals may become significantly dehydrated and have electrolyte abnormalities, primarily hyponatremia and hypochloremia with metabolic acidosis. These foals generally require intravenous fluid support, whereas less severely affected foals may require only symptomatic therapy. Definitive diagnosis is by detection of the virus in the feces of foals with diarrhea. However, none of the available tests are particularly sensitive, and the virus also may be found with other intestinal pathogens. Recently, vaccination of pregnant mares has been suggested as a means of prevention, with preliminary results suggesting efficacy.[394,395] Although a definitive role for adenovirus has not been established in the foal, adenovirus is a common co-isolate from foals with rotaviral diarrhea.[396] A specific equine coronavirus recently has been identified from an immunocompetent foal with diarrhea, and a second report of cornavirus diarrhea was published recently.[397,398] One case report suggests a parvovirus caused diarrhea in the foal.[399]

Treatment of viral diarrhea in foals is primarily supportive. Intravenous fluid and parenteral nutritional support may be necessary in severe cases. Very young foals may benefit from intravenous plasma administration and broad-spectrum antimicrobial coverage to limit bacterial translocation. One can administer sucralfate orally in these cases as a gastrointestinal protectant and to discourage bacterial translocation. Foals with moderate to severe metabolic acidosis may benefit from sodium bicarbonate administration if their ventilatory function is normal. One administers sodium bicarbonate at half the calculated deficit (0.5 × standard base excess × body mass in kilograms) as an isotonic solution at the maintenance fluid rate. One should reevaluate sodium and bicarbonate (or standard base excess) concentrations regularly. Nonspecific therapy of diarrhea is discussed elsewhere in this text.

19.11.8.3 Bacterial Diarrhea

Diarrhea is frequently the primary presenting complaint in foals with sepsis, so one should rule out this differential diagnosis in foals less than 1 week of age. One should evaluate all neonatal foals with diarrhea for possible sepsis and should include a blood culture whenever possible.

Clostridium perfringens and *C. difficile* are recognized increasingly as serious pathogens of the foal.[400–403] Foals with either pathogen generally have abdominal pain, dehydration, and profuse watery diarrhea. Some foals may have red-tinged or frankly bloody feces, which carries a poorer prognosis. Most foals with this type of diarrhea require intensive care or, at the minimum, intravenous fluid administration. Outbreaks of this type of diarrhea on farms occasionally occur, and the suggestion is that the dam has a role in transmission of

the bacteria. Diagnosis is by recognition of the offending organism by Gram stain of the feces, by bacterial isolation from the feces, and by detecting the presence of toxins associated with the organisms. Specific treatment includes oral administration of metronidazole and broad-spectrum antimicrobial coverage as prophylaxis for bacterial translocation associated sepsis in younger foals. Foals with severe blood loss in their feces may require transfusion of whole blood.

Salmonella spp., *Escherichia coli, Bacteroides fragilis,* and *Aeromonas hydrophila* have been implicated in diarrhea in foals. *Salmonella* generally is associated with septicemia in foals, and although some convincing evidence exists for a role for *E. coli* in foal diarrheal disease, the extent of *E. coli* as a pathogen of the gastrointestinal tract in foals has yet to be described fully.[371,404–407]

Proliferative enteropathy is a transmissible enteric disease caused by *Lawsonia intracellulare*.[408,409] Most foals have been weaned *before* the appearance of clinical signs of depression, rapid and significant weight loss, subcutaneous edema, diarrhea, and colic. Poor body condition with a rough hair coat and a pot-bellied appearance are common in affected foals. Clinicopathologic abnormalities included hypoproteinemia, leukocytosis, anemia, and increased serum creatine kinase concentration. Postmortem reveals characteristic intracellular bacteria within the apical cytoplasm of proliferating crypt epithelial cells of the intestinal mucosa. Antemortem diagnosis of equine proliferative enteropathy is based on clinical signs,
hypoproteinemia, and the exclusion of other common enteric pathogens. Fecal polymerase chain reaction 1418
analysis may be positive for the presence of *L. intracellulare,* and affected foals develop antibodies against *L.* 1419
intracellulare.[410] Treatment with erythromycin estolate alone or combined with rifampin for a minimum of 21 days is recommended with additional symptomatic treatment when indicated.

19.11.8.4 Protozoal Diarrhea

Cryptosporidium spp. cause gastroenteritis and diarrhea in many animal species and are not host-specific. *Cryptosporidium* has been implicated as the casual agent of diarrhea in foals, but the organism is isolated from the feces of diarrheic foals and normal foals with the same frequency and concentration, making a clear role for the organism difficult to elucidate.[411–413] Diarrhea caused by *Cryptosporidium* in other species and that described for foals is generally self-limiting, with a clinical course of between 5 to 14 days. Immunosuppressed patients, including foals compromised by concurrent disease, are thought to be at increased risk for complications resulting from infection with this organism.[411,412] Treatment is symptomatic. Cryptosporidiosis is a disease with zoonotic potential, and one should take appropriate precautions, including use of gloves and frequent hand washing, if organisms are identified in the feces of any patients so as to prevent spread to other patients and personnel. *Eimeria leukarti, Trichomonas equi,* and *Giardia equi* have been identified in the feces of normal horses and horses with diarrhea. Transmission studies have failed to produce reliable clinical signs, and the prevalence and significance of these organisms in the genesis of foal diarrhea remain unknown.

19.11.8.5 Parasitic Diarrhea

Strongyloides westeri is a common parasitic infection of foals.[392,414] Transmission is transmammary, and patent infection is recognizable in the foal by 8 to 12 days of age. This nematode previously was associated anecdotally with foal heat diarrhea, but the association has not been demonstrated clearly. The diarrhea is generally mild and is treated effectively by deworming with benzimidazole or ivermectin anthelmintics.[391]

Strongylus vulgaris fourth-stage larvae cause diarrhea in young foals during migration through the arterioles of the cecum and descending colon. Clinical signs may resemble thromboembolic colic.[414] The prepatent period is about 6 months, and diagnosis is based on clinical examination, clinicopathologic changes, and farm deworming history. Patients with diarrhea associated with this parasite may have peripheral leukocytosis, neutrophilia, eosinophilia, and hypoproteinemia. Appropriate deworming with ivermectin (label dose), fenbendazole (10 mg/kg/day orally for 5 days), or thiabendazole (440 mg/kg/day orally for 2 days) is recommended, with the last two drug dosages being larger than the label dose.

Cyathostomiasis, or diarrhea resulting from the sudden emergence of encysted cyathostome larvae, is an unusual cause of diarrhea in the foal.

19.12 Neonate Therapy

19.12.1 FLUID THERAPY IN NEONATES

The clinician managing critically ill neonates must recognize that intravenous fluid therapy simply cannot be scaled down from adult management approaches. Fluid management of the ill neonate, particularly over the first few days of life, must take into consideration that the neonate is undergoing a large transition from the fetal to the neonatal state and that important physiologic changes are taking place.[166] These transitions include shifts in renal handling of free water and sodium and increased insensible losses because of evaporation from the body surface area and the respiratory tract. The newborn kidney has a limited ability to excrete excess free water and sodium, and the barrier between the vascular and interstitial space is more porous than that of adults. Water and sodium overload, particularly in the first few days of life, can have disastrous long-term consequences for the neonate.[416,417] In the equine neonate, excess fluid administration frequently manifests as generalized edema formation and excessive weight gain, frequently equivalent to the volume of excess fluid administered intravenously. In cases in which antidiuretic hormone secretion is inappropriate, as in some foals with PAS, generalized edema may not form, but the excess free water is maintained in the vascular space. This syndrome of inappropriate antidiuretic hormone secretion is recognized in the foal that gains excessive weight not manifested as edema generally, with decreased urine output and electrolyte abnormalities such as hyponatremia and hypochloremia.[418] The foal manifests neurologic abnormalities associated with hyponatremia. The serum creatinine concentration varies in these cases, but urine always is concentrated compared with the normally dilute, copious amounts of urine produced by foals more than 24 hours of age on a milk diet. If measured, serum osmolarity is less than urine osmolarity. The treatment for this disorder is fluid restriction until weight loss occurs, electrolyte abnormalities normalize, and urine concentration decreases. If the clinician is unaware of this differential diagnosis, the neonate can be assumed mistakenly to be in renal failure, and the condition can be exacerbated by excessive intravenous fluid administration in an attempt to produce diuresis.

The problem of appropriate fluid management in critically ill neonates has been recognized by medical physicians for years and has resulted in changes in fluid management of these patients. The approach taken has 1419
been one of fluid restriction, in particular sodium restriction but also free water restriction, and has resulted in 1420
improved outcome and fewer complications, such as patent ductus arteriosus and necrotizing enterocolitis.[416,417] The calculations used for maintenance intravenous fluid support in these patients takes into consideration the ratio of surface area to volume and partially compensates for insensible water losses. Maintenance fluids are provided as 5% dextrose to limit sodium overload and provide sufficient free water to

restore intracellular and interstitial requirements. The calculation for maintenance fluid administration is as follows:

First 10 kg body mass	100 ml/kg/day
Second 10 kg body mass	50 ml/kg/day
All additional kilograms of body mass	25 ml/kg/day

As an example, the average 50-kg foal would receive 1000 ml/day for the first 10 kg of body mass, 500 ml/day for the next 10 kg of body mass, and 750 ml/day for the remaining 30 kg of body mass for a total of 2250 ml/day. This translates to an hourly fluid rate of about 94 ml/hr.

One should adjust the fluid and sodium requirements for ongoing losses exceeding the maintenance requirements. These losses can take the form of diarrheal losses and excessive urine output, such as those with glucose diuresis and renal damage resulting in an increased fractional excretion of sodium. The normal fractional excretion of sodium in neonatal foals is less than that of adult horses, usually less than 1% (J.E. Palmer, unpublished data). In the critically ill foal the sodium requirement can be met with as little as 140 mEq of sodium per day, about that administered in a single liter of normal equine plasma. One can address sodium deficits by separate infusion of sodium-containing fluids, although this may not be necessary if one considers the sodium being administered in other forms, including drugs administered as sodium salts and any constant rate infusions (pressors, inotropes, etc.) that are being provided as solutions made with 0.9% sodium chloride.

The author has used this approach to fluid therapy in her NICU for the last few years and believes that the percentage of foals suffering from generalized edema and related problems has decreased. If one takes this approach to fluid therapy, one should take the weight of the patient once daily, or even twice daily, and monitor the fluid intake and output as closely as practical. One should evaluate any larger than anticipated weight gains or losses. One should not expect urine output to approach the reported normal of 300 ml/hr for a 50-kg foal because the free water administered is limited, unless the patient is experiencing diuresis (glucosuria, resolution of the syndrome of inappropriate antidiuretic hormone secretion, resolution of previous edematous state, renal disease). One should obtain the urine specific gravity several times daily and should determine fractional excretion of sodium at regular intervals. If the volume of urine produced by the patient is measured accurately, one can determine sodium losses accurately and can obtain creatinine clearance values. One should obtain blood pressure measurements at regular intervals throughout the day because hypotension can be a problem in these patients, particularly in septic foals and foals suffering from PAS, and one may need to increase fluid therapy to maintain adequate vascular volume. Patients with hypotension may need inotrope and pressor support.

19.12.2 PRESSOR AND INOTROPE THERAPY IN NEONATES

Inotrope and pressor therapy generally is restricted to referral centers where these drugs can be administered as constant rate infusions and blood pressure can be monitored closely. Blood pressure can be monitored directly or indirectly by the use of cuffs placed on the base of the tail. Both techniques have advantages and disadvantages. Although direct blood pressure measurements are considered the gold standard and are generally more accurate, the difficulty in placing and maintaining arterial catheters and lines in these patients severely restricts the utility of this method. Indirect techniques can be inaccurate and are affected by cuff size and placement. However, indirect techniques are easier to use in the NICU and can be useful if trained staff are using the equipment. In the author's NICU, once practitioners identify the appropriate cuff size, they dedicate that cuff to that patient for the duration of the hospitalization to decrease variability caused by using different

cuffs. One should monitor the blood pressure of all recumbent patients at regular intervals, and trends upward or downward should prompt the clinician to make necessary adjustments.

Foals suffering from PAS and sepsis are the patients most at risk for significant hypotension and perfusion abnormalities. Perfusion is maintained by supporting cardiac output and blood pressure with judicious use of intravenous fluid support and inotrope/pressor support. The author does not aim for any specific target systolic, mean, or diastolic pressure. Instead the author monitors urine output, mentation, limb perfusion, gastrointestinal function, and respiratory function as indicators that perfusion is acceptable. For NICU patients to require inotrope and pressor therapy is not unusual, but in some cases hypoxic and septic damage is sufficiently severe to blunt the response of the patient to the drugs. One must approach each patient as an individual, and no single inotrope/pressor protocol will suffice for all patients.

Dobutamine is a β-adrenergic inotrope that is frequently used as first choice therapy in NICU patients. Its effects are β_1 at the lower dose range. Neonates have a limited ability to increase stroke volume in an effort to 1420

maintain cardiac output, and one may observe tachycardia in these patients as heart rate increases to maintain 1421
cardiac output and vascular pressure. Dobutamine is useful after patients are volume replete for support of cardiac output. The dose range is between 2 to 20 μg/kg/min provided as a constant rate infusion.

Dopamine has dopaminergic activity at low doses, β_1 and β_2 activity at moderate doses, and α_1 activity at high doses. Dopamine causes norepinephrine release, which has lead to the suggestion that this is its major mode of action at higher doses. At doses greater than 20 μg/kg/min, intrapulmonary shunting, pulmonary venous vasoconstriction, and reduced splanchic perfusion may occur. Dopamine also produces natriuresis at lower doses through a direct effect on renal tubules. For these reasons, dopamine has fallen out of favor at some referral institutions.

Norepinephrine has α_1 and β_1 activity but variable β_2 activity, resulting in potent vasopressor effects; it has inotropic and chronotropic effects, but its chronotropic effect usually is blunted by vagal reflexes slowing the heart rate induced by the increase in blood pressure. In many critical care units, norepinephrine has become a pressor of choice and frequently is used along with dobutamine. Evidence suggests that splanchic perfusion is maintained better with norepinephrine than with some other pressors.[419] The dose range is 0.2 to 2.0 μg/kg/min, although larger doses have been used when necessary in certain patients.

Epinephrine has α_1, α_2, β_1, and β_2 activity; β activity predominates and results in increased cardiac output and decreased peripheral resistance at low doses. Epinephrine has been associated with hyperglycemia, hypokalemia, lipolysis, increased lactate concentration, and increased platelet aggregation. The effect on renal function is controversial. Use of epinephrine usually is limited to those patients not responding to other pressors.

Vasopressin (antidiuretic hormone) is a pressor gaining a great deal of attention in the critical care literature. Vasopressin appears to be depleted from the neurohypophysis in septic shock,[420] and short-term administration of vasopressin spares conventional vasopressor use, in addition to improving some measures of renal function.[421] Low-dose vasopressin infusion increases mean arterial pressure, systemic vascular resistance, and urine output in patients with vasodilatory septic shock that are hyporesponsive to catecholamines. These data indicate that low-dose vasopressin infusions may be useful in treating hypotension in patients with septic shock.[422] The author has been using low-dose vasopressin in patients in her NICU for the past few years and has the clinical impression that blood pressure is defended more readily using this agent in concert with other management strategies. The author commonly uses low-dose vasopressin constant rate infusion with dobutamine constant

rate infusion as the initial inotrope/pressor therapy in cases requiring pressure defense, although no prospective studies are yet available regarding this drug in veterinary medicine.

19.13 19.1—Musculoskeletal Disorders of Foals

Elizabeth M. Santschi

The advances in medical care of equine neonates in the last 20 years have resulted in the survival of many foals that previously would have died from sepsis, asphyxia, and prematurity; and the successful management of their musculoskeletal system can be a major challenge. Major factors adding to the challenge are the immaturity of components of the musculoskeletal system and the demands placed on them by a growing and active foal. Additional pressures to treat orthopedic conditions in foals have come from an overall increase in the demand for quality health care for animals, advances in medical science, and in some breeds the increasing value of the juvenile equine athlete. Equine veterinarians that encounter pediatric orthopedic problems are only beginning to get the information needed to make appropriate treatment decisions.

19.13.1 NEONATAL MUSCULOSKELETAL SYSTEM

The equine neonate has specific differences in structure and physiology from adults that one must consider when designing an optimal therapeutic or management strategy. Few investigations have focused on the equine neonatal musculoskeletal system,[1–6] but a large body of clinical information exists, and one can make cautious extrapolations from work in other species.[7] Neonatal equine bones have accelerated modeling and remodeling processes[5] that result in accelerated fracture healing and an increased susceptibility to deformation caused by excessive loading. Contralateral limb varus deformities of the growth centers (most commonly distal radius and metacarpus/metatarsus) are common in overloaded limbs. The increased plasticity of the skeletal structure also is mirrored in the soft tissue support system, for these units become flaccid within 2 weeks of immobilization.[4] This laxity is important, because it further compromises the use of the fractured limb and can last as long as the coaptation was in place. Additional divergences from adult physiology include musculoskeletal immaturity (generalized or focal) and immune system differences. Finally, foals are lighter and can tolerate and will assume recumbency more readily than adults. The net results of these differences are that one must consider the use of external coaptation carefully, fractures heal quickly, one must consider damage to the contralateral limb from overstress, reducing weight bearing is possible, and infection is always lurking.

19.13.2 TRAUMA

19.13.2.1 Long Bone Fractures

Stresses can affect the musculoskeletal system of the foal at any time, including in utero. Although rare, reports describe in utero fractures (K. Sprayberry, personal communication, 2003) that result in foal locomotor problems and even maternal uterine damage from sharp bone ends. The cause is presumably from vigorous muscular activity of the foal, but one cannot rule out direct trauma. The fractures result in foal lameness and can increase the likelihood of dystocia and caused colic in one mare when the broken bones damaged the uterus. Treatment depends on how long the fracture has been present and on the fracture location and configuration, but if the fracture is repairable, internal fixation probably is necessary. Fractures 1431
occurring during foaling result from aggressive obstetric manipulation (mandibles) or chest compression. 1432
One should stabilize unstable mandibular fractures. Appendicular fractures usually do not occur during parturition because of the robust character of the bones of the foal.

After birth, foals are susceptible to external trauma from many sources. The dilemma is that younger foals with fractures are more likely to heal but also are more likely to develop contralateral limb problems because of excessive weight bearing and affected limb flexor tendon laxity if the limb is immobilized fully. As a result, internal fixation is often the best choice for neonatal fractures to keep the fractured limb in use.

19.13.2.2 Small Bone and Avulsion Fractures

Proximal sesamoid bone fractures result from hyperextension of the fetlock joint. Foals are lame after the fracture, but the lameness can be mild and often diminishes quickly. Soft tissue swelling occurs over the sesamoids. Fractures are usually simple, can occur uniaxially or biaxially, and can be apical, midbody, or basilar. Fractures can occur in any joint and can affect multiple sesamoids in one foal. However, they most commonly are single forelimb fractures[8] and in Thoroughbreds are most frequent in the left front medial proximal sesamoid (J.P. Morehead, personal communication, 2003). Of particular interest to neonatologists

is that proximal sesamoids fractures often occur in recovered neonatal patients that are allowed too much exercise too soon. Foals from the NICU need a gradual introduction to pasture turnout to allow their musculoskeletal system to adjust. Mares are often in need of turnout, but in the interest of their foals, they must wait.

Treatment of proximal sesamoid fractures in foals is stall confinement with support bandaging. Healing occurs, albeit with some distortion of the shape of the sesamoid. Severely displaced fragments result in large and misshapen sesamoids, and surgery may be considered for these foals, because restriction of fetlock flexion can occur after conservative therapy.

Third phalangeal fractures are also common in foals. These foals have a lameness that worsens with hoof compression. Hoof abscesses are uncommon in young foals but should be considered. Most commonly, radiographs reveal nonarticular small fractures on the wings on the third phalanx. The fractures are associated with hard ground and exercise. The fractures heal with stall confinement, and unlike adults, leave no discernable radiographic fibrous union.

Avulsion fractures of the proximal insertion of the peroneus tertius and the origin of the long digital extensor tendon have been reported.[9,10] Both soft tissue structures attach to the extensor fossa of the distal femur. The two affected foals had lameness of a hindlimb associated with swelling, pain, and crepitation. Radiographs revealed multiple avulsion fractures of the extensor fossa. Because of the intraarticular fragments in the femoropatellar joint, and the fear of later degenerative joint disease, fragments were removed arthroscopically. Both foals were juveniles at last follow-up; one foal was considered normal, and one had a mild residual lameness.

19.13.2.3 Tendon and Ligament Damage

Tendon and ligament damage is uncommon in neonates probably because of their low body weight. Extensor tendon damage following flexural deformities is the most common tendon problem and is discussed in Congential Flexural Deformities of Foals. Gastrocnemius ruptures are one of the most devastating problems and have occurred after forced extraction because of a breech presentation, severe flexor tendon laxity, and tarsal contracture. Loss of gastrocnemius function usually results in a non–weight-bearing limb, although an intact superficial digital flexor tendon may make some weight bearing possible. Complete loss of support is difficult to treat successfully. Coaptation of the limb is logical but difficult to obtain. Schroeder-Thomas splints have been used but are difficult to manage. Tube casts also are used but must be changed frequently, and cast sores are inevitable (L.R. Bramlage, personal communication, 2003). The prognosis for athletic function is guarded.

Treatment for ligamentous injuries is usually some form of coaptation, although surgical repairs have been performed when coaptation was unworkable.[11] Coaptation in proper limb alignment allows the ligaments to heal and should be used if the injury will destabilize a joint and cause damage to growing epiphyses or cuboidal bones. One can achieve coaptation with casts or splints under a bandage. Casts are initially a greater expense, and cast sores and their resulting white hairs are a risk, but the rigid immobilization and the lack of the requirement for daily adjustment makes them preferable. Important to musculotendinous health is some measure of weight bearing to avoid laxity after coaptation removal, which one can achieve by using tube casts and splints that allow weight bearing. Following coaptation, bandaging and a gradual return to exercise are recommended for ligamentous injuries.

19.13.3 LUXATING PATELLAE

Patellar luxation can affect foals in one or both hindlimbs, and the luxation can vary from a laxity in the medial attachments to complete luxations that cannot be replaced in the patellar groove of the distal femur.[12,13] Medial luxations have not been reported. Clinical signs vary from a slight discontinuous motion during stifle flexion to an inability to stand. Many foals have a crouching stance on the affected limb because of an inability to extend 1432
the stifle. The pathophysiology of patellar luxations is unknown. Congenital bilateral luxations are common in 1433
Miniature horse foals and are believed to be genetic. Luxations are rarer in other breeds and are occasionally traumatic. The affected limbs are usually not grossly abnormal except for effusion of the femoropatellar joint and the luxation. A shallow trochlear groove has been reported to be a cause of patellar luxation, but objective evidence is lacking.

One should evaluate foals for the ability to stand. Once the appropriate supportive care is provided, if a foal cannot stand, euthanasia is recommended. Most bilateral luxations in horses fit in this category. However, Miniature horse foals often can stand sufficiently to nurse despite bilateral luxations, and one may consider treatment. Treatment consists of replacing and stabilizing the patella and sometimes surgically deepening the patellar groove. Delaying surgical repair until the foal is approximately 30 days old is recommended to avoid neonatal problems, allow the musculoskeletal system to mature, and provide good anchors for suture. Some surgeons worry that delay may cause further femoropatellar developmental abnormalities, but in a small number of cases, this has not been an issue. The prognosis for Miniature horse foals appears to be good because of their low body weights and modest performance expectations. Too few reports about the correction of unilateral luxations in light horses exist to make a definitive statement about prognosis except that success and failure have been experienced.[12,13]

19.13.4 CONGENITAL FLEXURAL DEFORMITIES

Congenital flexural deformities in foals can be classified as severe (rarely correctable), moderate (correctable with therapy), or mild (self-correctable). Examples of severe flexural deformities include arthrogryposis (deformities of multiple limbs and often the head and neck), severe carpal deformities (flexor angle of the carpus less than 90 degrees), and tarsal contractures (rare). Extraordinary methods have been used to correct severe deformities[14] but are often unsuccessful.

Mild flexural deformities are those that result in an upright conformation to the limb, but the foal can bear weight on the limb and load the flexor structures. These foals require no specific treatment and will self-correct with controlled exercise.

Moderate flexural deformities are those that make bearing weight on the limb and loading the flexor structures and ligaments difficult for the foal. When these deformities occur bilaterally (most common), the foals cannot rise to suckle or does so with great difficulty, and the lack of weight bearing worsens the flexural deformity. Examples of moderate flexural deformities include carpal and forelimb fetlock flexural deformities that usually occur together, hindlimb fetlock flexural deformities with coronopedal flexion or hyperextension, and the uncommon coronopedal flexural deformity alone.

Treatment of moderate flexural deformities aims to place the solar surface of the foot on the ground so that the weight of the foal can stretch the flexor structures. Splints are useful for restoring the limb to normal orientation but require attention to detail because the splints often exert an extreme amount of tension on the soft tissues,

and the skin of the foal is thin. Pressure sores are easy to create and at a minimum result in an extended convalescence.

The first step in splint application is to apply a separate heavy bandage to the limb, which should be reapplied as necessary because the bandage can slip and cause focal constriction. Commercial gauze over cotton bandage material works better than sheet cotton as a bandage. The splint is made of polyvinyl chloride pipe cut in half or thirds. Using 50% of the diameter of the pipe results in less splint rotation but is bulkier and leaves more splint exposed to cause trauma. One cuts off the corners of the splint and pads the ends with gauze or roll cotton covered with tape. Palmar or plantar placement of the splint is preferable, but severe deformities may require initial dorsal placement. As the limb straightens, one can bend the splint to tape the fetlock into the bend to extend it. One can tape the splint tightly to the limb over the bandage with nonelastic (white or duct) tape. This procedure requires at least two persons, one to extend the limb firmly and hold the limb and one to tape. One should leave the splint on for 8 to 12 hours and then remove it for 8 to 12 hours. One can reapply splints as necessary.

In addition to splints, some medications are of value for treating flexural deformities. Oxytetracycline (40 to 50 mg/kg) given intravenously appears to relax the soft tissues.[15] The mechanism of action is unknown, and the drug is most efficacious when given in the first 3 days of life. This dose is high but appears to be safe for healthy foals and can be repeated at 24-hour intervals. Foals should be normovolemic during tetracycline administration. One should use the drug with caution in foals with renal impairment. Foals should be urinating and have reasonable urinary parameters (serum urea nitrogen, creatinine, and urinalysis) before tetracycline use. Diarrhea is an uncommon sequela to tetracycline use. One should monitor the unaffected limbs closely because all limbs experience a relaxation of the palmar/plantar support.[15,16] Discontinuation of tetracycline therapy before affected limbs are normal but after they can bear weight is common because of worsening laxity in the "normal" limbs. One also can use phenylbutazone (4 mg/kg) for a short time when the splints are used. Some analgesia appears to help the foals use the limbs and stretch the soft tissues. One should not use phenylbutazone for long periods of time because of the potential of inducing gastric ulcers.

Surgical treatment of congenital flexural deformities rarely is indicated. Severely affected foals rarely respond 1433
favorably to surgery, and mildly affected foals do not need it. Surgery is most appropriate for foals with 1434
moderate flexural deformities that are neglected or have not responded to splinting and tetracycline. The most common surgical therapy performed for congenital flexural deformities is the inferior check ligament desmotomy for fetlock or coronopedal flexural deformities.

Ruptures of the extensor tendons commonly occur with congenital flexural deformities and result from the foal overloading the extensor tendons. No specific therapy for the ruptures is necessary. If the rupture is extensive, it can interfere with the ability to extend the fetlock and to place the foot flat. These foals then tend to knuckle over, even after correction of the flexural deformity. A firm fetlock bandage extends the digit and assists in foot placement until the extensor tendons heal.

19.13.5 CONGENITAL EXTENSION DEFORMITIES

Foals commonly are born with hyperextension deformities of the fetlock of varying degrees of severity. All but the worst deformities self-correct as muscle tone improves. A deeply bedded stall is all that is usually necessary to protect the soft tissues, but one can apply a light bandage to the coronary band and pastern if trauma is a problem. Severe deformities are more problematic but rare, so therapeutic recommendations are not available. Hyperextension of the carpus occasionally occurs and usually is treated conservatively. However, a tube cast to align the limb may be necessary to protect the dorsal surface of developing carpal bones.

19.13.6 CONFORMATIONAL DEVIATIONS

Neonatal foals exhibit three categories of forelimb conformational deviations: angulation, rotation, and carpal offset. Angular deviations most commonly are centered in the metaphysis and epiphysis, but their location is described by the closest joint, usually the carpus and fetlock. When the deviation of the distal limb is lateral to the long axis, the deviation is valgus, and when the deviation is medial, the deviation is varus. More than one joint can be affected, and although rare in neonates, valgus and varus can occur in different joints in one limb.

Rotational deformities appear to originate most commonly in the diaphysis or metaphysis of the radius or the metacarpus. In neonates the direction of rotation of the distal limb at both sites is almost exclusively outward. Associated angular and rotational deviations occur.[17] In neonates, limb deviations occur in foals with narrower chests and less developed pectoral muscles than in straight foals, and they appear to have an initial greater overall weakness in the musculoskeletal system because it first interacts with gravity, body mass, and ground reaction forces. However, after the first few days of life, the asymmetric loading of the growth centers does affect limb deviations. Angulation results from a compressive load that is asymmetric in a frontal plane but is uniform in the sagittal plane, and rotation occurs when the compressive load is asymmetric in both planes and the limb develops around an overloaded axis point. Considered this way, valgus and outward rotation deviations in young foals are coupled, as are varus and inward rotation in older foals. The loading asymmetry for valgus/outward rotation foals is accentuated as foals assume a base-wide posture that is more stable side-to-side but promotes a lateralization of the limb load. The specific effects of intermittent versus static loads, strain magnitude versus strain rate, and shear and hydrostatic stress on growing bones is only beginning to be understood. However, clinical experience supports the general observation that excessive cartilage compression is deleterious to bone growth.

Offset carpal conformation describes a joint that appears to deviate outwardly and then inwardly, all within the carpus. The deformity is thought to be centered at the radiocarpal joint, but the specific structural cause of offset has not been determined. This conformation is more common in older foals but occasionally occurs in neonates. The deviation is particularly common when incomplete ossification of the carpal bones is present.

The causes of conformational deviations are a matter of some debate. As always, the major factors are genetics or environment. Genetic influences include the assortment of alleles that controls bone form and growth and the assortment that modulates bone remodeling. Many in the horse industry believe that genetics is a strong determiner of limb conformation. Environmental influences are many and include the intrauterine environment, the postnatal limb load, nutrition, and bad luck. Suffice to say, the situation is complex, but one must consider biologic and mechanicobiologic influences when evaluating the growth of long bones.[18]

Several factors may contribute to the common occurrence of deviations in the carpus. First, the carpus is in the middle of the limb and is subject to the greatest bending forces. Second, the carpal anatomy is complex and perhaps is not understood completely. The carpus has seven cuboidal bones, two long bones, and two epiphyses (distal radial and lateral styloid); and cartilage surrounds all. The ligamentous support includes collateral ligaments, innumerable intracarpal ligaments, and a palmar carpal soft tissue ligament. The distal radial physis is not flat transversely, but undulates in the frontal and sagittal planes.[3] A separate center of ossification for the lateral styloid process is found at its palmar-lateral aspect. Because of this separate center of ossification, more cartilage and less bone are in the lateral aspect of the distal radial growth center, suggesting it may be more susceptible to growth alterations from load. 1434

Less common conformation deformities in young foals include hindlimb deformities, windswept conformation, diaphyseal deviations (usually of the metacarpus/metatarsus), gross congenital malformations such as agenesis and polydactyly, and acquired varus deformities of the carpus and fetlock. Hindlimb conformational deviations can manifest as tarsal and fetlock angular deformities and external limb rotation, usually centered above the tarsus. Windswept foals have limbs (usually both forelimb or both hindlimbs) that are curved in the same direction in the frontal plane. Diaphyseal deviations, agenesis, and polydactyly are rare and have various presentations. Acquired varus deformities are caused by excessive loading, which appears to be focused medially on the growth plates. 1435

19.13.6.1 Evaluation

One should evaluate the limbs to determine the location, extent, and potential cause of the deviation. Evaluation consists of observation and then palpation for heat, swelling, or ligament laxity. Ligamentous laxity of the medial carpal ligaments is an important cause of carpal valgus and should be evaluated carefully. Lameness is not a characteristic of uncomplicated angular limb deformities and suggests further evaluations are necessary. Radiography is indicated for foals with severe deviations (all tarsal valgus), ligamentous laxity, lameness, or joint effusions. Ultrasonography may be valuable for selected soft tissue evaluations.

19.13.6.2 Nonsurgical Treatments

Conservative therapy is by far the most commonly used therapy in foals less than 30 days of age.[19] Mild to moderate carpal valgus and external rotation of the carpus and fetlock are common and normal in neonates, particularly light breed horses. Most congenital limb deviations improve with age, if the developing musculoskeletal system is protected from overuse and abnormal loads. Approximately 90% of Thoroughbred foals with congenital carpal valgus self-correct. Those foals that do not most often have abnormal bone (incomplete ossification) with normal stress or normal bone with abnormal stress (ligamentous laxity or contralateral limb lameness). Correction continues for several months, and on average, foals reach their straightest conformation (regarding angulation) at approximately 10 months of age (E.M. Santschi, unpublished data).

TABLE 19-10 Exercise Recommendations for Foals With Uncomplicated Carpal Valgus*

TIME	VALGUS CATEGORY (APPROXIMATE ANGULAR DEVIATION) MILD (4°–10°)	MODERATE (11°–16°)	SEVERE (>16°)
Initial exercise	Paddock turnout	Stall confinement; playing while mare is walked in hand daily	Large stall confinement; limited walking in hand
After 1–2 weeks	Pasture turnout	Paddock turnout	Stall confinement; playing while mare is walked in hand
Maintenance	Pasture turnout	Pasture turnout	Paddock turnout

* Increasing levels of exercise are allowed as the angulation decreases; static and worsening deviations are indications for further evaluation.

Determination of the appropriate treatment for foals with angular limb deformities is based on the age of the foal, the severity and location of the deviation, and its causes. One must evaluate the entire foal and the affected limb. If the carpal collateral ligaments have no laxity and carpal incomplete ossification is not suspected, one may use an exercise program such as in Table 19-10, assuming that the foal has no contradicting additional problems. Exercise is essential for the robust development of almost every body system for neonates, and fresh air and good ventilation reduce the occurrence of respiratory disease. Appropriate limb loading along with growth and maturity is what straightens limbs, but excessive amounts of loading can be deleterious. For example, one should use exercise cautiously in foals with very asymmetric deviations. When one limb is much more deviated than the other, it appears to be loaded excessively and compromised more than if both limbs were affected similarly. And finally, limb deviations are additive. Foals with external rotation and carpal valgus improve more slowly than those with one type of deviation.

Incomplete ossification of cuboidal bones and focal ligamentous laxity are complicating matters of great potential impact on adult conformation. They generally manifest as a moderate to severe limb deviation. Physical examination indicates laxity because angular limb deviations are reducible. Radiographs are the best way to evaluate the extent of carpal bone ossification. Incomplete ossification of the cuboidal bones can be
focal or widespread. Focal immaturity is not common but can result in severe angulation. Generalized 1435
immaturity is more frequent and initially often manifests as an offset conformation with valgus angulation. 1436
When the foal becomes heavier, assumes a base-wide stance, and is allowed exercise, crushing of the bones of the lateral carpus (usually the lateral styloid process of the radius, the ulnar, the fourth and the intermediate facet of the third carpal bone) results in a permanent intracarpal valgus deviation. The same result occurs when significant medial carpal ligament laxity goes untreated.

In the forelimb, foals with collateral ligamentous laxity and moderate to severely immature cuboidal bones should have external coaptation placed on the affected limb to maintain axial orientation. Tube casts that allow weight bearing on the digit are preferred to splints. Ligamentous laxity in the carpus usually responds to tube casting for 7 to 10 days followed by bandaging and cautious exercise. The duration of similar coaptation necessary for immature carpal bones depends on the degree of immaturity and the speed with

which the bones mature. Because casts cannot be left on neonatal limbs for more than 7 to 10 days because of their fast growth, more than one cast may be necessary.

Treatment of tarsal valgus and rotational deformities is much less common than in the forelimbs because deviations are less common than in the forelimb, because some breeds prefer an outward position to the hindlimb, and perhaps because owners recognize it less frequently.[20] Hindlimbs generally are unaffected by ligamentous laxity, but tarsal incomplete ossification is common and often is associated with tarsal valgus. Treatment of tarsal incomplete ossification is important because tarsal crushing results in an unfavorable prognosis for athletic performance.[20,21] Hindlimbs require a slightly different approach to coaptation than forelimbs because of their anatomy. Foals can rise to stand if their forelimbs are fixed in extension but cannot do so if their hindlimbs are extended. The multiple bony protuberances of the hock make cast sores more likely than in the forelimb, so casts are problematic. Gutter splints are not useful because of the angle of the hock. Severely limiting exercise is part of allowing the tarsus to mature without cartilage crushing, but foals cannot always be recumbent. Extra small articulated anterior cruciate ligament splints for human beings (Playmaker Wraparound, dj Orthopedics, Vista, California) have given the best results. For small foals, a padded bandage is necessary under the splint, which is reversed to conform to the angle of the hock. The splints allow enough flexion in the hock for the foal to rise but appear sufficient when combined with stall rest to protect the cartilage from crushing. Splints are left on the hocks until the cuboidal bones have ossified as shown by radiography.

Fetlock conformational deviations in neonates that are treated best conservatively are rare. Outward rotation is the most common deviation but is thought to have minimal effect on the performance and improves with maturity. The only therapy used is to rasp the toe square to promote central breakover. Severe outward rotation can promote a fetlock valgus conformation, so one can use a medial hoof wall extension of epoxy to bring the limb load medially. The most commonly treated fetlock deviations are inward but usually occur in foals older than 30 days. However, if the deviation is noticed in neonates, one can use small lateral hoof wall extensions that generally are made of epoxy with fiberglass cloth embedded to prevent chipping.

Windswept foals are born with multiple deviations. Evaluating the foal as a whole is best rather than focusing on individual joints. Most of these foals become straight over time with conservative therapy.

19.13.6.3 Surgical Treatment

No surgical procedures are commonly accepted for direct treatment of rotational or carpal offset deviations, so angular deviations are described. Surgical procedures to correct carpal and fetlock valgus include periosteal transection and elevation and transphyseal bridging. Periosteal elevation is thought to accelerate growth on the concave side of the metaphysis, and transphyseal bridging is used to restrict the growth on the convex side of the physis. Studies indicate an approximately 80% improvement of carpal valgus foals after periosteal transection and elevation, but unfortunately they do not compare foals that had surgery with controls that did not.[22,23] Recently, some have suggested that most of the correction was unrelated to the surgery,[24] and one experimental study supports that conclusion.[25] As a result, at this time making firm recommendations about the indications for periosteal transection and elevation is difficult. However, periosteal transection and elevation has a low likelihood of complications and may be effective. The procedure is inexpensive and can be done in the field and therefore may be an option for clients with foals with carpal valgus in which a transphyseal bridging is undesirable or unnecessary. One indication is the very young foal born with a notably asymmetric epiphysis that results in a severe carpal valgus. This distal radial appearance is not particularly common, but the lack of ossification in the epiphysis can make a firm hold

with a transphyseal bridging difficult to achieve. However, one can use distolateral radial periosteal elevation at an early age in an attempt to accelerate correction of the valgus and protect developing carpal bones.

Often a degree of anxiety exists about correction of fetlock angulations because of the much shorter time period for physeal growth. Most fetlocks are in their final conformation by 60 days of age, so correction is best accomplished with earlier treatment, usually by 4 weeks of age. One can perform periosteal elevation on 1436
the medial (for varus deviations) or lateral (for valgus deviations) aspect of the distal metacarpus/metatarsus. 1437

The definitive treatment of limb angulation at a growth plate is transphyseal bridging. One should consider using the procedure at about 3 weeks of age for all moderate to severe fetlock deviations, at about 4 weeks for severe carpal deviations, and 6 to 8 weeks for mild fetlock deviations, moderate carpal deviations, and any worsening angular deformities. One must perform bridge removal when the limb straightens to prevent overcorrection.

Diaphyseal deviations are rare but can occur in varying degrees of severity. If the foal can bear weight on the limb, a conservative approach is indicated. One can consider periosteal elevation of the length of the concave surface of the long bone. If the foal cannot bear weight on the limb because of the severity of deviation, euthanasia is probably the best option. However, a revision osteotomy and internal fixation may be appropriate for selected foals.[26] Polydactyly is also rare and sometimes can be corrected surgically. The outcome is based on the degree of articular involvement.

19.13.7 ORTHOPEDIC INFECTIONS IN NEONATAL FOALS

Bacteria may invade the foal musculoskeletal system and cause orthopedic infection after delivery by the circulation, by direct extension from another system, or by direct inoculation. Hematogenous delivery is by far the most common and results in infection of synovial structures (joints, tendon sheaths, bursae) and bone. Extension from another site without hematogenous delivery is rare. Direct inoculation almost exclusively results from traumatic rather than surgical wounds.

Much is still to be learned about the pathophysiology of orthopedic infection, including the source of the infecting bacteria. The umbilicus commonly is accepted as a possible source of bacteria,[27] but many believe that the gastrointestinal and respiratory tracts are at least equally responsible. Associated conditions in foals with septic arthritis include failure of passive transfer, pneumonia, and enteritis.[28] The classification of orthopedic sepsis in foals into infection of bones and joints is probably irrelevant because most foals with septic arthritis also have infectious osteitis or osteomyelitis.[27,29] Septic arthritis is more readily recognizable because the reactivity of the synovium to the bacteria causes joint effusion and lameness and because early radiographic signs of bone infection in foals are equivocal.

Also unclear are the reasons for the apparent site predilection for orthopedic infection in foals. The femoropatellar joint and the tarsocrural joint are affected most frequently, followed by the carpal and fetlock joints, and finally an assortment of miscellaneous joints such as the elbow, shoulder, and hip.[28] The common association of osteomyelitis of the distal femoral, tibial, and metacarpal/metatarsal physes with a newly recognized septic arthritis suggests that the infection in that area started at the growth center (epiphysis, physis, or metaphysis). The localization of the apparent initial site of infection to the growth center has been suggested to result from “looping” metaphyseal vessels with sluggish blood flow that allow pathogens more time to escape the circulation.[29,30] However, transmission electron microscopy indicates that osteogenic cells and the

vascular endothelium are a continuous network in developing embryos,[31] indicating that the relationship between circulation and bone is more intimate than previously suspected.

A possible association between osteomyelitis and thickened or traumatized cartilage exists. Focal osteomyelitis lesions occur commonly at the bone cartilage junction[27,29] and particularly in areas where cartilage is attached at an angle to the long axis or where thickened.[29] An association also exists between incomplete ossification of the central and third tarsal bones and osteomyelitis.[32] Trauma to the metaphysis is a known predisposing cause of osteomyelitis in young bacteremic rabbits.[33] A trend exists for foals with more than one joint affected to be affected bilaterally in the same joint, rather than in random joints. This trend suggests that a “window” exists when a joint may be more susceptible to infection and that trauma to the developing cartilage may be a contributing factor. In neonates, cartilage is vascular,[34] and possibly small traumatic cartilage lesions with associated hemorrhage and exposure of bacterial binding sites might be the inciting cause for the location of infection.

The pathogens most commonly associated with septic arthritis in young foals are also those that frequently are implicated in neonatal sepsis. The most commonly isolated gram-negative organisms are *Escherichia coli* and other Enterobacteriaceae, *Actinobacillus equuli,* and *Salmonella* spp. Frequently isolated gram-positive organisms include *Streptococcus* spp., *Staphylococcus* spp., and *Rhodococcus equi*.[28] Anaerobic bacteria and fungi are rare but should be considered in refractory cases.

The diagnosis of orthopedic sepsis can be challenging. The most common clinical sign is lameness, followed by swelling around a joint or metaphysis. Joint effusion alone may cause the swelling, but edema is also common, especially if metaphyseal osteomyelitis is present. But effusion and edema can be difficult to detect because of the tissue surrounding the focus of infection in the shoulder, elbow, hip, and coffin joints. One should evaluate lame foals carefully by palpation to localize pain and swelling. If one can find no pain or swelling, one should obtain a complete blood count and fibrinogen level. Although a complete blood count is not always abnormal in 1437
foals with septic arthritis, abnormalities should raise the index of suspicion of infection. Elevations in 1438
fibrinogen are fairly common in septic arthritis,[28] and fibrinogen almost always is elevated if the infection involves bone. If hematologic values are normal, the lameness could be caused by trauma, but the foal should be monitored closely for improvement, and closer evaluation is indicated if improvement is not rapid.

An arthrocentesis is the diagnostic test of choice for confirmation of septic arthritis. One should perform joint puncture in a sterile fashion, and sedation is indicated to get an atraumatic tap. Short-term anesthesia is preferable when joints have effusion because one may perform joint lavage at the same time. Normal joint fluid should be clear to slightly yellow, should be viscous, and should contain less than 2500 nucleated cells per deciliter. The cell ratio should be roughly 50:50 polymorphonuclear and mononuclear. The total protein content should be less than 2.5 mg/dl. One should consider joints to be infected if the nucleated cell count is greater than 10,000 cells/dl. For joints falling between 2500 and 10,000 cells/dl, if the polymorphonuclear cell count is >90%, one should consider the joints infected. Cytologists are often reluctant to diagnose infection when nuclear degeneration or bacteria are not visible. This is overly conservative and results in delay in treating infections because bacteria and nuclear degeneration are rare in early cases of joint infection. Out of an abundance of caution, one should treat lame foals with suspicious joints as infected unless they are clearly normal. One should always culture joint fluid in an attempt to identify the offending organisms, but because of difficulties in culturing pathogens from joint fluid samples, absence of growth does not mean absence of infection. One obtains the best culture results if the foal has not been treated with antimicrobial agents beforehand. One should obtain as much joint fluid as possible for culture and should incubate it overnight in

blood culture media before plate inoculation. As always in potentially septic foals, blood culture may assist in the isolation of the organism.

Other orthopedic infections that do not involve the joint may be more difficult to detect. Often these are not apparent until infection breeches the joint and causes lameness. However, astute caretakers may notice early clinical signs such as mild lameness, fever, or edema centered at a growth center. Radiography and advanced imaging modalities such as magnetic resonance imaging are the best diagnostic tools for the localization of areas of osteitis and osteomyelitis. One should examine the area of concern carefully, giving particular attention to the growth centers and subchondral bone. Interpretation of radiographs may be difficult because these areas are complex and normally have irregular bone margins in the growing foal. If a normal contralateral joint is available, comparison radiographs may be useful. Because of the high metabolic turnover in growing foal bone, changes occur faster than with adults, so radiographs at the earliest sign of potential infection of bone and joint are recommended. If evidence of osteolysis is clear, aspiration of the area may yield material for culture.

The goals of treatment are to eliminate infection immediately and then resolve inflammation. Bacteria and products of inflammation elicited by infection are responsible for destruction of bone and cartilage. The ultimate aim of treatment is to protect the structures critical to athletic performance such as subchondral bone and cartilage in weight-bearing areas. Advances in the treatment of sepsis have resulted in hospital discharge rates of 78% for foals with septic arthritis, but their rate of high performers is 30%,[28] indicating a need for improvement. Equine veterinarians cannot replace what has been destroyed, so early identification and aggressive therapies are presently the best methods to improve performance rates.

One achieves the goals of treatment by physical removal of bacteria, products of inflammation, and debris and by medications to kill the bacteria and reduce inflammation. One should optimize the physiology and general health of the foal to assist this process; one should include other treatments and supportive therapies for septic foals, especially treatment of failure of passive transfer, in the therapeutic plan. Intravenous administration of antimicrobials (see Chapter 4) is the cornerstone of treatment of orthopedic infection, and if the drug is administered early in the course of infection and bacteria are susceptible, intravenous administration may be sufficient to eliminate the organisms. However, treatment of many foals does not begin until disease is advanced. If treatment begins after bacteria have had a chance to establish themselves, one should bring all appropriate methods to bear to end the infection.

Additional therapies for septic arthritis include joint lavage, arthrotomy (for drainage),[35,36] debridement (arthroscopically or arthrotomy),[37] intraarticular administration of antimicrobials, intravenous regional perfusion,[38] and antimicrobial beads.[39,40] One can use any sterile isotonic solution to flush a joint, and additives do not appear to give significant additional benefit. If radiographs do not indicate osteomyelitis, lavage, intraarticular antibiotics, and if possible, regional perfusion are recommended. If osteitis or osteomyelitis is present, debridement is indicated arthroscopically or via arthrotomy (one should culture the debris if the pathogen is unknown). If the joint is closed, one may use antibiotics intraarticularly. If the joint is left open to drain, regional perfusion is useful. Antimicrobial beads theoretically are best to use if the wound is closed, but they appear to give benefit even if the wound is open under a bandage. Because of concerns about 1438
the use of beads in a joint,[41] beads often are used in tissue defects and the surrounding tissues. The major goal 1439
is to remove material that is compromising healthy tissues and to obtain high concentrations of antimicrobials in infected tissues.

High antimicrobial concentrations are necessary because adhered bacteria are difficult to kill and may require many times the in vitro bacterial minimum inhibitory concentration. Intraarticular administration of

antimicrobials has been used for many years and has great value.[35] Regional perfusion of diluted antimicrobials recently has come into use and may be administered intraosseously[42] or intravenously. Intravenous perfusion is preferable because no special equipment is needed, but intraosseous perfusion may be valuable where intravenous access is impossible. The concept behind both procedures is to fill the venous vasculature in the area of the infection with antimicrobials diluted by a sterile balanced electrolyte solution. One isolates the anatomic area of interest using one or two tourniquets. The perfusate diffuses into all tissues and achieves much higher concentrations than are possible using intravenous therapy. This technique has shown excellent results as an adjunct therapy for orthopedic infection.[43] For foals, 12 to 20 ml total of perfusate containing 250 mg amikacin is useful for most single joint sites. Amikacin has given consistently good results without complication and is a good choice based on its concentration-dependent activity. One may use a higher volume for the stifle, but the thigh musculature makes an effective tourniquet difficult to achieve. Because of concerns that perfusion might dislodge bacteria and renew systemic sepsis, high concentrations of systemic antimicrobials are recommended at the time of the perfusion.

If joint lavage and intraarticular administration of antimicrobials are not sufficient to resolve infection, one may perform arthrotomy to assist the joint to drain. Passive and active drains add foreign material and so are not useful. Maintaining the joint under a sterile bandage is critical and can be difficult to do in proximal joints such as the stifle and elbow. Tie-over bandages can be useful in this application.

The best measure of success is the resolution of lameness and local inflammation. Radiographs may be helpful, but the most common sign of success is a failure of the infection to progress, rather than radiographic healing. One should continue intravenously administered antimicrobials for at least 1 week after the resolution of lameness. If an appropriate drug is available, one should give foals antimicrobials orally for at least 2 weeks more. A total of at least 4 weeks of antimicrobials is recommended for most foals with orthopedic infection.

Treatment failures usually result from an inability to kill bacteria adhered to isolated tissue (usually dead bone). Sometimes this failure is caused by incomplete debridement or an inability to access a known site of infection, but more frequently it is because infection has flourished in an unknown site. For this reason, multiple imaging modalities (radiographs, ultrasound, computed tomography, and magnetic resonance imaging) used multiple times are recommended for all refractory cases of septic arthritis.

Osteomyelitis not associated with a joint still involves a growth center. The ideal treatment for these infections is surgical debridement, systemic antimicrobial therapy, and some form of local antibiotic delivery.[44,45] Even in the face of large initial osseous defects, infection may resolve, the defect may heal, and the foal may regain normal limb anatomy and function with appropriate therapy.

20 CHAPTER 20 TOXICOLOGIC PROBLEMS

David G. Schmitz

In today's society, any list of substances that are toxic or potentially toxic is probably incomplete. Industrial society is producing new and different compounds continuously that are potentially hazardous or fatal to human beings and many species of animals. Knowledge of toxic compounds and the mechanisms whereby they produce disease also is changing constantly, so certain substances that previously were thought to be inert now are known to affect the health of animals or human beings.

It behooves the veterinary clinician to be as informed as possible concerning the potentially toxic substances found in the environment. Not all toxins are distributed uniformly in nature (this is particularly true of toxic plants), so another reasonable assumption seems to be that in any given geographic area, certain toxicities are much more common than others.

Many factors influence the toxicity of a given substance, and exposition of these factors in great detail is not within the scope of this chapter. Books have been written on specific aspects of toxicity and all the different mechanisms that come into play relating to a specific substance causing harm to a specific animal at a specific point in time. The reader is referred to other sources for information regarding general toxicologic principles and measurements and quantification. One should note that factors such as age, species of animal, reproductive status, nutritional status, management, diet, and numerous other factors relating to the animal can influence the toxicity of a given substance. Other factors related to the compound itself—such as its bioavailability, its chemical form or structure, its concentration, and so forth—also can influence the toxicity of a substance at any point in time.

Most toxins do not damage a solitary tissue, organ, or organ system preferentially but frequently affect several organs or body systems at the same time. Although for clinical signs to be related predominately to a single organ system is not unusual, multiple organ involvement is the rule rather than the exception. This fact necessitates a thorough examination and evaluation of any animal presented for diagnosis of possible toxicosis. One should evaluate all body systems adequately in the animal that is suspected of having a toxicity.

The clinical manifestations of many toxicologic problems occur some time following initial exposure to the toxin. This delay can make diagnosis and treatment difficult. For this reason, many cases of suspected toxicity are treated empirically. If a specific antidote is available or indicated, however, one should use it in the treatment regimen. General rules of thumb regarding treatment of suspected toxicoses include the following:

1. Removal of the source from the environment, if possible
2. Removal of the toxin from the body of the animal, if possible
3. Cleaning the skin or contact surface with suitable agents if the route of exposure is superficial
4. Evacuation of the gastrointestinal tract by appropriate means if contamination was via ingestion
5. Maintenance of normal body functions and physiologic processes as much as possible by means of fluid administration and blood pH and electrolyte modification
6. Maintenance of body functions not affected by the toxin
7. Aiding elimination of the toxin source from the system of the animal as expeditiously as possible

8. Not causing damage to a secondary organ or system while treating the primary toxicosis

9. Preventing reexposure or recontamination of the animal by the toxic substance

In this chapter the toxins have been divided into broad categories of general clinical signs. A toxin is discussed most completely under the system to which the major clinical signs are referable. One must remember, however, that most toxins involve more than one organ system, so a number of toxins can be found in several categories. Specific antidotes are given where appropriate, and treatment aimed at symptomatic care is given at the end of each section.

20.1 Toxicoses Causing Signs Relating to the Gastrointestinal System

There is a wide range of toxic agents capable of inducing signs of gastrointestinal disease. Signs can vary from wild of chronic to peracute and life threatening. At times, determination that a toxicosis is the cause of a problem like diarrhea or colic can be difficult, time consuming, and relatively costly.

20.1.1 PLANTS

20.1.1.1 Oak (*Quercus* Species)

20.1.1.1.1 Clinical Signs

Oak blossoms, buds, leaves, stems, and acorns can be toxic to livestock. Most reports of toxicosis in livestock involve cattle and sheep, with a rare occurrence in the horse. Clinical signs attributed to acorn toxicosis in horses are acute onset of severe abdominal pain, rectal straining, hemorrhagic diarrhea, and pronounced intestinal borborygmi. One may note acorn parts in feces. Occasionally, horses are found dead, but other signs are hemoglobinuria and elevated heart and respiratory rates.

20.1.1.1.2 Pathophysiology

The toxicity of oak is attributed to tannins or their metabolites. Digallic acid is the major active metabolite produced by oak tannins. Following bacterial fermentation, digallic acid is converted to gallic acid and pyrogallol, both of which are considered toxic.[1] Pyrogallol and gallic acid are toxic to renal tubules and result in acute tubular necrosis, anuria, electrolyte abnormalities, and uremia.[1,2] Pyrogallol is also responsible for causing hemorrhagic gastroenteritis, subcutaneous hemorrhage, and hemolysis. Tannic acid itself is thought to result in increased vascular permeability, hemorrhage, and subsequent fluid loss into body spaces.[1]

20.1.1.1.3 Diagnosis

The diagnosis of oak toxicity is based on clinical signs and a history of exposure to the plant. Under adequate forage conditions, horses would seem to have a distaste for oak leaves and acorns, so most horses exposed to the plant do not develop toxicity. Toxicosis is more likely to result when abnormal conditions coupled with environmental factors result in large numbers of acorns being produced and becoming accessible to horses.

Laboratory findings compatible with oak toxicosis include dehydration or hemoconcentration to varying degrees, azotemia, hyperphosphatemia, hypocalcemia, and hypoproteinemia. Abnormal urine findings might include occult blood, proteinuria, and casts. An increase in gallic acid equivalent content in urine also has been used to support a diagnosis of oak toxicity.[1]

Necropsy findings suggestive of oak toxicosis include pericardial, thoracic, and peritoneal effusion; gastrointestinal and mesenteric edema; and pale and swollen kidneys that may bulge on cut surface. The intestinal tract may contain large quantities of acorn parts, and colonic ulceration has been reported.[1]

20.1.1.1.4 Specific Treatment and Management

No specific antidote for oak toxicity is available. Animals should be removed from further access to oak. Treatment of the acutely affected animal aims to maintain fluid and acid-base balance and to correct any electrolyte abnormalities. Balanced polyionic fluids given intravenously to promote diuresis are the basic therapy. One should supplement this therapy with calcium, bicarbonate, and other electrolytes as necessary. Anuric animals may gain additional benefit from furosemide at 1 mg/kg intravenously or dimethyl sulfoxide (DMSO) at 1 g/kg intravenously given as a 10% solution in addition to fluid therapy. One should attempt evacuation of the intestinal tract using mineral oil or other suitable laxative.

The prognosis for affected horses is guarded. A paucity of information exists concerning mortality rates in affected horses, but death caused by ingestion of acorns has been reported.[1]

20.1.1.2 Oleander *(Nerium oleander)*

20.1.1.2.1 Clinical Signs

In the literature, sudden death is the most common sign attributed to oleander poisoning. Other reports suggest that affected horses exhibit lethargy, inappetence, and occasional signs of abdominal pain.[3,4] Profuse, watery, catarrhal, or bloody diarrhea also may occur within a few hours of ingestion.[5] Cardiac irregularities, including alternating bradycardia and tachycardia, may be accompanied by a variety of arrhythmias.[5,6] The extremities of the horse may feel cold to the touch, and mucous membranes may appear blanched. Profuse sweating and muscle twitching are followed by weakness and death. Death may occur less than 12 hours following ingestion.

The green plant apparently is unpalatable to horses. Most toxicities occur when leaves have been incorporated into lawn clippings and offered to horses. Drying does not affect the toxicity of the leaves; therefore leaves incorporated into hay also may be toxic. According to reports, 0.005% of the horses body weight of green oleander is lethal to horses.[3] 1442

1443

20.1.1.2.2 Pathophysiology

Common oleander contains at least five cardiac glycosides that are found in all parts of the plant.[3,5,7] These glycosides (oleandrin, digitoxigenin, neriin, folinerin, rosagenin) inhibit the Na^+,K^+-ATPase (adenosinetriphosphatase) system, resulting in hyperkalemia, conduction abnormalities, and ventricular

arrhythmias. Which glycosides or metabolites cause specific symptoms is unclear because of undefined pharmacokinetics of the individual glycosides.[7]

20.1.1.2.3 Diagnosis and Treatment

Exposure to the plant along with the aforementioned clinical signs should alert the clinician to the possibility of oleander toxicity. The rapidity of onset of clinical signs or the finding of dead animals may preclude any effective treatment. One should initiate symptomatic therapy in those animals in which toxicosis is suspected. Evacuation of the intestinal tract by laxatives and enemas may be useful. Atropine and propranolol have been advocated, but one must use them wth extreme caution.[5,6] One should not use fluids containing calcium because they may augment the effects of the glycoside on the myocardium.[3]

20.1.1.3 Castor Bean *(Ricinus communis)*

20.1.1.3.1 Clinical Signs

Castor beans contain ricin, a protein phytotoxin that acts as a potent proteolytic enzyme with significant antigenic qualities.[6] A latent period ranging from hours to several days usually occurs before the onset of clinical signs in affected horses. The bean is apparently distasteful to horses, and intoxication most likely occurs when the bean inadvertently is mixed into the feed source.

The most commonly reported clinical signs of castor bean toxicosis described in the literature are varying degrees of abdominal pain, diarrhea, depression, incoordination, profuse sweating, and increased body temperature. One occasionally observes muscle twitching, convulsions, and prominent cardiac contractions. If the horse absorbs enough ricin, signs of shock and anaphylaxis predominate.[5,6] Death may ensue as soon as 24 to 36 hours following ingestion.

Ricin is reported to be toxic to horses. One reference cites a dosage of 0.1 μg/kg as a lethal dose,[6] and a second source indicates 25 g of castor beans is lethal.[5] No recent report of ricin or castor bean toxicosis could be found, but a published report in 1945 describes seven deaths attributed to castor bean toxicosis from a stable of 48 horses in London in 1931.[8] The exact number of affected horses was not reported. A recent review of the human literature suggests that castor bean (ricin) toxicosis in human beings is not nearly as lethal as reported in the early twentieth-century literature.[9] Whether this holds for horses is open to speculation.

20.1.1.3.2 Pathophysiology

The oil extract of the bean contains ricinoleic acid. Within the small intestine, ricinoleate acts to reduce net absorption of fluid and electrolytes and stimulates peristalsis.[10] The fibrous residue of the seed contains the water-soluble toxalbumin ricin. Ricin is absorbed from the gastrointestinal tract and is a potent inhibitor of protein synthesis. Ricin contains two polypeptide chains. Chain B, a lectin, binds to the cell surface to facilitate toxin entry into the cell. Chain A disrupts protein synthesis by activating the 60S ribosomal subunit. The red blood cell agglutinating properties of ricin are independent of these toxic effects.[7]

20.1.1.3.3

Diagnosis

One makes the diagnosis by a combination of history of exposure to the plant, clinical signs, and the identification of seeds in feed material or feces. Radioimmunoassay for ricin content in urine is available from certain laboratories.[7]

20.1.1.3.4

Treatment

Ricin has no specific antidote. Initial therapy aims to combat shock, alleviating abdominal pain, and evacuating the bowel. Maintenance of fluid and electrolyte balance is important. Various sedatives and analgesics may be useful to control abdominal pain, if present. Oral administration of laxatives and protectants such as mineral oil and charcoal is indicated. Antihistamines also have been recommended.[6]

20.1.1.4

Pokeweed *(Phytolacca americana)*

20.1.1.4.1

Clinical Signs

No reports of pokeweed intoxication in horses could be found in the literature. However, one text reports that horses show signs of gastrointestinal irritation and abdominal discomfort as the primary clinical signs. The plant also produces a burning sensation of the oral mucous membranes and may cause a hemolytic crisis. Fatalities caused by pokeweed ingestion are said to result from respiratory failure and convulsions.[11]

20.1.1.4.2

Pathophysiology

The plant contains phytolaccine, a powerful gastrointestinal irritant, which in human beings causes symptoms ranging from a burning sensation of the alimentary tract to severe hemorrhagic gastritis. Five nonspecific mitogens that have hemagglutinating and mitotic activity have been isolated. These substances vary in concentration in the plant throughout the growing season. Noncardiac steroids and triterpenoid glycosides (saponins) are also present in significant quantities, but their role in pokeweed toxicity is not known.[7] Saponins may potentiate gastrointestinal toxicity and produce vasodilation when given parenterally.

20.1.1.4.3

Diagnosis and Treatment

No specific diagnostic test is available. One must treat horses suspected of having toxicosis symptomatically. One should attempt to evacuate the gastrointestinal tract using laxatives. Adsorbents such as charcoal and protectants may be useful. If animals develop a hemolytic crisis, ancillary therapy such as whole-blood transfusions may be lifesaving. One must maintain fluid and electrolyte balance in such animals to attempt to prevent or minimize hemoglobin nephrosis.[11] 1443

20.1.1.5 ## Nightshade (*Solanum* Species)

20.1.1.5.1 ### Clinical Signs

A number of species of *Solanum* have been incriminated in causing toxicity in horses. However, these plants are rarely a source of natural intoxication to horses. Reported clinical signs are referable to the gastrointestinal and central nervous systems. The primary gastrointestinal signs noted are salivation, abdominal pain, increased borborygmi, and diarrhea. Signs of central nervous system (CNS) dysfunction include mydriasis, dullness, depression, weakness, and progressive paralysis, which can lead to prostration and death.[16,17]

20.1.1.5.2 ### Pathophysiology

Solanine is the toxic substance found in *Solanum* species, is a water-soluble glycoalkaloid capable of producing local irritation,[5,7,11] and is absorbed poorly from the gastrointestinal tract. Intravenous doses caused ventricular fibrillation in rabbits, and intraperitoneal doses caused mild to moderate inhibition of specific and nonspecific cholinesterases.[7]

20.1.1.5.3 ### Diagnosis and Treatment

No specific diagnostic test is available. One should treat animals suspected of having toxicosis symptomatically. Evacuation of the gastrointestinal tract using laxatives and protectants is indicated. Charcoal also has been recommended for treatment of toxicosis in human beings.[7] One should monitor fluid, electrolyte, and acid-base status of affected animals and make corrections as needed.

20.1.1.6 ## Jimson Weed (*Datura* Species)

20.1.1.6.1 ### Clinical Signs

Several species of *Datura* grow throughout North America, all of which can produce signs of toxicosis in livestock. However, these plants are rarely a source of natural intoxication to horses, probably because of the unpalatability of the plant.[12,13] One report of equine acute toxicosis resulted when ingested feed was contaminated heavily with jimson weed seeds. In this report, one horse was affected acutely and died because of gastric rupture and gas-filled intestinal loops. A second horse was treated for several days before being euthanized. Clinical signs noted in the treated horse included abdominal distention with gas-filled intestinal loops, prolonged ileus, mydriasis, tachycardia, hyperpnea, and dry mucous membranes.[14]

20.1.1.6.2 ### Pathophysiology

The toxic substances found in *Datura* species are the tropane alkaloids atropine (a racemic mixture of d- and l-hyoscyamine) and scopolamine (l-hyoscine).[12–14] These substances exert an antimuscarinic effect by competitive inhibition with acetylcholine for receptor sites, resulting in attenuation of the physiologic

response of neuroeffector junctions to parasympathetic nerve impulses. Blockade of the muscarinic receptors of different tissues accounts for the various clinical signs observed.

20.1.1.6.3 Diagnosis and Treatment

One may suspect toxicity when animals exhibit signs compatible with atropine overdose. Identification of seeds in ingesta, gastric lavage contents, or feedstuffs may support diagnosis. Treatment is largely symptomatic, including immediate removal of the offending feed or plants, evacuation of the gastrointestinal tract, and supportive care. The use of pilocarpine and physostigmine to counteract the atropine-like effects of these alkaloids is controversial.[12,13]

20.1.1.7 Blue-Green Algae

20.1.1.7.1 Clinical Signs

The occurrence of algal poisoning in livestock is sporadic, and reports of intoxication in horses are rare. Most cases of toxicity involve other grazing animals, principally cattle and sheep, but horses are reported to be affected.[15] Toxicity may occur during times that favor algal growth in surface water. The two most important factors that favor algal growth are a nutrient source (such as nitrogen or phosphate) and warm temperature. Therefore toxicosis is most likely to occur during periods of warm weather (late spring through fall) when surface water may be contaminated with fertilizer runoff or organic waste high in nitrogen, such as that from feedlots.[15,16]

At least eight genera of blue-green algae are known to be toxic; these are *Anabaena, Aphanizomenon, Microcystis,* Coelosphaerium, Gloeotrichia, Lyngbya, Nodularia, and *Nostoc,* but the first three are of most concern in veterinary medicine. Common signs of algal poisoning are rapid appearance of abdominal pain, diarrhea, muscle tremors, dyspnea and cyanosis, prostration, and death. These signs frequently develop within a few minutes (<1 hour) of ingestion. Some cases may show rapid onset of CNS dysfunction with seizures, prostration, and death. Animals surviving several days may exhibit hemorrhagic diarrhea, muscle tremors, signs of liver damage, and photosensitization.[15,16]

20.1.1.7.2 Pathophysiology

Anabaena flos-aquae contains a low-molecular-weight alkaloid named anatoxin A, or very-fast-death factor. This toxin produces a potent postsynaptic depolarizing neuromuscular blocking agent that has a curare-like action. Death results from respiratory arrest. Blooms of *Aphanizomenon flos-aquae* produce a neurotoxin (saxitoxin) and at least three related toxic compounds of unknown structure.[7,15] Saxitoxin blocks sodium conductance through excitable membranes, which subsequently stops nerve action potential. Death resulting from saxitoxin is from respiratory neuromuscular paralysis.[15]

Microcystis aeruginosa produces at least two toxic substances. Microcystin (fast-death factor) is a lethal, low-molecular-weight cyclic peptide endotoxin that is released by *M. aeruginosa* on cellular decomposition.[7,15] This algal species also contains a cyclic peptide hepatotoxin that is potent, rapid acting, 1444
and causes hepatocellular necrosis and collapse of the hepatic parenchyma. The immediate cause of death 1445
is hemorrhagic shock resulting from the liver lesions.[17]

20.1.1.7.3
Diagnosis and Treatment

No practical means of isolating and identifying toxins from affected animals or suspect water is available. Because the concentrations of algae and toxins can vary tremendously over a short time, recovery of the toxin from water may not be possible when clinical signs are noted. Likewise, no specific assay for toxin has been developed for use on animal tissues. At best one can make a presumptive diagnosis when conditions favoring algal overgrowth are present, coupled with exposure of animals to the algal source and the rapid onset of clinical signs. One can analyze water samples for identification of specific blue-green algae, and their presence may support a diagnosis of algal toxicity.[15]

No specific antidote is available, and animals often are found dead before treatment can be initiated.[15] Algal growth in surface water can be controlled by a variety of herbicides and copper sulfate. When water is treated with these compounds, one must take care to ascertain the compounds are being used in a safe manner for all susceptible livestock.

20.1.2
MEDICATIONS

20.1.2.1
Lincomycin and Clindamycin

20.1.2.1.1
Clinical Signs

Signs of illness in horses generally are not apparent until 2 to 4 days following exposure. Subsequently, affected horses show signs of colitis and endotoxemia, with development of moderate to severe abdominal pain, tachycardia, congested mucous membranes, loose to watery feces that may contain blood, and elevated rectal temperature. Leukopenia may be present initially, and dehydration can develop rapidly. Some horses also develop laminitis during the episode or following acute illness.[15,18]

20.1.2.1.2
Pathophysiology

Lincomycin is elaborated by an actinomycete, *Streptomyces lincolnensis,* and largely has been replaced in human medicine by its derivative, clindamycin.[19] Although no reports of equine toxicosis involving clindamycin were found, one should consider the antibiotic potentially toxic to horses because of its similarity to its parent compound, lincomycin. The oral minimal toxic dose of lincomycin in horses has not been established, but in one report, a dosage of less than 0.5 mg/kg body mass daily for 2 days caused clinical illness.[18]

Several mechanisms have been suggested to cause the necrotic and pseudomembranous lesions in the colon of affected horses. These mechanisms include bacterial overgrowth of certain pathogens, particularly *Salmonella,* Clostridium perfringens, and *Clostridium difficile;* direct toxic action of the antibiotic; and a hypersensitivity reaction to the drug.[15,18,20] Overgrowth of *C. difficile* now is thought to be the primary reason for the toxic signs in human beings.[19] Because these drugs have the potential to disrupt the normal cecal and colonic microflora, one suggestion is that their toxicity may involve colonization and invasion of the colon by pathogenic bacteria and release of bacterial toxins.[20]

20.1.2.1.3 Diagnosis and Treatment

A history of exposure to lincomycin, accompanied by a delayed onset of acute diarrhea and signs of endotoxic shock, suggest possible toxicosis.[15] Signs of colitis and endotoxemia from other causes are similar to those of lincomycin and clindamycin. Feed can be analyzed for lincomycin content.

Specific antidotes are not available. One should remove the suspect feed immediately and should treat affected horses symptomatically. Evacuation of the bowel using laxatives and orally administered gastrointestinal protectants may be useful to prevent further colonization and invasion of pathogenic bacteria. One should maintain fluid volume and normal electrolyte and acid-base concentrations by appropriate means. Other specific therapies for acute colitis, endotoxemia, and laminitis may be found elsewhere in this book.

20.1.2.2 Other Antibiotics

The oral administration of certain other antibiotics also is reported to induce colitis in horses. The use of trimethoprim-sulfonamides and erythromycin base has been associated with diarrhea in a small number of horses.[20] The mechanism whereby they induce colitis also may be related to their ability to alter normal intestinal microflora and allow overgrowth of pathogenic bacteria.

20.1.2.3 Imidocarb

Imidocarb diproprionate has been used to treat *Babesia* infections in horses. The recommended dose for *Babesia caballi* is 2 mg/kg intramuscularly for each of 2 consecutive days. *B. equi* is more difficult to eliminate from the horse and a dosage of 4 mg/kg intramuscularly at 72-hour intervals for a total of five injections is recommended. However, one cannot rely even on this high dosage to eradicate *B. equi*. Higher doses than this are usually toxic to the animal.[21,22]

20.1.2.3.1 Clinical Signs

The clinical signs of toxicity are dose-dependent. All horses given an intramuscular dose of 4 mg/kg exhibited signs of parasympathetic stimulation characterized by lacrimation, excessive sweating, and serous nasal discharge for 30 minutes after treatment.[21] Larger doses, including 16 mg/kg and 32 mg/kg, resulted in horses showing pronounced systemic signs of violent peristalsis and projectile diarrhea, colic, dyspnea, miosis, and depression leading to recumbency for 1 to 4 hours following treatment. Subsequently these horses became anorectic 1 to 2 days following injection. Local swelling at the injection site is almost 1445
always present. Fatal intoxications induced profound depression before coma and death. The median lethal 1446
dose (LD_{50}) was determined to be approximately 16 mg/kg, with mortalities occurring within 6 days of the first injection.[21]

20.1.2.3.2 Pathophysiology

Imidocarb has been proposed to exert its parasympathomimetic activity by inhibiting cholinesterase. Imidocarb is absorbed rapidly from muscle, is disseminated widely in tissues, but selectively concentrates

in the CNS, kidney, and liver. Imidocarb causes diffuse, acute necrosis of the proximal convoluted tubules in the kidney and hepatocellular necrosis and biliary stasis in the liver. The degree of hepatic and renal damage is dose-dependent.[21] The toxic mechanism at the cellular level has not been elucidated.

20.1.2.3.3 Diagnosis and Treatment

Diagnosis of toxicity must be consistent with exposure to the drug. Certain clinicopathologic abnormalities are common in affected horses. Laboratory evidence of hepatic and renal damage is evidenced by increased serum concentrations of aspartate aminotransferase (AST), sorbitol dehydrogenase, and urea nitrogen. Elevated creatine kinase (CK) concentration in serum probably reflects the myositis that develops at the injection site.[21]

No specific antidote for imidocarb toxicity is available. Therapy is largely symptomatic and must aim at supportive therapy for the liver and kidney. Because the toxicity is dose-dependent, no therapy is effective for horses receiving a lethal dose of greater than 16 mg/kg body mass.

20.1.2.4 Atropine

Atropine is a commonly used medication in equine practice in diagnosis and treatment of a variety of disorders. Toxicity from atropine administration most likely results from its physiologic effects on the different body organs and systems rather than from any toxic effect of atropine itself. Complications of excessive atropine administration principally involve abnormal function of the gastrointestinal system.

20.1.2.4.1 Clinical Signs

Clinical signs of atropine overdose in the horse essentially are those of colic.[23] Reduced gastrointestinal motility and ileus may lead to signs of severe abdominal pain characterized by sweating, pawing or kicking at the abdomen, attempts to lie down and roll, and so forth. The severity of signs depends on the amount and degree of gaseous distention of the bowel, the tolerance of the horse to painful stimuli, and any complication associated with severely distended bowel impinging on or affecting another organ or tissue. Reduced motility may be present for several hours. If secondary problems are avoided, the horse usually returns to normal within 12 to 24 hours.

20.1.2.4.2 Pathophysiology

Atropine interacts with muscarinic receptors of effector cells and by competitive antagonism prevents acetylcholine from affixing to the receptor area. The net effect is that physiologic responses to parasympathetic nerve stimulation are attenuated or abolished. Although atropine acts immediately distal to all postganglionic cholinergic nerve endings, the net pharmacologic effect in a particular organ is influenced by the relative dominance of sympathetic or parasympathetic tone in that organ. Salivary and sweat glands are susceptible to small doses of atropine, and increasing dosages are required for a vagolytic effect on the heart and for relaxation of gastrointestinal and urinary tract smooth muscle.

20.1.2.4.3

Diagnosis and Treatment

Most cases of atropine toxicity occur when the drug is used therapeutically. Therefore the primary treatment should be withdrawal or reduced administration of the drug and treatment of any secondary complications of sympathetic nervous stimulation, if necessary. Unless horses become violently painful because of gastrointestinal gas distention, withdrawal of the drug until symptoms subside is usually all that is necessary. Because atropine blockade of muscarinic sites of cardiac muscle, smooth muscle, and glands is caused by competitive antagonism, large doses of acetylcholine or other cholinomimetic drugs may overcome the inhibitory effects of atropine at these sites.

20.1.2.5

Dioctyl Sodium Sulfosuccinate

Dioctyl sodium sulfosuccinate (DSS) is an anionic surface active agent commonly used to treat constipation and intestinal impaction in horses. The recommended dose of DSS is 17 to 66 mg/kg with a maximum dose of 200 mg/kg.[24,25]

20.1.2.5.1

Clinical Signs

Signs of overdose commence within 60 to 120 minutes in affected horses. Initial signs are restlessness and increased intestinal sounds accompanied by steadily increasing heart and respiratory rates. Abdominal pain, watery diarrhea, and dehydration become apparent soon afterward, and horses gradually deteriorate to lateral recumbency and death within 14 to 72 hours.

20.1.2.5.2

Pathophysiology

Much information about the pharmacologic action of DSS remains uncertain.[10] The primary organ of involvement is the small intestine, where epithelial denudation, villous atrophy, and submucosal edema and congestion occur. Dioctyl sodium sulfosuccinate has been suggested possibly to cause epithelial detachment by lowering the surface tension on the basement membranes of intestinal epithelial cells.[25] Once detachment occurs, loss of fluid and electrolytes into the intestinal lumen is extreme. The absorptive capacity of the epithelium is lost, and the osmotic effect of intestinal content causes further loss of fluid into the lumen. With extensive mucosal damage, the horse also becomes much more susceptible to endotoxemia. The rapid death in affected animals is caused by hypovolemic shock, endotoxemia, and circulatory collapse resulting from the loss of fluids and electrolytes into the intestinal lumen. 1446

1447

20.1.2.5.3

Diagnosis and Treatment

Diagnosis of DSS toxicity depends on observation of the aforementioned clinical signs along with oral DSS administration. No specific antidote for DSS exists, and once clinical signs commence, treatment aims at circulatory support and combating the effects of systemic endotoxin. Specific treatment for circulatory collapse and endotoxemia is covered elsewhere, but medications that might be useful include polyionic electrolyte solutions, electrolyte supplementation, corticosteroids, nonsteroidal antiinflammatory drugs (NSAIDs), bicarbonate, and orally administered gastrointestinal protectants.

20.1.2.6 Nonsteroidal Antiinflammatory Agents

The NSAIDs used extensively in equine practice and until recently were thought to be relatively nontoxic. However, in recent years, excessive intake of these agents has been shown to produce signs of toxicity and death. Phenylbutazone has been studied most widely, but flunixin meglumine (Banamine, Schering Corp., Kenilworth, New Jersey) also has been demonstrated to have toxic effects.

The toxic dose of phenylbutazone appears to be 8 to 10 mg/kg body mass, which must be administered for several days to cause signs of toxicosis.[26–29] Dosages of 15 mg/kg or greater, when given on multiple days, can be lethal to horses, with death occurring as early as day 4 of treatment.[27] Ponies may be at greater risk of developing toxicosis, for 10 mg/kg given once daily to ponies resulted in death of several of the animals by day 7 of administration.[28] Foals have been suggested to be more susceptible than adult horses to developing toxicosis when phenylbutazone is given in therapeutic dosages.[30]

Flunixin meglumine appears to be less toxic than phenylbutazone, but foals given 1.1 mg/kg for 30 days developed signs of toxicosis.[31] In another study, administration of flunixin meglumine at a dosage of 6.6 mg/kg/day intravenously for 5 days was necessary to produce signs of toxicosis in a group of foals.[32]

Excessive intake of NSAIDs has been associated with three syndromes: (1) gastrointestinal ulceration,[26–32] (2) renal medullary crest necrosis,[27,28,33] and (3) ulceration of only the right dorsal colon.[30,34,35] Phenylbutazone toxicosis has caused all three syndromes, but flunixin meglumine has been associated only with gastrointestinal lesions. Ulceration and erosion of the digestive tract almost always affect the glandular stomach, large colon, and cecum. The small intestine can be affected, but the predominant lesions tend to involve the large colon.[26–32] Extensive edema of the colonic mucosa often occurs and may precede the development of erosions and ulcers in the large bowel. In isolated cases, only the right dorsal colon has been affected. Renal medullary crest necrosis occurs along with renal tubular epithelial cell necrosis. Renal dysfunction occurs in horses with toxicosis and may progress to acute or chronic renal failure. In clinical situations, renal dysfunction also may be a manifestation of more prolonged use of NSAIDs or the concurrent use of these products in horses with already compromised renal function.

One should use NSAIDs with caution in horses that are dehydrated or hypovolemic or that have preexisting renal disease because these animals are at greater risk of developing toxicosis. Additional factors that may increase the risk of toxicosis include concomitant use of other NSAIDs or other medications with nephrotoxic potential and administration of phenylbutazone in amounts greater than 8.8 mg/kg/day for periods longer than 4 days.

20.1.2.6.1 Clinical Signs

Signs of NSAID toxicosis include anorexia, depression, colic, diarrhea, melena, weight loss, ventral and peripheral edema, petechial hemorrhages and cyanosis of mucous membranes, and ulcerations of the oral cavity and digestive tract.[26–32,34,35] Oral ulcerations can be extensive and can involve the tongue, hard palate, and mucocutaneous junction at the commissure of the lips. Other signs of endotoxemia—that is, fever, impaired cardiovascular function, hemoconcentration, and neutropenia—may be present in some horses. Renal medullary crest necrosis rarely is considered a primary cause of any clinical sign, but signs

of renal dysfunction can accompany some horses with NSAID toxicity. Signs of toxicity can occur as early as the second to fourth day of treatment when excessive quantities are given.[27]

20.1.2.6.2 Pathophysiology

The mechanisms whereby NSAIDs cause gastrointestinal damage and ulceration still are being elucidated. These agents may exert a local irritative effect on the oral and gastrointestinal tract mucosa.[26,30] However, the major mechanism whereby damage occurs may be by inhibition of prostaglandin synthesis in the bowel, which is necessary for normal mucosal integrity and function.

Prostaglandins are formed in various body tissues by the action of cyclooxygenase on arachidonic acid. The intermediate endoperoxides formed then are converted by specific enzymes to metabolically active prostaglandins. Within the gastrointestinal tract, prostaglandins E_1 and E_2 (PGE_1, PGE_2) are of primary importance and exert a number of beneficial effects; they enhance mucosal microcirculatory blood flow, promote reepithelialization following mucosal injury, stimulate bicarbonate and mucous secretion at the mucosal surface, and decrease hydrochloric acid and pepsin secretions in the stomach. These prostaglandins also appear to have other cytoprotective properties that are effected by unknown mechanisms.[29,32]

The NSAIDs inhibit prostaglandin synthesis by inhibition of cyclooxygenase. Within the gastrointestinal tract mucosa, depletion of endogenous PGE_1 and PGE_2 is suggested to result in vasoconstriction of the 1447

1448 microvasculature, leading to mucosal ischemia and subsequent ulcer formation.[29,30] Support for this theory stems from the ability of synthetic PGE_2 to prevent mucosal injury induced by phenylbutazone administration.[29]

Arachidonic acid metabolism may have other effects on gastrointestinal tract function. Several lipoxygenase enzymes act on arachidonic acid to form leukotrienes, which have a variety of effects on the gastrointestinal tract. These substances influence inflammatory cell chemotaxis, fluid and electrolyte secretion, vasoconstriction, and vasodilation. Therefore the use of NSAIDs may shunt arachidonic acid metabolism toward production of these endogenous eicosanoids and may modify the synthesis of prostaglandins within the gastrointestinal tract and other organ systems.

A recent study proposes that phenylbutazone-induced gastrointestinal ulceration results from direct toxic injury to the mucosal microvasculature.[36] This study suggests that the initial toxic injury induced by phenylbutazone in the intestinal tract is damage to the endothelial cells of the microvasculature. As a result, vascular swelling, stagnation and occlusion of blood flow, fibrin formation, and perivascular leakage occur, with subsequent formation of edema, thrombosis, and necrosis of the mucosa. Eventually the mucosal epithelium is sloughed. This study concluded that vasoconstriction was not the primary cause of the mucosal necrosis, and that once formed, erosions and ulcers may be perpetuated by processes not mediated by prostaglandins, such as bacterial invasion.

The mechanisms involved in production of right dorsal colon ulceration are probably similar to those involved in ulcerogenesis in other regions of the digestive tract. Why the lesion is expressed only in the right dorsal colon in some horses is unknown.

Gastrointestinal edema and ulceration are responsible for most of the clinical signs noted with NSAID toxicity. Protein loss, diarrhea, melena, abdominal pain, and endotoxemia are related directly to abnormal gastrointestinal function induced by toxic levels of NSAIDs.

Renal medullary crest necrosis is thought to be caused by inhibition of prostaglandin synthesis within the kidney by NSAIDs. Prostaglandin E_2, $PGF_{2\alpha}$, prostacyclin, and thromboxane are produced in the kidney, with greater amounts being generated in the medulla than in the cortex. The renal prostaglandins are thought to function as local vasodilators to maintain renal blood flow and glomerular filtration rate under adverse conditions but have little or no control over basal renal blood flow and glomerular filtration rate in healthy animals. As a consequence of prostaglandin inhibition, renal medullary ischemia can occur, leading to medullary crest necrosis.[37] Dehydration and hypovolemia may play a significant role in the development of this lesion, along with concurrent phenylbutazone administration.[33]

20.1.2.6.3

Diagnosis and Treatment

One should suspect NSAID toxicity when compatible clinical signs are evident and the animal has a history of inappropriate drug administration. In addition, certain clinicopathologic abnormalities are fairly characteristic of NSAID toxicosis and aid in diagnosis. Hypoproteinemia and hypoalbuminemia are hallmarks of NSAID toxicity, and serum protein concentration can become dangerously low.[26–30,32,34,35] Other abnormalities that are frequently present include increased concentrations of serum urea nitrogen, creatinine, and phosphorus. Serum bilirubin and AST concentrations occasionally are elevated. Serum calcium concentration invariably is decreased and is another consistent abnormal finding. Decreased serum chloride concentration occurs occasionally, and many horses are neutropenic.[26–30]

Treatment of NSAID toxicity is largely symptomatic and directed toward the specific disorders that are present. In all cases, one should evaluate the use of NSAIDs critically and withdraw them if possible. One should administer plasma to severely hypoproteinemic horses, and broad-spectrum antibiotic therapy may be indicated if signs of sepsis or septicemia are present. One should choose antimicrobials with minimal to no nephrotoxic potential, if necessary. One should correct fluid, electrolyte, and acid-base abnormalities but should use caution when giving fluids to an already hypoproteinemic horse. Treatment of gastric ulceration, endotoxemia, and renal failure are discussed elsewhere.

20.1.3

MISCELLANEOUS AGENTS

20.1.3.1

Arsenic

Arsenicals are found in a number of products, including insecticides, herbicides, defoliants, rodenticides, livestock dips, medications, wood preservatives, paint pigments, detergents, and certain insulation materials.[15,38] Horses are most likely to be exposed to arsenic by eating contaminated forage.[38]

20.1.3.1.1

Clinical Signs

The clinical signs associated with arsenic toxicity are essentially those of a severe gastrointestinal irritant. Most toxicities result from inorganic forms of arsenic, and signs are similar in several animal species.

In peracute cases the animals may be found dead with no premonitory signs. Acute signs of toxicity include severe colic, staggering, weakness, salivation, diarrhea that may contain blood or shreds of mucosa, and signs of shock that indicate cardiovascular collapse. Death usually occurs in 1 to 3 days.[15,38,39] In subacute poisoning, animals may live for several days exhibiting signs of depression, anorexia, colic, diarrhea that may contain blood and mucus, polyuria followed by anuria, and subsequent shock before death. Horses that are poisoned by topical application of arsenic can show signs of blistering and edema of the skin.[15] Chronic arsenic poisoning rarely occurs in domestic animals. 1448

1449

20.1.3.1.2 Pathophysiology

Many factors play a role in the development of arsenic toxicosis in horses. In general, horses that are debilitated, weak, or dehydrated are more susceptible to toxicosis than normal animals. The formulation of the compound (trivalent arsenicals are more toxic than pentavalent forms), the solubility of the compound, the route of exposure, the rate of absorption from the gastrointestinal tract, and the rate of metabolism and excretion by the individual animal are factors that can influence the toxicity of the various arsenic formulations.[15] The most hazardous preparations are products in which the arsenical is in a highly soluble trivalent form, usually trioxide or arsenite. Sodium arsenite is 3 to 10 times more toxic than arsenic trioxide. The average total oral lethal doses of these compounds for the horse are 10 to 45 g arsenic trioxide and 1 to 3 g sodium arsenite.[15,38]

Soluble forms of arsenic are absorbed from all body surfaces. Less soluble arsenicals such as arsenic trioxide are absorbed poorly from the gastrointestinal tract and essentially are excreted unchanged in the feces. Following absorption, trivalent arsenic is excreted readily via the bile into the intestine, and pentavalent arsenic is excreted via the kidney. Regardless of whether an introduced arsenical is in the trivalent or pentavalent form, all the major actions can be attributed to the trivalent form.[15]

All arsenicals are thought to exert their effects by reacting with sulfhydryl groups in cells. Trivalent arsenic acts primarily by combining with the two sulfhydryl groups of lipoic acid, thereby inactivating this essential cofactor necessary for the enzymatic decarboxylation of the keto acids pyruvate, ketoglutarate, and ketobutyrate. By inactivating lipoic acid, arsenic inhibits the formation of acetyl, succinyl, and propionyl coenzymes A. The net effect is the blocking of fat and carbohydrate metabolism and cellular respiration.[15,38] Trivalent arsenic also may inactivate sulfhydryl groups of oxidative enzymes and the sulfhydryl group of glutathione and other essential monothiols and dithiols. Arsenic also causes a local corrosive action on the intestine.[38]

Arsenic seems to prefer tissues rich in oxidative enzymes such as the liver, kidney, and intestine. The capillary endothelial cells in these organs appear sensitive to arsenic because it relaxes capillaries and increases capillary permeability. Blood vessels with smooth muscle in their walls also dilate. In the intestinal tract, the mucosa easily sloughs away because of the accumulation of fluid in the submucosa. In the kidney, renal tubular degeneration occurs.[38]

20.1.3.1.3 Diagnosis

The clinical signs described previously should cause one to consider inorganic arsenic poisoning. Antemortem laboratory findings are consistent with gastrointestinal, hepatic, and renal damage. Feces may

contain blood, mucus, and increased numbers of white blood cells. The liver enzymes sorbitol dehydrogenase, lactate dehydrogenase (LDH), AST, and γ-glutamyltransferase (GGT) may be increased in serum, and urine might contain protein, red blood cells, and casts. Urine arsenic concentration in affected animals often exceeds 2 ppm.[15]

Postmortem findings are characteristic of a severe gastroenteritis and may include hepatic lipidosis and necrosis. In suspect horses, one should evaluate the liver, kidney, stomach and intestinal contents, and urine for arsenic content. One also can test blood and milk. Levels greater than 10 ppm confirm arsenic toxicosis.[15]

20.1.3.1.4 Treatment

Specific therapy for arsenic toxicity is dimercaprol (BAL). This chelating agent forms a nontoxic and easily excretable complex with arsenic. However, dimercaprol may mobilize stored arsenic in tissues and cause an initial exacerbation of clinical signs by allowing more arsenic to circulate to the intestine and liver. Dimercaprol also can be toxic if overdosed. Signs of overdosage include tremors, convulsions, coma, and death. In horses the recommended dose is 3 mg/kg intramuscularly as a 5% solution in a 10% solution of benzyl benzoate in peanut oil. One should give this dose every 4 hours for the first 2 days, every 6 hours on the third day, and twice daily for the next 10 days until recovery.[38]

Sodium thiosulfate also has been advocated for treatment of arsenic toxicosis, but its efficacy is questionable. The recommended dose for horses is 20 to 30 g orally in 300 ml of water, plus 8 to 10 g intravenously in a 10% to 20% solution.[38]

Symptomatic care of affected animals includes evacuation of the gastrointestinal tract with laxatives and oral demulcents to coat the intestinal tract. One should evaluate fluid, acid-base, and electrolyte indexes and provide support if necessary. Because endotoxemia may develop as a result of the intestinal and liver lesions, prophylactic use of flunixin meglumine at a dosage of 0.25 mg/kg t.i.d. may be beneficial. Other therapy to prevent shock and cardiovascular collapse also may be indicated.

20.1.3.2 Aluminum

One report describes an unexpectedly high incidence of horses on a single premise showing clinical signs compatible with granulomatous enteritis and the presence of abnormally high levels of aluminum in various body organs and tissues of the affected horses.[40] Clinical signs included weight loss with or without diarrhea, hyperkeratosis, ulcerative coronitis, and neurologic deficits compatible with cervical stenotic myelopathy. Laboratory abnormalities included hypoalbuminemia and elevated serum concentration of alkaline phosphatase in some horses. All horses had histologic evidence of granulomatous inflammation of the gastrointestinal tract in varying degrees of severity and distribution. Granulomas occurred in the mucosa, 1449
submucosa, and serosa of the small and large intestine and in the abdominal lymph nodes, portal areas of the 1450
liver, and pancreas. Aluminum was found in granulomas, and elevated aluminum levels were present in kidney and liver tissue.

Chronic environmental exposure to aluminum was postulated as a cause for the condition. Environmental factors (particularly acidic pH of soil, water, plants, etc.) may have an effect on the bioavailability of aluminum, and repeated exposure was suggested as possibly inducing hypersensitivity to aluminum in these horses. In human beings, aluminum is known to induce nonimmunologic (foreign body) and immunologic

granulomas following administration of aluminum-containing vaccines and hyposensitization products.[41] The association between high environmental concentrations of aluminum and increased incidence of generalized granulomatous inflammation in horses warrants further investigation.

20.1.3.3 Petroleum Distillates

Horses are exposed to excessive amounts of crude oil or petroleum distillates primarily by contamination of rangeland with by-products of the oil industry or by iatrogenic application, for petroleum distillates are used commonly as carrier agents for many insecticides.

20.1.3.3.1 Clinical Signs

The most noted signs associated with ingestion of petroleum products are essentially those of gastrointestinal and respiratory dysfunction. Petroleum products are irritating to mucous membranes, and hence prominent signs of gastrointestinal dysfunction might include salivation and fluid feces. The feces actually may contain oil or oily substances. Chronically affected animals also may exhibit anorexia and weight loss over several days to weeks.

Signs of respiratory dysfunction are a common manifestation of petroleum toxicity. Aspiration of the oil or fumes is irritating to pulmonary tissue, and aspiration pneumonia is probably the most serious consequence of petroleum toxicity.[15] Signs of toxicity include increased respirations, anorexia, depression, weight loss, a variable degree of fever, and possibly increased nasal discharge.

Products that are applied inadvertently to the skin might cause some degree of respiratory embarrassment, but they are more likely to cause signs related to the absorption of excessive lead or toxic hydrocarbons.[42] Topically applied agents also may cause signs associated with a contact irritant.

20.1.3.3.2 Pathophysiology

The toxicity of crude oil is correlated with the amounts of gasoline, naphtha, and kerosene content in the oil. Crude oil rich in these low-temperature distillates is more toxic than petroleum containing a lot of sulfur but less of the low-temperature distillates.[42] Petroleum products are irritating to mucous membranes, and their oily nature makes them difficult to remove from skin and mucous membranes and virtually impossible to remove from the respiratory epithelium. Once aspirated, they serve as a focus for foreign body pneumonia that may progress to abscessing pneumonia, pleuritis and pleural effusion, and death.

20.1.3.3.3 Diagnosis

History of possible exposure, clinical signs, and pathophysiologic signs are important in establishing a diagnosis. Suspect contents, that is, gastrointestinal content, may be mixed with water, and if oil is present, it will float to the surface and be readily visible. One sometimes can use infrared spectrophotometry to establish the identity of an oil.[15]

20.1.3.3.4

Treatment

Treatment is supportive. One should evacuate and protect the gastrointestinal tract using laxatives and demulcents. One can remove products applied to the skin using soap and water. Aspiration pneumonia may be frustrating to treat, and supportive care such as fluids and electrolytes, NSAIDs, and broad-spectrum antimicrobial therapy is potentially helpful.

20.1.3.4

Slaframine

Slaframine is an indole alkaloid produced by *Rhizoctonia leguminicola,* a mold that infects red clover and other legumes.[15,43,44] *R. leguminicola* is a ubiquitous soil fungus that infects certain legumes during conditions of high rainfall or humidity.[44] The toxin can survive and persist in dried and baled hay.[15]

20.1.3.4.1

Clinical Signs

The most consistently reported clinical sign is excessive salivation characterized by profuse, viscous, clear saliva.[44] Salivation may begin within 30 to 60 minutes after eating the affected plants, and response from one feeding may persist for up to 24 hours. Other clinical signs are anorexia, polyuria, and sometimes watery diarrhea.[15] One case of abortion in an affected mare has been reported.[44] Clinical signs generally abate within 48 to 96 hours once infected hay is removed from the diet.[15]

20.1.3.4.2

Pathophysiology

Slaframine apparently is activated by liver microsomes following absorption. The active compound seems to have direct histaminergic effects or possibly a histamine-releasing effect, which is borne out in laboratory animal studies in which clinical signs responded better to antihistamines than to atropine.[43]

20.1.3.4.3

Diagnosis

The combination of acute clinical signs of excessive salivation coupled with digestive disturbances and identification of *R. leguminicola* in forage is generally adequate to establish a diagnosis. One can identify slaframine by chemical means, but usually such procedures are unnecessary.[15]

20.1.3.4.4

Treatment

No specific treatment is usually necessary. Animals generally recover uneventfully in 48 to 96 hours following withdrawal of the contaminated forage.[15] Atropine and antihistaminic therapies have been suggested to help control clinical signs,[15,43] but their efficacy is questionable. 1450

20.1.3.5 Pentachlorophenol

Documented instances of horses becoming intoxicated with pentachlorophenol are rare. However, because pentachlorophenol is used routinely as a wood preservative and because other domestic animals, including cattle and swine, are affected, some aspects of this toxin require description.

The chlorophenols (which include pentachlorophenol) are generally not water soluble but are soluble in oils and organic solvents.[42,45] Pentachlorophenol is volatile and can give off toxic vapors.[42] The chlorophenols are absorbed readily from the gastrointestinal tract, by inhalation, and from intact skin and are excreted rapidly via the kidney.[42,45]

Several factors affect the toxicity of chlorophenols. High ambient temperature, physical activity, poor body condition, oily or organic solvent vehicles, prior exposure, and hyperthyroid states serve to enhance toxicity in human beings and other animal species. Cold temperatures, antithyroid drugs, and increased amounts of body fat help to diminish the toxicity.[42]

The mechanism whereby the chlorophenols exert their toxicity involves the energy production sites of mitochondria, where they uncouple oxidative phosphorylation. The chlorophenols act at sites of adenosine triphosphate (ATP) production to decrease or block their production without blocking the electron transport chain. Free energy from the electron transport chain then is converted to body heat. As the body temperature is increased, the heat-dissipating mechanisms are overcome and metabolism is increased. The electron transport chain responds by using more oxygen in an effort to produce ATP, but much of the free energy is liberated as more body heat. Eventually the oxygen demand overcomes the oxygen supply and energy reserves become depleted.[42]

Clinical signs, if observed, include fever, tachycardia, dyspnea, sweating, lethargy, incoordination, weakness, cyanosis, collapse, and death. Less severely affected animals may primarily manifest signs of hyperthermia and oxygen deficiency.[42] Pentachlorophenol in high doses to pregnant animals also is reported to cause embryonic and fetal deaths but is not teratogenic.[15]

Diagnosis of pentachlorophenol toxicity is associated with the combination of clinical signs and blood pentachlorophenol levels greater than 40 ppm. No specific treatment is available, but saline diuresis has been suggested to be helpful in certain instances of human toxicosis.[15]

20.1.3.6 Chlorates

Chlorate salts (sodium chlorate or potassium chlorate) commonly are used as herbicides and defoliants. Horses become exposed by grazing areas that have been sprayed recently or by the mistaken substitution of sodium chlorate for sodium chloride as a feed additive.

20.1.3.6.1 Clinical Signs

Initial signs are those of gastrointestinal irritation and include colic and diarrhea. Hematuria and hemoglobinuria are also present early in the disease course. Within hours, the horse shows dyspnea, cyanosis, and increased respiratory effort. Death can occur suddenly without obvious symptoms.[15]

20.1.3.6.2

Pathophysiology

Chlorates are absorbed readily from the intestine, and once absorbed they continue to exert their damaging effects as long as they are present.[15,42] A dose of 250 g is reported to be lethal to horses.[15]

Chlorates cause toxic changes by three different mechanisms of action:

1. Direct irritation of the gastrointestinal tract
2. Oxidation of hemoglobin to methemoglobin
3. Inducement of severe hemolysis by some undeter-mined action on erythrocyte membranes

The net effect of methemoglobinemia and hemolysis is a severe compromise in the oxygen-carrying capacity of blood, and animals may be affected severely enough to die from anoxia.[42]

20.1.3.6.3

Diagnosis

The prolonged, extensive methemoglobinemia found in affected animals should alert the veterinarian to the possibility of chlorate poisoning. A history of exposure to chlorates also should accompany these clinical signs for one to make a presumptive diagnosis. One can determine chlorate concentration in blood, urine, or tissues analytically, and because chlorates normally are not found in animals, their presence in a suspect sample would confirm poisoning if clinical signs, history, lesions, and response to therapy also suggest this diagnosis.[42]

20.1.3.6.4

Treatment

Once one makes the diagnosis, one should seek out and remove the chlorate source immediately from the environment of the horse. One treats methemoglobinemia with methylene blue at a dose of 4.4 mg/kg given as a 1% solution by intravenous drip. This dose may be repeated in 15 to 30 minutes if clinical response is not obtained.[24,42] Other recommended therapeutic measures include gastric lavage with 1% sodium thiosulfate and the oral administration of intestinal protectants and demulcents.[15,24] Blood transfusion and oxygen supplementation may be beneficial in certain instances.[42]

20.1.3.7

Pyriminil (Vacor)

Pyriminil currently is not commercially available but in previous years was marketed as a rodenticide. Reports of toxicosis in horses are rare,[46] and deaths caused by pyriminil ingestion are not reported.[46,47]

20.1.3.7.1

Clinical Signs

Reported signs in affected horses include severe muscular fasciculation, profuse sweating, dehydration, and mydriasis with a weak pupillary response. Hindlimb weakness, ataxia, persistent inappetence, and abdominal pain also have been reported.[46] Hyperglycemia is a fairly consistent laboratory finding.[15,46] 1451

20.1.3.7.2

Pathophysiology

Pyriminil is absorbed from the gastrointestinal tract and excreted in the urine. Pyriminil acts as a nicotinamide antagonist, but its exact mechanism of action is unknown.[15,24,47] Pyriminil also has been shown to damage the pancreatic β-cells and to depress glucose uptake by erythrocytes.

20.1.3.7.3

Diagnosis

Presumptive diagnosis is based on compatible clinical signs and history of exposure to the rodenticide.

20.1.3.7.4

Treatment

Specific therapy for pyriminil toxicity is reported to be nicotinamide. However, the use of this drug in human beings appears to be effective only when given within 1 hour of ingestion of pyriminil. The reported dosage is 50 to 100 mg nicotinamide intramuscularly every 4 hours for up to eight injections. This dosage is followed by 25 to 50 mg orally 3 to 5 times daily for 7 to 10 days.[15] Other symptomatic therapies that may be beneficial include gastric lavage and the oral administration of mineral oil and activated charcoal.[15,47] Apparently, affected horses recover, for no deaths caused by pyriminil toxicosis are recorded.

20.1.3.8

Tetrachlorodibenzodioxin

The polychlorinated dibenzodioxins include a large number of isomers that differ chemically only in the number and location of chlorine atoms on the dioxin nucleus but that vary greatly in their toxic potential to various animal species. Of the 75 possible isomers of polychlorinated dibenzodioxin, the specific isomer designated 2,3,7,8-tetrachlorodibenzodioxin (TCDD; dioxin) is most toxic and generally is considered the most toxic synthetic molecule known. Tetrachlorodibenzodioxin is a contaminant of certain herbicides and is a by-product of certain chemical manufacturing and combustion processes.[15] The chemical is a highly stable contaminant in the environment, with a half-life in soil of about 1 year.[48]

20.1.3.8.1

Clinical Signs

In one reported outbreak the initial signs began 4 days following exposure and included abdominal pain, polydipsia, anorexia, severe weight loss, alopecia, skin and oral ulcers, conjunctivitis, dependent edema, joint stiffness, and laminitis. A total of 85 horses were exposed, 58 became ill, and 43 subsequently died. The length of illness varied from 4 to 132 weeks in the terminally ill horses, with those having a heavier exposure exhibiting a shorter disease course (average of 32 weeks) than others (average of 74 weeks). In addition, abortions occurred in pregnant mares, and many foals that were exposed only in utero died at birth or shortly thereafter.[48] Other reported signs in animals include gastrointestinal hemorrhage with necrosis and ulceration of the gastrointestinal mucosa, cerebrovascular hemorrhage, hepatotoxicity, and thymic and peripheral lymph node atrophy.[15,48]

20.1.3.8.2
Pathophysiology

Tetrachlorodibenzodioxin is absorbed readily by oral and dermal routes, and following absorption appears to be retained primarily by liver and adipose tissue. The mechanism of action of TCDD in various organs in not well defined. Tetrachlorodibenzodioxin is known to induce microsomal mixed function oxidases in liver and kidney, and hepatic δ-aminolevulinic acid synthetase and aryl hydrocarbon hydroxylase, but the role of these processes in the induction of toxicity of TCDD remains to be elucidated.[15] The mechanism whereby TCDD induces immunosuppression by causing thymic and peripheral lymph node atrophy is undetermined.

20.1.3.8.3
Diagnosis

A combination of the described clinical signs and possible exposure to industrial waste oil products should alert the veterinarian to the possibility of TCDD toxicity. One can confirm dioxin content in tissue by means of gas-liquid chromatography and mass spectroscopy, but few laboratories offer this service, and the analysis is generally expensive.[15]

A characteristic liver lesion seen at necropsy in a number of horses was microscopic evidence of bile stasis, hepatocyte necrosis, bile duct proliferation, and extensive fibrosis that was pronounced around the central veins but minimal in the peripheral liver lobules. Other microscopic changes noted were thickened vascular walls and endothelial proliferation in the smaller blood vessels of several different organs.[48]

20.1.3.8.4
Treatment

No known antidote exists for TCDD toxicity once clinical signs develop. Following their onset, one can offer only symptomatic and supportive care, and one should use every precaution to prevent laminitis. Soil and activated charcoal appear to bind strongly to TCDD and inhibit its absorption, so if known ingestion has occurred, immediate oral administration of activated charcoal may have beneficial effects by reducing the amount absorbed.[15]

20.1.3.9
Monensin

Monensin is one of several biologically active compounds categorized as ionophore antibiotics because they can form lipid-soluble complexes with specific alkali metal cations and transport them across biologic membranes. Monensin is produced by the fungus *Streptomyces cinnamonensis* and is selective in transporting sodium and potassium ions between intracellular and extracellular spaces.[15,49,50] Monensin is used routinely as a poultry coccidiostat and as a feed additive to improve feed efficiency in pasture and feedlot cattle. Horses are the most sensitive domestic animal to monensin toxicosis. The LD_{50} of monensin for the horse is 2 to 3 mg/kg.[15]

20.1.3.9.1
Clinical Signs

Several syndromes of toxicity occur and seem to be dose-related. Peracute toxicity may manifest as a progressive, severe hemoconcentration, hypovolemic shock, and death within a few hours of ingestion.

The acute form of the disorder is characterized by partial to complete anorexia, abdominal pain, occasional watery diarrhea, intermittent profuse sweating, stiffness and progressive muscle weakness most prominent in the hindquarters, progressive ataxia, tachycardia, hypotension, dyspnea, and polyuria. Affected horses may show clinical signs for 1 to 4 days before death.[50–52] Horses surviving sublethal doses of monensin exhibit signs of reduced athletic performance, unthriftiness, and cardiac failure. Cardiac arrhythmias, including atrial fibrillation and tachycardia, a prominent jugular pulse, and pleural and pericardial effusion are apparent.[15] Intravascular hemolysis also may occur to a limited degree.[49] 1452 1453

20.1.3.9.2

Pathophysiology

The primary action of monensin is selective transport of sodium and potassium ions between the intracellular and extracellular spaces. Two mechanisms have been suggested to explain the toxic action.

One theory suggests that monensin interacts with the mechanism regulating potassium entry into cell organelles, especially the mitochondria.[15] Low concentrations of monensin lead to a net accumulation of potassium within the cell, whereas higher doses cause a net loss of potassium from the cell.[49] Because potassium is required for ATP hydrolysis by the mitochondria, the effect of monensin might be to inhibit ATP hydrolysis in mitochondria. As a result, cell energy production is decreased and can result in loss of cell function and death.[15,49]

The second hypothesis suggests that increased intracellular calcium concentration is the mechanism responsible for cell death. When the intracellular calcium concentration is increased, the mitochondria are forced to maintain calcium homeostasis by sequestering the excess calcium. This requires energy, which could take priority over ATP production. When the mitochondria become overloaded with calcium, oxidative phosphorylation is inhibited and less energy is produced to pump calcium out of the cell. When intracellular calcium levels reach a critical level, degradative enzymes are released, swelling of the mitochondria and sarcoplasmic reticulum occur, and cell necrosis and death follow.[15,49]

The heart is the primary target organ of monensin toxicosis, and electron microscopic studies of acute monensin toxicosis in ponies have shown structural changes in myocardial cells consistent with severe mitochondrial damage.[53] In horses ingesting a sublethal dose of monensin, the myocardial sarcolemma is damaged and is replaced by fibrous tissue in the healing process. Myocardial lesions are characterized microscopically by pale myofibers, loss of fiber striation, multifocal vacuolar degeneration, and scattered areas of necrosis. The end result is a structurally weakened heart that can succumb to stress and cause acute collapse of the horse. Other lesions that may be present in affected horses include pericardial, pleural, and peritoneal effusions; hemopericardium; and epicardial hemorrhage. Chronically affected horses also may have hepatic congestion with centrilobular necrosis and hydropic degeneration of the renal tubules.[15,49]

20.1.3.9.3

Diagnosis

One should suspect monensin toxicosis when horses show clinical signs of anorexia, muscle weakness, and heart failure and when a possible exposure to contaminated feed has occurred. One can evaluate suspect feeds for monensin content.

Clinicopathologic abnormalities are nonpathognomonic but include early signs of severe hemoconcentration and dehydration in horses affected peracutely. Serum potassium and calcium may be decreased moderately in the first 12 to 16 hours but then tend to come back to normal levels. Blood urea nitrogen (BUN) and creatinine concentrations are elevated in horses acutely affected but return to normal in surviving animals. Other enzymes that show elevated serum activity include CK, AST, and LDH isoenzyme fractions 1 (cardiac muscle) and 2 (red blood cell origin). Total serum bilirubin also may be elevated.[15,49]

Abnormal findings in urine can include a progressive decrease in urine osmolality during the initial few hours of the disease course.[15] One also might expect elevations in urinary activity of renal tubular enzymes such as GGT and *N*-acetylglucosaminidase. Urinalysis abnormalities tend to correlate well with the degree of renal insult and are nonspecific indicators of renal damage.

20.1.3.9.4 Treatment

No specific antidote exists for monensin. One should treat horses that have ingested a large amount early and aggressively with polyionic fluids to combat hemoconcentration and hypovolemic shock. One should perform electrolyte and acid-base analysis, if possible, and correct deficiencies. One should attempt to evacuate the bowel of the horse using orally administered laxatives such as mineral oil; activated charcoal may help decrease the absorption of monensin. One should keep affected horses as quiet and nonstressed as possible for weeks following exposure to allow the damaged myocardium to heal.[15,49]

Digitalis glycosides should never be used in acutely affected horses because they and monensin have been shown to be synergistic and immediately fatal to cardiac muscle cells. One should use digitalis glycosides only with great caution in the weeks following recovery from the toxic episode. Likewise, one should not give calcium to acutely affected horses for two reasons. First, serum hypocalcemia is transitory, and serum calcium usually recovers to normal by 24 hours. Second, calcium can be dangerously irritating to an already injured myocardium.[49]

One should note that affected horses are susceptible to cardiac damage, which is often permanent. A critical evaluation of cardiac function and the integrity of any previously intoxicated horse that is destined to return to some form of athletic endeavor is judicious. 1453

1454

20.1.3.10 Lasalocid

Lasalocid is another carboxylic ionophore antibiotic, is a fermentation product of the mold *Streptomyces lasaliensis,* and is used commercially as a poultry coccidiostat and as a feed additive to improve feed efficiency in ruminants.

20.1.3.10.1 Clinical Signs

The signs observed in horses given toxic amounts of lasalocid are similar to those of monensin toxicosis. Affected horses exhibited depression, ataxia, paresis, and paralysis with partial anorexia. Once recumbent, some horses would rise when given assistance. Most horses that survived appeared normal 2 to 3 days following exposure. The lowest dose that caused fatality was 15 mg/kg body mass, but the LD_{50} for a

single oral dose of lasalocid was estimated to be 21.5 mg/kg. Death occurred between 31 and 96 hours following oral dosing in the nonsurvivors.[54]

Results of a toxic feeding study indicated that poultry rations containing approved concentrations of lasalocid (75 to 125 g per metric ton) are not toxic or lethal to horses. This study revealed that horses voluntarily reduced their feed intake with increasing amounts of lasalocid in the ration and refused to eat the commercial premix when offered it in place of their normal ration.[54]

20.1.3.10.2 Pathophysiology

The mechanism of action of lasalocid is thought to be similar to that of monensin. Lasalocid is the least toxic of the ionophores and differs from monensin in that it accepts divalent and monovalent cations.[22]

20.1.3.10.3 Diagnosis

No signs or laboratory findings are pathognomonic for lasalocid toxicity. In suspect horses, one can analyze feedstuffs for lasalocid content.

Abnormal laboratory findings in affected horses include hypocalcemia, hypophosphatemia, and hypokalemia early in the disease course (within 24 hours of exposure), but these values returned to normal ranges by 120 hours after ingestion. Serum activity of AST frequently is increased, as is total serum bilirubin and glucose concentrations. Occasionally the BUN concentration is increased.[54]

20.1.3.10.4 Treatment

Initial treatment should include removal of all suspected feed sources and the oral administration of laxatives to enhance evacuation of the gastrointestinal tract. Other nonspecific supportive care may be helpful, but horses receiving a sublethal dose probably will recover with minimal assistance. If a lethal dose is forced into an animal inadvertently, oral laxatives and adsorbents such as activated charcoal may help bind lasalocid and reduce the amount absorbed.

20.1.3.11 Salinomycin

Salinomycin is an ionophore, also marketed as a coccidiostat, that is related more closely to monensin than is lasalocid. The ionic affinity of salinomycin is predominantly to sodium and potassium, and its mode of action and cellular effects are similar to those of monensin.[22]

In one report of affected horses, the clinical signs were similar to those of the other ionophore toxicoses. The range of clinical signs included anorexia, depression, occasional sweating, colic, dyspnea, weakness, ataxia, and recumbency. Occasionally, horses showed reduced performance for several weeks following exposure, but many horses that became recumbent were destroyed humanely. The clinicopathologic abnormalities exhibited by affected horses included elevated serum activities of CK, AST, and alkaline phosphatase.[55]

The diagnosis of salinomycin toxicity is hampered by the fact that none of the clinical signs are pathognomonic and tissue samples do not reveal toxic levels. However, one may assay suspect feed and intestinal content for the presence and quantity of salinomycin.

Treatment of affected horses is mostly symptomatic because no specific antidote is available. Evacuation of the bowel by laxatives may be helpful in reducing the amount of toxic material available for absorption. One should maintain fluid balance and electrolyte and acid-base indexes within normal ranges. Affected horses generally require an extended convalescence, and one should consider the possibility of a persistent cardiomyopathy.[55] Affected horses should undergo a rigorous cardiac examination before returning to performance events.

20.1.3.12 Cantharidin Toxicosis (Blister Beetle Toxicosis)

Cantharidin toxicosis results from ingestion of dead blister beetles that become entrapped in hay during harvesting. Essentially all reports are of horses being fed alfalfa hay or alfalfa products, but anecdotal reports of horses intoxicated by ingesting grass hay have been communicated to the author. More than 200 species of blister beetles inhabit the continental United States, but toxicity results primarily from beetles of the genus *Epicauta*.[56]

Cantharidin is the sole toxic principle and is contained in the hemolymph, genitalia, and possibly other tissues of the beetle. Cantharidin is a highly irritating substance that causes acantholysis and vesicle formation when in contact with skin or mucous membranes, and the substance is absorbed from the gastrointestinal tract and rapidly excreted by the kidney. Storage of hay does not reduce the toxicity of cantharidin.[56]

20.1.3.12.1 Clinical Signs

The signs associated with toxicosis are many and varied and are dose-dependent. Horses affected with a minimal dose may show only signs of depression, anorexia, and occasionally polyuria, whereas horses ingesting a lethal dose may show signs of profound shock, gastrointestinal and urinary tract irritation, myocardial dysfunction, and hypocalcemia.[56,57] The onset and duration of clinical signs vary from hours 1454
to days, but horses that succumb to cantharidin generally die within 48 hours of onset of signs. Horses that 1455
live longer than 48 hours have a better prognosis for recovery if no complications arise.

The most commonly observed clinical signs include varying degrees of abdominal pain, anorexia, depression, and repeatedly submerging the muzzle in water or frequently drinking small amounts of water. The respiratory and cardiac rates are elevated, and cardiac contractions are occasionally forceful enough to be observed through the thoracic wall. Mucous membranes are congested and cyanotic, and capillary refill time is prolonged. The feces may be watery in consistency but rarely contain blood or mucus. Profuse sweating is typical of horses more severely affected and may be a sign of severe abdominal pain. Affected horses often make frequent attempts to void urine. The urine is grossly normal early in the disease course but later may become tinged with blood or contain clots of blood. Gross hematuria, if it occurs, is usually in the later stages of the disease process. Less commonly observed signs include synchronous diaphragmatic flutter, erosions of the gingival and oral mucous membranes, and occasionally a stiff, short-strided gait similar to that seen in acute myositis. Sudden death also has been reported.[56]

20.1.3.12.2

Pathophysiology

The mechanism of action of cantharidin at the cellular level has not been elucidated fully. Acantholysis and vesicle formation result from disrupted cell membranes. Cantharidin does not have a direct effect on membranes but is thought to interfere with oxidative enzymes bound to mitochondria. These enzyme systems are involved directly in active transport across the plasma membrane, and their failure results in cell death caused by significant permeability changes in the cell membrane.[56]

Hypovolemic shock and pain develop rapidly in more severely affected horses. The normal transfer of fluid, nutrients, and electrolytes across the intestinal mucosa is disrupted because of the morphologic changes induced by cantharidin. Although renal tubular damage is not severe enough to cause death, changes in the renal tubular epithelium also may be related to the development of fluid, acid-base, and electrolyte abnormalities.[56,57]

Hypoproteinemia develops later in the disease course, probably as a result of protein loss across the damaged intestinal mucosa. Protein also is lost into the peritoneal space, and a minor amount may be lost via the urine.[56]

The profound hypocalcemia and hypomagnesemia that occur in many horses have not been explained fully. Calcium loss or derangement of calcium homeostasis or a combination of both is the most likely explanation because the acute onset of the disease eliminates reduced intake as a possible cause. Calcium can be lost via urine, sweat, and as protein-bound calcium through the damaged intestinal wall. An influx of intracellular calcium also may occur in certain tissues. Whether cantharidin has an effect on calcium-binding sites on proteins or in cells is unknown.[56]

The low urine specific gravity in most horses may be caused by decreased permeability of the collecting ducts to water. Other findings, however, point to a mild pathologic insult as a cause of the low urine specific gravity. These findings include the facts that a low specific gravity occurs suddenly within hours of toxin exposure; specific gravity returns to normal in 2 to 4 days in surviving horses; only mild to moderate changes are noted in other renal function tests; and the histologic renal lesions are mild, and neither acute nor chronic renal failure is associated with cantharidin toxicosis in horses.[56]

Myocardial necrosis is a common finding in affected horses and may be caused by the direct effect of cantharidin on cardiac muscle. Dose-related intracellular changes involving the mitochondria, cristae, nuclear chromatin, sarcoplasmic reticulum, and myofibrils have been observed in the cardiac muscle of rabbits that were given cantharidin. A proposed mechanism for these changes suggests that an excess transport of calcium into the myocardial cells occurs, leading to an intracellular calcium overload. This overload may result in a high-energy phosphate deficiency within the cell, leading to necrosis and cell death.[56]

20.1.3.12.3

Diagnosis

One should consider cantharidin toxicosis when horses exhibit signs of abdominal pain, depression, or polyuria, and their diet contains alfalfa hay or alfalfa products. One can make the diagnosis when horses have clinical signs and laboratory findings compatible with cantharidin toxicosis and when one finds beetles in the hay. The beetles can be difficult to identify in hay, so one should search thoroughly. One can

assay cantharidin using high-pressure liquid chromatography and gas chromatography–mass spectrometry techniques.[56,58] Samples to be tested are urine and stomach content from suspect horses.

Laboratory findings are nonpathognomonic, but several abnormalities typically are noted. Packed cell volume (PCV) and serum protein concentrations are elevated early, but hypoproteinemia frequently develops after about 24 hours. Mild hypokalemia can occur but is not a striking feature of this disease. Blood urea nitrogen concentration may be elevated moderately, and hyperglycemia is almost always present initially.[56]

Serum calcium and magnesium concentrations are significantly decreased in most horses and remain low for longer than 48 hours if untreated. The urine generally contains red blood cells and has a low specific gravity, even in the face of clinical dehydration. Abnormal peritoneal fluid findings include increased protein concentration but relatively normal fibrinogen and white blood cell values. Feces are often positive 1455
for occult blood. Serum CK activity may be elevated in more severely affected horses and augurs a poor 1456
prognosis.[56] Although not diagnostic, laboratory findings of prolonged hypocalcemia and hypomagnesemia and elevated CK concentration may help differentiate cantharidin toxicosis from other causes of acute abdominal crisis.

20.1.3.12.4 Treatment

No specific antidote is available for cantharidin. Once one suspects the diagnosis, one should remove all suspect feed from the environment of the horse and should have hay that is subsequently fed to horses carefully examined for the presence of beetles.

One should give mineral oil early to horses suspected of having cantharidin toxicosis. The oil helps evacuate the bowel and also may help reduce the amount of cantharidin available for absorption because cantharidin is lipid soluble. Activated charcoal given via nasogastric tube also may have beneficial effects.[56]

One should administer polyionic fluids intravenously throughout the disease course to correct dehydration and promote diuresis. One also may give diuretics once the horse is volume loaded. Analgesics usually are required because of the severity of the abdominal pain, and glucocorticoids may be necessary to aid in treating shock. One should give calcium gluconate to elevate the serum calcium concentration and should replace calculated deficits of magnesium by slow intravenous infusion.[56]

20.1.3.13 Phosphorus

Elemental phosphorus is available in red and white forms. Red phosphorus is used in manufacturing fertilizers and safety matches and is considered inert and nontoxic. White phosphorus is used as a rodenticide and is commercially available in pastes containing from 1.5% to 5.0% phosphorus. The reported toxic dose for horses is 0.5 to 2.0 g.[15]

20.1.3.13.1 Clinical Signs

The toxic manifestations of phosphorus poisoning are generally threefold: toxic signs commence within hours of ingestion, are followed by a latent period of 48 hours to several days when the animal may appear recovered, and finally recur with greater severity.

The initial signs are characterized by severe abdominal pain and gastrointestinal irritation, with occasional episodes of diarrhea. Blood may be present in feces. Cardiac arrhythmias may occur during this phase, and if the dose is sufficiently large, cyanosis, shock, incoordination, and coma can develop, and the animal may die before the second and third stages develop.[15]

The latent period may occur from 48 to 96 hours following the onset of clinical signs, and during this time the animal may appear normal. The third stage presents as a recurrence of severe abdominal pain, and signs of liver dysfunction may become evident. One may note icterus and a tendency to bleed from the gingiva, stomach, intestine, or kidney.[15]

20.1.3.13.2 Pathophysiology

Phosphorus is absorbed from the gastrointestinal and respiratory tracts. Although dermal exposure may cause skin irritation or burning, absorption does not occur via this route. The mechanism of action of phosphorus is unknown but is noted for causing irritation and necrosis of affected tissue. Phosphorus is also known to cause peripheral vasodilation.[15]

20.1.3.13.3 Diagnosis and Treatment

Clinicopathologic abnormalities reflect hepatic and renal damage. Hypoglycemia may be pronounced, and liver enzymes such as AST, LDH, and sorbitol dehydrogenase are elevated. Renal damage is reflected by increased BUN and creatinine concentrations. One may find albumin, blood, and increased concentrations of amino acids in the urine. The phosphorus concentration in blood is usually normal. Although elemental phosphorus in tissues can be assayed, in time a large portion may be oxidized to phosphates, thereby making confirmation of poisoning difficult by chemical means.[15]

No specific antidote is available for phosphorus intoxication. Therapy is essentially symptomatic and supportive.

20.1.3.14 Thallium

Thallium is toxic to all animals, including human beings, but no reports of clinical toxicosis in horses could be found in the literature. However, a dose of thallous acetate 27 mg/kg orally has been suggested as potentially lethal to horses.[38] Thallium has been used in recent years as a rodenticide, but its use now is restricted only to government agencies.

20.1.3.14.1 Clinical Signs

Thallium ingestion can result in acute, subacute, or chronic syndromes. In the acute form, clinical signs usually begin within 1 to 4 days of ingestion. Initial signs are those of severe gastrointestinal insult and include vomiting, severe hemorrhagic diarrhea, abdominal pain, and anorexia. Labored breathing is apparent early in the disease course, and motor paralysis and trembling may occur. Signs suggesting renal dysfunction also may occur.[15]

The subacute form generally manifests signs in 3 to 7 days after ingestion. Signs of gastric distress and motor disturbances are less marked than in the acute form, but they persist for a longer time. In this form, reddening of the skin and pustule formation occur. A pronounced reddening of the oral mucous membranes also seems to be unique to this particular toxicosis. Other clinical signs observed include conjunctivitis, hair loss, and crusty skin lesions. Secondary bacterial infections also may develop in affected animals.[15]

The chronic stage requires 7 to 10 days to appear. Signs of gastrointestinal and nervous system dysfunction are mild, but hair loss and dry, scaly skin become pronounced.[15] 1456

1457

20.1.3.14.2 Pathophysiology

Thallium is absorbed readily from the intestinal tract or through the skin; is distributed in all body tissues, although higher levels accumulate in the kidneys and liver; and is excreted principally in feces, and to a lesser extent in urine, and undergoes an enterohepatic cycle for resorption and excretion.[38]

Thallium is thought to combine with mitochondrial sulfhydryl enzymes at a specific yet unknown place in the scheme of sulfur metabolism. Thallium therefore interferes with oxidative phosphorylation within cells. Recent evidence suggests that thallium exchanges for potassium in muscle and nerve cells primarily and also has a necrotizing effect on the intestinal tract, kidney, and occasionally the brain.[15,38]

20.1.3.14.3 Diagnosis

One may suspect thallium toxicosis based on clinical signs, and one can assay urine for thallium content. The finding of thallium in tissue in any amount is diagnostic, but liver and kidney levels tend to be higher than in other tissues.

20.1.3.14.4 Treatment

Chelation therapy using diphenylthiocarbazone (dithizon) at a dosage of 70 mg/kg orally t.i.d. has been recommended for use in dogs.[15] However, cats react adversely to this agent. Its effect in horses is unknown.

Potassium chloride may aid in the elimination of thallium and can be given intravenously or orally, but the oral route is contraindicated in animals that also are being treated with an ion exchange agent.

One can attempt to trap thallium in the intestine with the ion exchange agent potassium ferric cyanoferrate-II (potassium–Prussian blue). Experimentally, potassium– Prussian blue is not absorbed from the intestinal tract and acts to immobilize the thallus ion by exchanging with the potassium of potassium–Prussian blue. Once trapped, thallium is not released readily from potassium–Prussian blue, and fecal excretion of thallium increases.[15,38]

Other forms of symptomatic therapy include intestinal protectants and demulcents, fluid and electrolyte support, analgesics, oral activated charcoal, and general nursing care.[38]

20.2 Toxicoses Causing Signs of Central Nervous System Stimulation

Dealing with horses showing signs of central nervous stimulation can be one of the most difficult and challenging situations the equine internist faces. Symptoms can be hard to control and clients' emotions can run high at the sight of a horse showing severe or uncontrollable signs like hyperexcitability, exaggerated gait abnormalities, and seizures. The immediate clinical emphasis is usually on minimizing the chances and/or severity of self-induced trauma. Etiologic diagnosis can be difficult and protracted.

20.2.1 PLANTS

20.2.1.1 Locoweed

A nervous syndrome in horses, cattle, and sheep has long been associated with eating plants of the genera *Astragalus* and *Oxytropis*. This group of plants is large. The *Astragalus* species that grow in North America number more than 300. Not all species of *Astragalus* and *Oxytropis* are toxic, however, and some species make nutritious forage for livestock.[59] Some debate still exists over the taxonomy of these species, but their clinical signs are essentially the same, and they are discussed together.

The toxic species of *Astragalus* produce three different syndromes in livestock. Some species contain nitroglycosides, which cause methemoglobinemia and competitive inhibition of certain cellular enzymes; others accumulate toxic levels of selenium; and a third group contains alkaloids that cause locoism.[59,60] The first group of plants is of minor importance to the horse, and the selenium concentrators are discussed in the section on selenium toxicosis. A discussion of the clinical syndrome called locoism follows.

The species of *Astragalus* and *Oxytropis* that induce locoism include *A. lentiginosus* (36 varieties); *A. mollissimus* (11 varieties); *A. wootonii* (2 varieties); *A. thurberi; A. nothoxys; O. sericea; O. lambertii;* and *O. saximontana*.[59] Additional *Astragalus* species incriminated in causing disease include *A. argillophilus, A. bisulcatus,* and *A. earlei*.[60] Geographically, locoweeds are found from western Canada southward to include the western United States and northern Mexico.[59]

20.2.1.1.1 Clinical Signs

Locoweeds cause a number of problems in livestock, including neurologic and reproductive dysfunction, emaciation, and habituation.[59] Typical signs exhibited by affected horses include a slow staggering gait, depression, an unthrifty appearance, emaciation, muscular incoordination, and nervousness, especially when the animal is stressed. The affected horse may become solitary and hard to manage and may have difficulty in eating and drinking. In some animals, sexual activity may become suppressed. Visual impairment also occurs in some horses, and mares ingesting locoweed during pregnancy have been known to abort or produce foals with various limb deformities.[60,61] Horses that are affected chronically are generally useless for riding or draft purposes because their behavior is so unpredictable.[59]

The onset of clinical signs varies from as short as 2 weeks to as long as 2 months after the horse starts to graze the plant. The plants generally are considered nonpalatable to horses, but once they start to ingest the plant, they seem to become addicted to it and will search it out.[59] The addiction can extend to subsequent

growing seasons, so clinical signs can worsen progressively in successive years if animals continue to graze the plant.[60] Affected horses can recover if feeding or grazing is discontinued before they become too emaciated and if nutritious forage is given.[59] However, the syndrome eventually may lead to death in chronically affected horses.[60] 1457 1458

20.2.1.1.2 Pathophysiology

The indolizidine alkaloids swainsonine and swainsonine *N*-oxide have been suggested as the toxic principles in locoweeds.[60] These alkaloids were first recovered from *Swainsona* species in Australia.[59,60] Swainsonine inhibits α-mannosidase, a lysosomal enzyme essential in the cellular metabolism of oligosaccharides. As a result, mannose-rich oligosaccharides accumulate in lysosomes and disrupt cellular function. These accumulations are visible microscopically as intracytoplasmic vacuoles. Vacuolization of the renal cortical tubular cells can occur as early as 4 days after feeding of locoweed is started, and neurons of the CNS, including Purkinje cells, may show vacuolization by 8 days. The vacuoles disappear shortly after consumption ceases in the early stages of disease, but if grazing is prolonged, permanent cellular damage occurs. Continuous feeding of the plant for 30 days or longer results in vacuolization of almost all tissues of the body except skeletal and cardiac muscle.[60]

Neurologic signs result from vacuolization of the axons, glial cells, and Purkinje cells of the cerebellum and cerebral cortex. The weight loss and emaciation result from impairment of the liver, pancreas, thyroid, and parathyroid glands. Vacuolization of cells of the retina and decreased lacrimation are responsible for impaired vision in some animals. Vacuoles also occur in lymph nodes, placenta, testicles, and lymphocytes.[59,60] The pathogenesis and lesions of locoism are similar to mannosidosis, a heritable lysosomal storage disease of Angus and Murray Grey cattle.[60]

20.2.1.1.3 Diagnosis and Treatment

No pathognomonic test is available for diagnosis of locoism. One should suspect the diagnosis when horses show clinical signs compatible with locoism and have a history of exposure to the plant. Laboratory testing is nonspecific, and one can expect test results consistent with multiple organ dysfunction. Microscopic lesions of intracytoplasmic vacuolization in various organs, including the CNS, are compatible with a diagnosis of locoism.[59,60] Peripheral lymphocytes that contain intracytoplasmic vacuoles also are considered indicative of locoism, if clinical signs are present.[60]

No effective cure exists for horses with chronic locoism that have had clinical signs for some time. Mild cases usually resolve in 1 to 2 weeks once ingestion ceases, so successful recovery from locoism depends on early recognition of the disease syndrome and preventing horses from further consumption of the plants. Reserpine has been suggested to be helpful in relieving some of the clinical signs of locoism in horses.[60]

20.2.1.2 Nervous Ergotism

Two forms of ergotism are observed in domestic animals, a nervous or convulsive form and a gangrenous form. Horses appear rarely to be affected with ergotism, but the nervous form is reported to occur much more frequently in horses than the gangrenous form.[62,63] Ergotism is caused by a number of alkaloids contained in

Claviceps purpurea, a fungus infecting many grains such as wheat, barley, rye, and oats and wild grasses such as quackgrass, smooth bromegrass, wheatgrass, bluegrasses, and wild rye. The fungal mass, or sclerotium, replaces the seed or kernel of the plant and may have the same general configuration of the seed but is usually larger, dark colored, and hard. Ergotism is rarely of concern in dry seasons, but abundant fungal growth can occur during wet periods.[62] Although well-documented cases of ergotism caused by *C. purpurea* in horses are absent in the literature, a nervous syndrome typical of *C. paspali* poisoning has been observed in horses in Australia. However, the cause of the clinical signs in these horses was suggested to have been the tremorogenic mycotoxins in *C. paspali* rather than the alkaloids found in ergot.[64]

20.2.1.2.1 Clinical Signs

The first sign of nervous ergotism is reported to be dizziness or an unsteady gait. This phase may be interrupted by convulsions and temporary posterior paralysis and drowsiness.[62] Other behavioral effects that have been described include incoordination, lameness, difficulty in breathing, excessive salivation, and diarrhea.[63]

20.2.1.2.2 Pathophysiology

Approximately 40 different alkaloids have been isolated from *C. purpurea*. All of these alkaloids are derivatives of the tetracyclic compound 6-methylergoline, a lysergic acid base structurally similar to a number of biogenic amines such as dopamine, serotonin, and norepinephrine.[7,62] The most pharmacologically potent alkaloids in ergot are ergonovine, ergotamine, ergotsine, ergocristine, ergocryptine, and ergocornine.[62] Additionally, tyrosine, tryptophan, tyramine, histamine, histidine, choline, and acetylcholine have been isolated from ergot sclerotia, but their clinical significance is uncertain.[7]

The mechanism whereby ergot alkaloids induce central nervous signs in horses has not been elucidated. Of 1458
the ergot alkaloids known to affect the nervous system in human beings, bromocriptine is the prototype. 1459
Bromocriptine is a long-acting dopamine agonist that has central stimulating effects and may cause hypotension. Another ergot alkaloid, isoergine (lysergic acid amide), has one tenth the mind-altering potency of the structurally related compound lysergic acid diethylamide (LSD). Lysergic acid diethylamide is thought to produce hallucinations by a series of complex agonist and antagonist actions on several central monoamine neurotransmitters, particularly serotonin.[7]

20.2.1.2.3 Diagnosis and Treatment

The diagnosis of nervous ergotism in horses is based primarily on clinical signs and eliminating other causes of CNS stimulation. One can assay the ergot alkaloid content of feed, but detailed analysis is required to determine the quantity of individual alkaloids present and their potency.[62]

No specific antidote exists for ergot alkaloid toxicity. Treatment of affected horses is largely symptomatic. Recommendations for control include the use of ergot-free feed, crop rotation, plowing deeply because shallow cultivation and seeding leave the sclerotia near the soil surface where they can germinate more readily, and mowing surrounding grasses to limit the spread of fungus into the cultivated crop.[63] Pasture

grasses that may be infested with ergot should be mowed before the development of seed heads because *Claviceps* replaces the seed or kernel of the plant.

20.2.2 MEDICATIONS

20.2.2.1 Carbamates

The carbamate pesticides are composed of cyclic or aliphatic derivatives of carbamic acid, and numerous ones are commercially available.[15,65] Carbamates are absorbed readily through the lungs, gastrointestinal tract, and skin. Carbamates do not accumulate in any particular tissue but do cross the rat placenta, depress fetal acetylcholinesterase, and are not metabolized readily in the fetus.[65] In human beings the carbamates poorly penetrate the blood-brain barrier and therefore produce few CNS symptoms.[7] Carbamates do not require activation by liver enzymes to exert their effect. Toxicity data are not complete for several domestic animals, but lethal doses of the different compounds vary from less than 1 mg up to several hundred milligrams per kilogram of body mass. Carbamates are not stable in the environment and are fairly insoluble in water, but organic solvents and oils can carry the compounds across cell barriers.[65]

20.2.2.1.1 Clinical Signs

Clinical signs can commence within a few minutes to several hours following exposure but are short-lived. The clinical episode frequently is less than 36 to 48 hours in length, with the animal succumbing or recovering during this time.[15,65]

Signs of toxicity in horses reflect muscarinic and nicotinic cholinergic overstimulation. The signs suggestive of muscarinic cholinergic overstimulation include profuse salivation, severe gastrointestinal disturbances characterized by hypermotility, severe pain, abdominal cramps and diarrhea, excessive lacrimation, miosis, sweating, dyspnea, cyanosis, and urinary and fecal incontinence. Affected animals also may cough frequently as a sign of excessive accumulation of respiratory tract secretions. The signs reflected by nicotinic overstimulation include excessive stimulation of the skeletal muscles. The muscles of the face, eyelids, tongue, and the general musculature may twitch. Some animals exhibit signs of generalized tetany whereby they walk in a stiff-legged fashion. This hyperactivity may be followed by weakness and paralysis of the skeletal muscles.[15]

Signs of CNS involvement in domestic food-producing animals may include hyperactivity reflecting excessive stimulation of the CNS, but domestic animals rarely exhibit convulsive seizures. Central nervous system depression is reported to occur more commonly than CNS stimulation.[15]

20.2.2.1.2 Pathophysiology

Carbamates induce excessive stimulation of the parasympathetic nervous system by inhibiting acetylcholinesterase and pseudocholinesterase. The carbamate pesticides occupy the anionic and esteratic sites of acetylcholinesterase, with the esteratic site being carbamylated. Acetylcholinesterase can hydrolyze carbamate pesticides but at a slower rate than that for acetylcholine. Therefore carbamates are reversible inhibitors of acetylcholinesterase, but toxicosis occurs when the amount of pesticide is large enough that the rate of carbamylation of acetylcholinesterase exceeds the rate of hydrolysis of pesticide by

the enzyme.[65] As a result, acetylcholine accumulates in neuroeffector and synaptic regions, resulting in the observed clinical signs of parasympathetic overstimulation.

The continuous stimulation of secretory glands leads to excessive salivation and accumulation of fluid within the respiratory tract and within the lumen of the bowel. Extensive pulmonary edema may occur and along with bronchoconstriction can lead to death in affected animals.[15]

Carbamates are removed from the circulation largely by spontaneous hydrolysis of the carbamate-cholinesterase complex. In addition, blood esterases also can inactivate a portion of the circulating carbamate, and certain liver microsomal enzymes break down the compounds within hours of exposure.[7,65] The clinical signs associated with carbamate toxicity are generally rather short-lived, with recovery occurring in less than 36 to 48 hours in most animals.

20.2.2.1.3 Diagnosis and Treatment

One is most likely to make a diagnosis from a history of possible exposure, clinical signs, and response to atropine treatment. Chemical analyses of body tissue for carbamate residue are usually unrewarding, probably because of the rapid metabolism of the compound. However, finding the pesticide in stomach contents or in feed samples in sufficient quantities to cause toxicosis could confirm the diagnosis.[15]

One also can use cholinesterase activity in blood and tissue to confirm a diagnosis. However, one must use discretion when interpreting these results because recommended therapeutic levels of carbamates applied to animals can result in some depression of blood cholinesterase activity. In one author's opinion, clinical signs of acute carbamate toxicity are associated with blood cholinesterase activity of less than 20% of
normal values. Because the inactivation of cholinesterase by carbamates involves a much weaker and less 1459
stable binding than that by organophosphates, one should not dilute blood samples from suspect animals 1460
and should refrigerate them and analyze them as soon as possible.[15]

One should treat affected animals as quickly as possible. Initial therapy should consist of atropine sulfate at 0.2 mg/kg body mass. One should divide this initial dose, giving approximately one fourth of the dose intravenously and the remainder subcutaneously or intramuscularly. Repeated doses of atropine may be required but should be used only to counteract the parasympathetic signs. The skeletal muscle tremors may not respond to atropine therapy.[15]

Orally administered adsorbents such as activated charcoal may be useful in binding ingested pesticide, and aqueous cathartics may further aid in evacuation of the intestinal tract. One probably should not give mineral oil orally in suspect cases because organic solvents and oils can carry the compound across cell barriers. Dermally exposed animals should be washed with soap and water to prevent further exposure. The oximes such as pralidoxime are of no benefit in treating carbamate toxicosis, and their use may or may not worsen the condition of the animals.[15,65]

20.2.2.2 Organophosphates

The organophosphates are being used increasingly in a variety of ways. Some of the typical uses for these compounds include animal insecticides and parasiticides; plant insecticides; soil nematocides, fungicides,

herbicides, and defoliants; rodenticides; insect repellents; and chemosterilants.[65] Horses can become intoxicated in a variety of ways because these products are used so commonly in the environment.

A wide variety of organophosphorous compounds have been developed, and their toxicity varies greatly among compounds and among animal species. Osweiler, Carson, Buck, et al. have tabulated a good list of various organophosphorous compounds and their relative toxicities.[15] In addition to variations in compound toxicity, a number of physicochemical factors also can affect the toxicity of organophosphorous compounds. The toxicity of these compounds decreases as they are degraded by sun, water, microbes, alkali, or metal ions such as iron or copper. An increase in toxicity may occur by storage activation, a process in which highly toxic isomers of certain pesticides are formed spontaneously in polar solvents or water. This reaction is speeded by heat. Parathion, malathion, fenthion, chlorpyrifos, diazinon, and coumaphos are some of the compounds that can undergo this type of storage activation.[65] The storage activation phenomena provide good reasons to use only freshly prepared preparations of organophosphate compounds on horses.

Other factors that can influence the toxicity of a particular organophosphorous compound are ambient temperature (higher temperatures may increase the toxicity of certain compounds); the vehicle in which the pesticide is dispersed; the age and sex of the animal; and the presence of other chemicals that may alter organophosphate toxicity. The combined effects of two organophosphates may be synergistic or antagonistic, and drugs that compete with organophosphates for target esterases, such as succinylcholine, phenothiazine, and procaine, may enhance organophosphate toxicity. In addition, drugs that have neuromuscular blocking properties (inhalant anesthetics, magnesium ions, certain aminoglycoside antibiotics, and the depolarizing and nondepolarizing neuromuscular blocking agents) also may enhance organophosphate toxicity. The organophosphates are poorly soluble in water but are soluble in organic solvents, fats, and oils. Oily vehicles or organic solvents also can facilitate passage of the organophosphates through the skin.[65]

20.2.2.2.1 Clinical Signs

Clinical signs of organophosphate toxicity are similar to those of carbamate toxicity, and essentially are those of overstimulation of the parasympathetic nervous system, skeletal muscles, and the CNS.

Overstimulation of muscarinic cholinergic sites results in profuse salivation and lacrimation; serous or seromucous nasal discharge; increased respiratory sounds resulting from bronchoconstriction and excessive bronchial secretions; profound gastrointestinal disturbances of increased motility, abdominal pain, and diarrhea; bradycardia; miosis; sweating; coughing; and frequent urination. Signs of nicotinic cholinergic overstimulation include muscle fasciculations, tremors, twitching, spasms, and a stiff or rigid gait. Central nervous system signs frequently include anxiety, restlessness, and hyperactivity.[15,65] If the exposure is not severe enough to result in death of the horse, the horse may require several days or weeks to recover completely.[65]

20.2.2.2.2 Pathophysiology

Organophosphates can be absorbed from the gastrointestinal tract and lungs and through the skin. Following absorption, they are distributed throughout the body but do not accumulate in any particular tissue. Most of the organophosphates must be activated by hepatic microsomal oxidative enzymes before they become potent esterase inhibitors. Phosphorothiolate and the phosphate class of organophosphates do not require activation and can inhibit esterases immediately on entry into the bloodstream.[65]

Organophosphates act as irreversible inhibitors of true cholinesterase and pseudocholinesterase in mammals. They irreversibly phosphorylate the esteratic site of cholinesterases throughout the body. As a result, endogenous acetylcholine is not inactivated. Therefore acetylcholine accumulates in neuromuscular junctions; parasympathetic postganglionic sites in smooth muscle, cardiac muscle, and glands; in all autonomic ganglia; and in cholinergic synapses within the CNS. The result is overstimulation of these sites, leading to clinical signs of toxicosis.[15,65] 1460

1461

Lethal amounts of organophosphates cause death by a combination of effects of nicotinic, muscarinic, and central cholinergic overstimulation or receptor paralysis. These effects include hypotension, bradycardia, bronchoconstriction and excessive bronchial secretion, inability of the respiratory muscles to work properly, cyanosis, and central respiratory depression. The animal actually dies of asphyxia.[65]

Detoxification of organophosphates is accomplished mostly by serum and liver esterases. However, other enzymes in the liver and in other tissues may attack the pesticides at rates dependent on the class of pesticide, the species, and the age of the animal. Water-soluble metabolites may be formed rapidly and the pesticide excreted quickly in the urine.[15,65]

20.2.2.2.3 Diagnosis and Treatment

One should suspect a diagnosis of organophosphate toxicosis when the horse has a history of possible exposure within the past 48 hours along with characteristic signs of parasympathetic overstimulation. One can perform tests for organophosphate content in body tissues or specimens and in other suspect materials, but the process is tedious. Body specimens analyzed for organophosphate content often yield negative results because the compounds do not stay in tissues long after the animal has been exposed.[15,65]

A test for cholinesterase activity in blood or tissue is the most important aid in determining if an animal has been exposed to excessive amounts of a cholinesterase inhibitor. Blood cholinesterase activity values of less than 20% to 25% of normal are compatible with exposure of the animal to excess organophosphates or other cholinesterase inhibitors. One should note that some depression of blood cholinesterase activity occurs when therapeutic levels of organophosphates or carbamates are used, so one should view these results with discretion.[15,65]

Treatment should involve immediate use of atropine sulfate at 0.2 mg/kg body mass. One should give approximately one fourth of this dose intravenously and the remainder subcutaneously or intramuscularly. One usually needs to repeat this dose at 3- to 6-hour intervals for a day or more. Because atropine does not block the nicotinic cholinergic effects, the horse may continue to show signs of muscle fasciculation or tremors.[15,65] One should use atropine with great discretion in the horse so as not to cause further complications such as gut stasis with atropine overdosage (see Atropine).

The oximes, such as pralidoxime and pralidoxime chloride, act specifically on the organophosphorus-enzyme complex to free the enzyme and also react directly with the organophosphate to form a nontoxic complex that is excreted in urine. However, the use of these products in horses may be economically unfeasible. The recommended dose varies between 20 mg/kg[98] and 25 to 50 mg/kg given as a 20% solution intravenously over several minutes. Oximes are reported to work best in the presence of atropine, so they should be given to the animal following atropine administration. One can repeat treatment with the oximes if signs reappear.[65]

Other treatment measures include removal of the source, if possible; use of orally administered activated charcoal; laxatives to aid in evacuation of the bowel; washing with soap and water if dermal exposure has occurred; and supportive therapy such as fluids and electrolyte administration, if necessary. *Drugs one should avoid when treating organophosphate toxicosis include phenothiazine tranquilizers, succinylcholine, and morphine*.[15,65]

20.2.2.3 Chlorinated Hydrocarbons

The use of chlorinated hydrocarbon pesticides is being discontinued or severely restricted because of their persistence in the environment and their incorporation into the food chain. However, certain agents still are being used, primarily as contact insecticides and as ectoparasiticides.[15,24,65]

The chlorinated hydrocarbon insecticides are poorly soluble in water but are soluble in organic solvents and oils. Oily vehicles or organic solvents also can facilitate penetration of the insecticide through intact skin. This group of compounds also is characterized by volatility, so exposure to the pesticide can occur via inhalation of the vaporized compound.[65] Because these compounds accumulate in body tissues, primarily adipose tissue, signs of toxicosis can occur following repeated exposure to lesser amounts or following a single excessive dose.[24] Toxicity varies greatly among the different compounds, and Osweiler, Carson, Buck, et al.[15] have tabulated the toxicity of a number of these compounds for various animal species.

20.2.2.3.1 Clinical Signs

The chlorinated hydrocarbons act as diffuse stimulants or depressants of the CNS, with the onset of signs ranging from several minutes to several days following exposure. The signs displayed may be progressively severe or explosive and fulminating.[15] Initially the animal may be hypersensitive, apprehensive, or belligerent. These behavioral aberrations may progress to abnormal posturing or frenzied or maniacal behavior. Nervous signs can begin with hypersensitivity and muscle fasciculations beginning around the head and facial area and proceeding caudally eventually to include the hindquarters. These muscle spasms can occur intermittently or continuously. Clonic-tonic seizures often follow and may result in death or may be followed by intermittent periods of CNS depression. Autonomic manifestations of profuse salivation, mydriasis, diarrhea, urination, and bradycardia or tachycardia with arrhythmias may
occur. Some animals may lose coordination and stumble while walking, may walk aimlessly, or may move 1461
in circles. Other notable signs may include increased rate and depth of respiration and fluid sounds in the 1462
lungs. Death may occur within minutes, hours, or days, or not at all.[15,24,65]

20.2.2.3.2 Pathophysiology

Chlorinated hydrocarbon pesticides gain entry into the body via the gastrointestinal and respiratory tracts and absorption through the skin. Once they gain entry into the bloodstream, they are thought to bind to serum lipoproteins and are distributed throughout the body. Eventually an equilibrium is reached in which the pesticide concentration varies among different body compartments. Most of the absorbed pesticide is stored in fat, but brain and fetus also can accumulate significant amounts.[15,65]

Adipose tissue is the main storage tissue for chlorinated hydrocarbons and as such can retain some of these compounds for an extended period of time. The pesticide also is mobilized slowly from fat, which can account for the presence of the pesticide in blood and milk for weeks to months.[65]

The chlorinated hydrocarbons are broken down by liver microsomal enzymes, and the pesticide and its metabolites are excreted in urine, bile, milk, and feces. This first stage of elimination is fairly rapid and may account for 40% to 50% of the compound being eliminated during the first 3 to 4 days after exposure.[65]

The exact mechanism of action of the chlorinated hydrocarbons is unknown, but they act as nonspecific stimulants of the CNS. A suggested mechanism is that the compounds easily enter neural membranes and prolong the time during which some of the sodium channels in the membrane are open during depolarization. In addition, potassium efflux from the cell is hindered. The net effect of these ion imbalances is a decreased transmembrane resting potential that causes a decreased firing threshold and an increased neuronal excitability.[65]

An increase in whole-brain free ammonia concentration and brain glutamine also occurs, but whether these changes are a cause or an effect of the sodium-potassium flux defect is unknown. However, the onset and disappearance of convulsions in animals is correlated with an increase and decrease of brain ammonia concentration.[65]

The depression produced by some chlorinated hydrocarbons may result from rapid depolarizing blockade of neurons of the reticular activating system. Excessive depolarization of the medullary neurons may be responsible for respiratory failure, which is the usual cause of death in chlorinated hydrocarbon pesticide toxicosis. The muscle tremors in chlorinated hydrocarbon toxicosis are thought to be partly central in origin and partly caused by direct depolarizing effects on peripheral motor nerves.[65]

20.2.2.3.3

Diagnosis and Treatment

One can make a tentative diagnosis when animals are known to have been exposed to an insecticide and they are exhibiting signs of convulsive seizures and neuromuscular dysfunction. One may assay tissue samples for residues of the specific compound, but one must interpret results with caution because some of the compounds may be found in fat of normal animals as a result of exposure to small concentrations in the environment. However, parts per million concentrations may have diagnostic significance if history and clinical signs are consistent with chlorinated hydrocarbon poisoning. Brain concentrations of pesticide are reported to be better correlated with toxicosis than are concentrations in body fat.[65] Other suitable tissue specimens include blood, milk, liver, kidney, and gastrointestinal contents.[15]

No specific antidote is available for the chlorinated hydrocarbons, so treatment is symptomatic. For animals exhibiting convulsive seizures or neuromuscular hyperactivity one can give chloral hydrate or pentobarbital intravenously carefully to effect. Sedative doses of these two agents should control most of the behavioral, nervous, and locomotor signs. One usually can discontinue sedation usually after 24 to 48 hours.

One should treat oral exposure with saline cathartics and an adsorbent such as activated charcoal. If exposure was via the dermal route, the animal requires a thoroughly bathing with soap and water. As in all cases of pesticide toxicity, one should eliminate the source of contamination if possible.[15,65]

20.2.2.4 Strychnine

The present day use of strychnine is primarily as a rodenticide. Although strychnine is available to the public through many retail outlets, instances of horses becoming intoxicated by strychnine are rare.[15,65,66] The approximate oral lethal dose for horses is 0.5 mg/kg.[15]

20.2.2.4.1 Clinical Signs

The clinical manifestation of strychnine toxicosis can appear as rapidly as 10 minutes to 2 hours following ingestion. Initial signs include apprehension, nervousness, and muscle stiffness. These signs are followed by violent tetanic seizures that may appear spontaneously or may be initiated by stimuli such as sound, touch, or light. These tetanic spasms may vary from a few seconds to a minute or more and are characterized by extreme extensor muscle rigidity. Apnea frequently occurs during the seizure. Intermittent periods of relaxation occur between seizures but become less frequent as the clinical episode progresses. In lethal cases the convulsive seizures become more frequent until death eventually occurs during a seizure or from exhaustion and anoxia. The entire clinical episode may last less than 2 hours.[15,65]

Additional signs that are reported in horses include sweating, incoordination, prostration, convulsions, and death within approximately 2 hours.[65]

20.2.2.4.2 Pathophysiology

Strychnine is absorbed rapidly from the intestinal tract but not from the stomach. The alkaloid nature of 1462
the compound promotes its ionization within an acid medium, hence minimal absorption occurs from the 1463
stomach.[15] Once absorbed, strychnine is distributed readily throughout the body. Strychnine does not accumulate in any given tissue, but significant concentrations occur in blood, liver, and kidney.[15,65] Strychnine is metabolized in the liver by hepatic microsomal enzymes, and it and its metabolites are excreted in urine.[15] Excretion of strychnine is rapid, with most of a lethal dose being eliminated within 24 hours.[65]

Glycine is an inhibitory neurotransmitter in the spinal cord and medulla that serves to dampen or modulate efferent motor neuron activity. The purpose of this modulating effect is to provide smooth, coordinated muscle contraction and activity that are appropriate and consistent with the requirements for locomotion and respiration. Strychnine acts competitively to antagonize glycine by blocking its uptake at postsynaptic sites on receptors in the spinal cord and brainstem. The result of this blockade is hyperexcitation of muscle groups from lack of normal inhibition. Muscle reflex activity is allowed to proceed in basically an uncontrolled manner. All striated muscles are affected, but the more powerful extensor muscles tend to predominate and produce generalized rigidity and tonic seizures.[15,65]

20.2.2.4.3 Diagnosis and Treatment

One may make a tentative diagnosis of strychnine poisoning based on history of possible exposure, characteristic clinical signs, and a rapid recovery in animals treated in time. To confirm the diagnosis, one may submit tissue samples for evaluation. Liver, kidney, and stomach contents are the most suitable specimens for analysis, but urine and CNS tissues also are useful.[15,65]

Treatment of strychnine poisoning is symptomatic because no specific antidote is available. The horse should be kept in a quiet environment with minimal stimulation. Of primary importance is maintenance of relaxation and prevention of asphyxia. One should give pentobarbital or chloral hydrate solutions intravenously to produce sedation effectively. Complete anesthetization of the horse usually is not required or desired. Other medications have been recommended for use in dogs and should be effective in horses as well. These medications include the centrally acting muscle relaxants methocarbamol (150 mg/kg intravenously) and guaifenesin (110 mg/kg intravenously) repeated as needed; diazepam and xylazine to control seizures; and inhalation anesthetics if necessary.[15] Oxygen therapy and assisted ventilation may be necessary in some animals.

Additional agents that may prove beneficial are activated charcoal given orally, followed by a laxative to evacuate the bowel. Acidification of urine with oral ammonium chloride at 132 mg/kg also may enhance excretion of strychnine. Although toxic doses of strychnine may be depleted from the body in a short time, one may have to maintain relaxation and sedation in the horse for 24 to 48 hours.[15]

20.2.2.5 Metaldehyde

Metaldehyde is used primarily as a molluscicide in snail and slug baits in coastal and low-lying areas. The baits are generally in the form of meal or pellets and are placed around crops or ornamental plants.[15,65] Horses can become poisoned through inadvertent exposure to these baits. No specific toxicity studies could be found regarding horses, but horses are reported possibly to be more susceptible to toxicosis than dogs, in which the acute oral LD_{50} may be as little as 60 to 100 mg/kg.[65] In two separate reports, horses died following ingestion of as little as 60 mg/kg[67] and 120 mg/kg. Experimentally, a parasitized yearling colt died following exposure to 0.1 mg/kg.[68]

20.2.2.5.1 Clinical Signs

The clinical signs reported in horses include acute onset of signs within 1 hour following exposure, excessive sweating, profuse salivation and restlessness, hyperesthesia, incoordination, and tachycardia. One horse exhibited violent muscle spasms just before death.[67] Other signs include muscle fasciculations, clonic spasms, and rapid and deep respiratory movements.[68] Death occurs rapidly (3 to 5 hours) in horses exposed to a lethal amount of metaldehyde[67,68] and is thought to result from acute respiratory failure.[65] Dogs also are reported to exhibit signs of convulsions and elevated body temperature.[15,65]

20.2.2.5.2
Pathophysiology

Metaldehyde is absorbed readily from the gastrointestinal tract. Gastric hydrochloric acid enhances its decomposition to acetaldehyde, and metaldehyde and acetaldehyde are absorbed and readily cross the blood-brain barrier. The exact mechanism of action of metaldehyde is yet to be elucidated.[65]

20.2.2.5.3
Diagnosis and Treatment

A history of possible exposure to a molluscicide coupled with the appropriate clinical signs can lead to a tentative diagnosis of metaldehyde toxicity. One can analyze stomach contents for acetaldehyde, and a formaldehyde-like odor may be present in the stomach contents.[15,65]

No antidote is available for metaldehyde. Treatment is symptomatic and aimed at sedation, removing the compound from the stomach, and supportive therapy such as maintaining proper fluid, electrolyte, and acid-base indexes. Sedatives such as xylazine, acepromazine, and diazepam may be useful to control convulsive behavior. Methocarbamol may help control muscle spasms and fasciculations, and one can give mineral oil orally to aid evacuation of the gastrointestinal tract.[15,65]

20.2.2.6
Methiocarb

This molluscicide has been reported to cause toxicity in two horses: one died and the other fully recovered.[69,70] In each instance the amount ingested was estimated to be from 100 to 125 g of a 4% weight per volume preparation. 1463

1464

20.2.2.6.1
Clinical Signs

The onset of signs was rapid, beginning within a few minutes of ingestion. Muscle tremors, which became severe, and profuse sweating and salivation were noted. Both horses had increased heart and respiratory rates, and the surviving horse also exhibited signs of abdominal discomfort. Clinical signs gradually lessened until they became absent approximately 12 hours following onset in the surviving horse.[70] The horse fatally intoxicated died about 12 hours after initially showing signs. Postmortem findings included severe generalized pulmonary congestion with froth accumulation in the airways, and a number of large hemorrhagic areas scattered throughout the intestinal tract.[69]

20.2.2.6.2
Treatment

The specific antidote for methiocarb is atropine sulfate.[69,70] Repeated dosing may be necessary. Other suggested remedies include supportive therapy consisting of sedatives, calcium solutions, and mineral oil.[70]

20.2.2.7
4-Aminopyridine

4-Aminopyridine is used commercially as a bird repellent and often is mixed with grain before its distribution. In the one reported instance of 4-aminopyridine toxicity, affected horses were exposed to corn that contained the substance.[71]

20.2.2.7.1
Clinical Signs

The two affected horses began showing signs of profuse sweating, severe convulsions, behavioral abnormalities, and rapid fluttering of the third eyelid. Both horses died within 2 hours of the onset of clinical signs, and about 8 hours after ingesting the contaminated corn. No specific lesions were noted at necropsy. The estimated lethal dose of 4-aminopyridine for these two horses was 2 to 3 mg/kg body mass.[71]

20.2.2.7.2
Pathophysiology

The mechanism whereby 4-aminopyridine causes death has not been elucidated. However, this substance readily crosses the blood-brain barrier and may enhance the release of acetylcholine and other neurotransmitters from prejunctional nerve endings.[72,73] The result is a stimulatory effect on the CNS.

20.2.2.7.3
Diagnosis and Treatment

One can confirm a diagnosis of suspected toxicity by testing the suspect material and stomach contents of affected horses. One can use high-performance liquid chromatography to identify and quantitate 4-aminopyridine in these samples.[71] No specific antidote for 4-aminopyridine toxicity is suggested, but one can give affected horses supportive therapy and mineral oil orally to enhance evacuation of the intestinal tract. From the known mechanism of action of this compound, CNS depressants such as phenobarbital would seem to have some value in treating the CNS signs of affected horses. However, the efficacy of this treatment regimen has not been proved and cannot be recommended at this time.

20.2.2.8
Levamisole

Levamisole has not gained widespread use as an equine anthelmintic, principally because of its limited efficacy in destroying strongyles and because its toxic dose is close to its therapeutic dose. Levamisole is effective, however, in eliminating lungworms, ascarids, and adult pinworms from horses. The drug also has been used in human beings and other animal species in an attempt to enhance immune system function.

20.2.2.8.1
Clinical Signs

Clinical signs associated with levamisole toxicity occur within 1 hour of administration and include hyperexcitability, muscle tremors, hyperactivity, and excessive sweating, and lacrimation. Recumbency may follow these signs, but animals that recover generally appear normal by 12 hours after exposure.[74–76] Adverse effects are more likely following subcutaneous injection than by oral drenching.[76] The toxic dose of 20 mg/kg is close to the therapeutic dose of 15 mg/kg, and 20 mg/kg may cause death in some horses.[77]

20.2.2.8.2

Diagnosis and Treatment

One should suspect a diagnosis when horses exhibit clinical signs suggesting levamisole toxicosis and exposure is known to have occurred. No specific antidote is available, so therapy includes supportive care. Most animals recover uneventfully if a sublethal dose has been given.

20.2.2.9

Carbon Disulfide

Carbon disulfide is seldom used as an anthelmintic in present times but has enjoyed widespread use in past years for treatment of infestation caused by *Parascaris equorum* and *Gastrophilus* species.[78] Carbon disulfide is a manufactured product used as a solvent for resins, pesticides, and waxes and as an agent to remove greases. The chemical is used widely as a fumigant to control insects in stored grain.[15] Carbon disulfide is an exceptional fat solvent and in the pure state is a clear, colorless volatile liquid with a sweet, aromatic odor resembling that of decaying cabbage. The chemical is well absorbed through the skin and lungs and following ingestion.[7,15]

20.2.2.9.1

Clinical Signs

Reported signs of acute toxicity in animals include dyspnea and cyanosis, spasmodic tremors, vascular collapse, prostration, convulsions, coma, and death.[15] Signs referable to local irritation following inhalation might include salivation and coughing. A combination product of piperazine–carbon disulfide and phenothiazine caused transitory signs of overtranquilization and unsteady gait when dosed 8 oz per 45 kg of body mass.[78] Whether any of these effects were related directly to carbon disulfide was not determined.

Chronic exposure causes neuropsychiatric changes, peripheral neuropathies, and cranial nerve dysfunction in human beings,[7] but chronic exposure in horses is unlikely.

20.2.2.9.2

Pathophysiology

1464

1465

Because carbon disulfide is a potent fat solvent, local skin contact results in erythema and pain, and prolonged contact produces chemical burns and vesiculation.[7] The chemical is irritating to mucous membranes when inhaled or ingested.[7,78]

At the cellular level, carbon disulfide acts to block enzymatic processes by reacting with nucleophilic compounds including pyridoxamine, monoamine oxidase in the cerebrum, and dopamine decarboxylase. Carbon disulfide binds to microsomal enzymes, thereby reducing their activity, and produces a centrilobular hepatic necrosis. In addition, carbon disulfide chelates copper and zinc and therefore can produce disturbances in tract mineral balance.[7]

20.2.2.9.3

Diagnosis and Treatment

No specific diagnostic test is available for use on animals suspected of suffering from carbon disulfide toxicosis. In one report, affected animals had increased BUN and bilirubin concentrations, increased serum

activities of AST and alanine aminotransferase, and increased serum cholesterol concentration. Affected horses also had depressed serum concentrations of protein-bound iodine and magnesium.[78]

In human beings the iodine-azide test is useful to identify carbon disulfide metabolites in urine,[7] but the efficacy of this procedure for diagnostic use in horses is unknown.

Treatment of toxicosis primarily involves removal of the source and symptomatic care.

20.2.3 MISCELLANEOUS AGENTS

20.2.3.1 Nicotine

Nicotine is an alkaloid contained in tobacco leaves. Although toxicosis might occur from ingestion of excessive amounts of tobacco leaves or cured tobacco in cigarettes or cigars, this route of toxicosis is probably rare in horses. Horses are more likely to be intoxicated by ingestion or exposure to the salt nicotine sulfate.[15,65] A concentrated solution of nicotine sulfate (Blackleaf 40) has been used to control leaf-eating insects and occasionally as a premises spray to control certain ectoparasites.[15,24] Horses may ingest this substance from spills of the solution, from contaminated containers, or from foliage that has been sprayed with the product.[65] Topical exposure may result when horses are housed in stables where this product has been used for mite control.[24] The lethal dose of nicotine in the horse is 100 to 300 mg.[15]

20.2.3.1.1 Clinical Signs

The signs of nicotine toxicity are rapid in onset, often occurring within a few minutes following exposure. Initially, the signs noted are those of cholinergic overstimulation, that is, excitement, increased respiration, and salivation. Increased peristalsis and diarrhea also can occur.[15,24] These signs are transitory and are followed rapidly by depression, muscle weakness and ataxia, slow and shallow respiration, and an increased heart rate. Convulsions also can occur. In fatal cases, these signs progress to collapse, coma, and death within minutes to hours following the onset of clinical signs.[15,24,65]

20.2.3.1.2 Pathophysiology

Nicotine is absorbed readily from the oral mucosa, respiratory tract, gastrointestinal tract (excluding the stomach), and through intact skin.[7,15] If ingested, nicotine also can exert a direct, rapid caustic action on the mucosa of the mouth and throat, esophagus, and stomach.[15] The substance is metabolized primarily in the liver, and nicotine and its metabolites are excreted in urine. In human beings, urinary acidification greatly enhances clearance of nicotine and its metabolites.[7]

Initially, and only for a short time, nicotine stimulates the autonomic nervous system ganglia, neuromuscular junctions, and some synapses in the CNS by depolarization of the postsynaptic membrane.[7,15] With toxicosis, however, the stimulation is followed rapidly by a depolarizing-type blockade of all these nicotinic cholinergic receptors.[7,15,65] Large doses result in a descending paralysis of the CNS, and death results from respiratory failure caused by paralysis of the diaphragm and chest muscles.[15,65] The effects of a sublethal dose should diminish in a few hours.[15]

20.2.3.1.3 Diagnosis and Treatment

No diagnostic lesions are present at necropsy. However, the distinct odor of nicotine may be present in stomach contents.[15,65] One can evaluate urine, blood, liver, kidney, and other tissues for nicotine content in suspect cases.[15]

Treatment often is ineffective because of the rapid course of the toxicosis. However, because no specific antidote exists for nicotine toxicity, one should treat affected horses symptomatically. If exposure has been via the skin, washing with soap and water is indicated.[15] Following oral exposure, one can treat affected horses with oral laxatives, tannic acid, or potassium permanganate in an attempt to reduce absorption of the toxin. Activated charcoal also may be beneficial in adsorbing residual nicotine in the intestinal tract.[15,24] Atropine sulfate is reported to be without value in affected horses because it does not protect vital nicotinic receptors in the respiratory muscles and in the CNS from the effects of nicotine.[65] Artificial respiration becomes the only means of maintaining life once the respiratory depression reaches a critical level. This last-ditch effort usually fails.[65]

20.2.3.2 Ammonia

Ammonia toxicosis in the horse can occur in two ways: by primary exposure to ammonia gas or by secondary metabolism of urea to ammonia within the body (see Urea and Nonprotein Nitrogen Substances).[7,15]

Primary exposure to toxic concentrations of ammonia gas is probably rare in horses, even though ammonia is the air pollutant most frequently found in high concentrations in animal facilities. The concentrations of ammonia found in stables may be irritating to horses but probably will never reach lethal concentrations. 1465
Another source of ammonia toxicosis to horses might be compressed anhydrous ammonia, which is used as 1466
an agricultural fertilizer. An accidental spill or spray of anhydrous ammonia onto a horse could have disastrous results that might be lethal.[15] Human beings can detect the odor of ammonia at a concentration of 30 ppm, eye and nasal irritation occurs near 50 ppm, and severe pulmonary dysfunction results from concentrations greater than 1000 ppm. Immediate death occurs at concentrations nearing 1500 ppm.[7]

20.2.3.2.1 Clinical Signs

Signs associated with low concentrations of aerial ammonia are those of irritation to the eyes and respiratory tract. Excessive tearing, shallow breathing, coughing, and nasal discharge are common findings. Higher concentrations can induce laryngospasm and pulmonary edema.[7] Exposure to anhydrous ammonia can result in permanent or impaired loss of eyesight, respiratory disease, and skin burns.[15]

20.2.3.2.2 Pathophysiology

Ammonia is a highly water-soluble, irritating alkaline gas that causes liquefactive necrosis at high concentrations.[7] Because ammonia is so highly water-soluble, it readily reacts with the mucous membranes of the eye and the respiratory tract.[15]

20.2.3.2.3

Diagnosis and Treatment

A diagnosis of aerial ammonia toxicosis is based primarily on history and physical examination findings. Laboratory evaluation is of little value in establishing a diagnosis of inhalation exposure,[15] but laboratory evaluation can be useful to assess the degree of damage to the respiratory tract and to evaluate the effectiveness of therapy.

Treatment involves removing the horse from the source of exposure. If exposure has been severe enough to result in ophthalmic or respiratory tract disease, one should treat these conditions accordingly.

20.2.3.3

Urea and Nonprotein Nitrogen Substances

Urea and other nonprotein nitrogen substances, including various ammonium salts, are added to ruminant rations as a source of nonprotein nitrogen because ruminants can use these compounds to provide a large percentage of their protein nitrogen requirements. Urea has additional uses as a fertilizer and as a substitute for salt in melting snow and ice in metropolitan areas.[15,38] Horses are only mildly susceptible to urea toxicosis, and for horses to ingest sufficient urea or urea-containing feedstuffs to cause clinical signs is highly unlikely.[15,24] However, horses are more susceptible to toxicosis by ingestion of ammonium salts,[15] which may occur by accidental exposure to these substances. In horses, urea is lethal when ingested at a rate of 4 g/kg of body mass, and ammonium salts are lethal at a dose of 1.5 g/kg body mass.[38] Urea and other nonprotein nitrogen formulations are toxic to animals simply because they are hydrolyzed to ammonia, which is responsible for causing the derangements associated with toxicosis. Therefore urea and nonaerosol ammonia toxicosis are considered together.

20.2.3.3.1

Clinical Signs

The spectrum and intensity of signs in ruminants with urea toxicosis vary, and the same is probably true for horses. The clinical course is usually acute and rapid, often occurring from a few minutes to a few hours following consumption.[15] Occasionally, animals are found dead, or they may die quickly following signs of weakness, dyspnea, colic, and terminal tonic convulsions. Other varied signs can be present. Behavioral abnormalities such as restlessness and dullness may be present. Excitement and even belligerency can follow these signs. Nervous signs including hyperesthesia, tremors, and muscle twitching and spasms can occur. Autonomic nervous system derangements can include salivation, bradycardia, hypertension, and severe colic. More terminal signs can include increased and labored respirations, cardiac arrhythmias, frothing at the mouth, and cyanosis. Intermittent tonic-opisthotonic seizures also can be elicited near death. The onset of signs may range from 10 minutes to 4 hours, and death may occur in a few hours to 3 to 4 days.[38]

20.2.3.3.2

Pathophysiology

Urea is hydrolyzed to ammonia by the action of the enzyme urease. This reaction is speeded by an alkaline pH, and in the horse these requirements are found in the cecum. In horses, urea is absorbed from the small intestine and excreted via the urine. The only urea that might contribute to toxicity in the horse would be that excessive amount that reaches the cecum and is available for hydrolysis.[24]

In normal animals, ammonia liberated from nonprotein nitrogen sources can be in the form of the ammonium ion. This ion is soluble, but its charge prevents it from being absorbed across membranes. Ammonia is also soluble, however, but because it lacks an ionic charge, it can be absorbed readily across membranes to enter the bloodstream.[38]

Ammonia is a normal by-product of tissue metabolism, and in the hepatocytes it is converted to urea by the urea cycle or is incorporated into glutamic acid in the synthesis of glutamine. Toxicosis occurs when the amount of ammonia absorbed into the bloodstream exceeds the ability of the horse to detoxify it.[38]

The primary mechanism of ammonia toxicosis is thought to be inhibition of the citric acid cycle, but the exact mechanism by which this occurs is not known.[38] Ammonia saturation of the glutamine-synthesizing system has been suggested to have an inhibitory effect on the citrate cycle, creating a decrease in its intermediates and a subsequent decrease in cellular energy production and respiration. As the citrate cycle fails, cells begin to malfunction. Cellular energy and respiration deficits may cause ultrastructural damage 1466
leading to degenerative changes and eventual cell death. The role of ammonia in causing signs of 1467
encephalopathy is controversial and not well understood.[79]

Laboratory abnormalities associated with ammonia toxicosis include elevated serum potassium, phosphorus, lactic acid, glucose, and concentration of the liver enzyme AST. Urine output decreases, and PCV increases as impending cardiac failure and shock ensue.[38]

The ultimate cause of death is inconsistent in urea toxicosis and poisoning by ammonium compounds. Cardiac failure may be induced by hyperkalemia, or ventricular fibrillation may result from the myocardial effects of ammonia itself. Convulsions may be prolonged and responsible for fatal anoxia. Pulmonary edema may be a complicating factor in some cases. Death also has been postulated to result from asphyxiation.[38]

20.2.3.3.3 Diagnosis and Treatment

Animals that die of ammonia toxicosis exhibit no characteristic lesions. Generalized venous stasis and congestion of organs may be present, along with pulmonary edema and scattered petechiation and ecchymoses. A strong odor of ammonia may be present, but this is probably much more characteristic of ruminants than of monogastric animals.[38]

Clinical signs and history can be helpful in establishing a diagnosis. One can perform laboratory evaluation for blood ammonia, but one must interpret the results with caution.[38] Storage of the sample, length of time between death and time of sampling, and length of time between sampling and analysis can influence the blood ammonia concentration. One should freeze tissue specimens immediately if they are to be analyzed.[15] One also can analyze suspect feeds for urea or nonprotein nitrogen content.

Treatment is often unrewarding because of the rapidity of onset. No specific antidote is available for ammonia, so therapy is mostly symptomatic. Orally administered laxatives such as mineral oil may be beneficial. One should correct any deficits in fluid volume or abnormalities in acid-base or electrolyte concentrations. One can control horses that are convulsing with pentobarbital, and one should maintain a patent airway. Assisted ventilation, if necessary, is usually futile because of the poor survival of animals affected so severely.[38]

20.3 Toxicoses Causing Signs Relating to Central Nervous System Depression

As with toxic problems associated with other primary clinical signs, it can be difficult to determine the source of central nervous depression. The principal task is to rule out the existence of primary cranial disease. Even with the availability of advanced imaging equipment, this can be difficult. Unless the clinical signs and/or history are definitive, the diagnosis of a toxic problem is often presumptive.

20.3.1 PLANTS

20.3.1.1 Black Locust *(Robinia pseudoacacia)*

No clinical reports of black locust toxicity were found in the literature. The tree has been described as being toxic to horses, however.[5,6]

The toxic principle is classified as a lectin, which is present in seeds, sap, roots, wood, leaves, and bark of the plant. Lectin has been used in cytologic research because of its ability to stimulate glycoprotein biosynthesis and cell proliferation in lymphocytes of various animal species.[80] Horses may become intoxicated by ingesting the bark. Only small amounts of lectin are reported to precipitate clinical disease.[6]

The clinical signs reported are mental depression, weakness, posterior paralysis, an irregular heart rate, pale mucous membranes, and anorexia. One also may note abdominal discomfort and diarrhea of varying degrees.[5,6]

No definitive diagnostic test is available. Treatment of suspected toxicosis is mostly symptomatic and should include removal of the source, evacuation of the intestinal tract, and maintenance of normal fluid, electrolyte, and acid-base indexes.

20.3.1.2 Bracken Fern *(Pteridium aquilinum)*

Bracken fern is found most commonly in forested areas, burns, or in abandoned fields in the northern and western United States.[6] Toxicity can occur at any time of year, but horses are more likely to consume the plant in late summer and fall when other forage is scarce. However, horses also might acquire a taste for the plant in pastures or when it is incorporated in bedding. Horses also can become intoxicated from hay contaminated with large amounts of bracken fern. The entire plant is considered to be toxic.[5]

20.3.1.2.1 Clinical Signs

Signs of toxicosis occur after the horse has been consuming the plant for 30 to 60 days. Horses also can exhibit signs even if they have not ingested bracken fern for 2 to 3 weeks.[5] The signs most frequently reported are incoordination, which may progress to severe ataxia; postural abnormalities, including arching of the back, crouching, and a base-wide stance; muscle fasciculations, which can progress to severe tremors; and bradycardia with cardiac arrhythmias early in the disease course, but tachycardia is most prevalent terminally. Terminal stages of the disease are characterized by signs of opisthotonus and clonic

convulsions.[5,6] One report also describes an affected horse showing signs of colic and acute hemolytic anemia.[81]

20.3.1.2.2 Pathophysiology

The agent in bracken fern that is toxic to horses is thiaminase.[5,6] Bracken fern also is reported to contain a heat-stabile antithiamine factor,[82] a radiomimetic factor capable of inducing bone marrow suppression, 1467
and a β-glucopyranoside which may enhance the release of endogenous histamine.[6] The significance of 1468
these last two compounds in the development of toxicity in horses is unknown. Thiamine plays an integral role in carbohydrate, fat, and protein metabolism and acts as a cofactor in enzymatic pathways responsible for energy production. Thiamine is an important cofactor in the decarboxylation of pyruvate to acetyl coenzyme A, which subsequently enters the tricarboxylic acid cycle.

Thiamine deficiency acts to interrupt these cellular energy processes and also limits certain metabolic pathways available for pyruvate metabolism, resulting in the systemic accumulation of a variety of metabolites, including pyruvate and lactate.

20.3.1.2.3 Diagnosis and Treatment

History and clinical signs are helpful in arriving at a diagnosis. No pathognomonic lesions or laboratory abnormalities occur, but expected laboratory findings include elevated blood pyruvate concentration and decreased plasma thiamine and red blood cell transketolase concentrations.[6]

One should administer thiamine to affected horses at a dose of 0.25 to 0.5 mg/kg body mass daily intravenously, subcutaneously, or intramuscularly for several days. Initially, one can give thiamine at a dose of 5 to 10 mg/kg intravenously, but one should dilute this dose in fluids and give it slowly because of the frequency of adverse reactions when thiamine is given intravenously. One usually can prevent thiamine deficiency by dietary supplementation of yeast or cereal grains.[6]

20.3.1.3 Equisetum *(Equisetum arvense)*

Equisetum, commonly called horsetail, marestail, or scouring rush, has geographic distribution similar to that of bracken fern. Like bracken fern, equisetum is unpalatable to horses, and toxicosis usually results from hay contaminated with the plant.[5,6]

Thiaminase is the toxic principle found in equisetum, and the clinical signs, pathogenesis, and treatment are virtually identical to those of bracken fern.[5,6]

20.3.1.4 Milkweed *(Asclepias* Species*)*

Several species of *Asclepias* have been reported to be toxic to large animals,[6,83] but no specific reports of horses intoxicated by this plant were found. The plants are reported to be distasteful to animals and not commonly grazed, but the plant may become incorporated into hay.

Affected animals are reported to have a weak, rapid pulse; dyspnea; loss of muscular control; and muscular spasms. Salivation, bloating, and convulsions also may occur.[6,83] Most animals that reach the convulsive stage die.[83]

Numerous compounds have been isolated from *Asclepias* species, including resinoids and cardioactive glycosides. One resinoid produces smooth muscle spasms of the gastrointestinal tract.[6] The mechanism of action of the other toxins has not been elucidated.

No specific antidote is available,[6] but supportive care, including evacuation of the gastrointestinal tract, is indicated.

20.3.1.5 White Snakeroot *(Eupatorium rugosum)* and Rayless Goldenrod *(Isocoma wrightii)*

Cases of white snakeroot intoxication have been reported primarily in the eastern half of the United States, from Michigan south to Alabama and eastward.[84] The toxic principle is tremetol, which has been described as a fat-soluble, high-molecular-weight alcohol.[43,85] Tremetol poisoning is reported to be most prevalent in dry years or in circumstances in which animals are subjected to inadequate pasturage. The toxin is excreted slowly and therefore tends to accumulate in animals grazing the plant. Because of this cumulative effect, repeated small doses can result in toxicosis as well as a single, larger exposure to the plant. A total amount of green plant varying from 1% to 10% of body weight may be lethal to horses.[84] The toxic principle remains in the dried plant after freezing.[85] In the southwestern United States, rayless goldenrod is the source of tremetol, and ingestion of this plant produces the same clinical syndrome as that of white snakeroot intoxication.

20.3.1.5.1 Clinical Signs

Depression, a stiff gait with frequent crossing of the hindlimbs, and patchy, profuse sweating seem to be the most profound signs of tremetol toxicity. Other, less frequently noted findings include muscle tremors, particularly of the shoulders and limbs; labored or shallow respirations; normal to subnormal body temperature; pupillary dilation; cardiac arrhythmias; and darkly discolored urine.[84,85]

The time of onset of signs can vary considerably from less than 2 days to as long as 3 weeks after the last exposure to the plant. Most horses showing clinical signs die. Recovery is reported to be rare and usually is prolonged and often incomplete. However, a recent report describes two horses that apparently fully recovered from suspected tremetol toxicity.[85] Death often follows the appearance of clinical signs within 1 to 3 days.[84]

Laboratory abnormalities routinely noted include hematuria, hemoglobinuria and proteinuria, mild elevations in serum alkaline phosphatase activity, elevated AST concentration, and significant elevation of serum CK activity. Acidosis, hyperglycemia, and glucosuria also have been documented.[84,85]

Postmortem findings primarily consist of mild renal tubular degeneration and necrosis; nonsuppurative colitis; pulmonary congestion; increased amounts of pleural and peritoneal fluid; and moderate to severe centrolobular vacuolar changes in the liver. Other significant findings can include pericarditis and extensive, patchy myocardial degeneration and necrosis. Extensive, minute epicardial hemorrhage also has 1468

been reported.[84,85] One reported case also exhibited moderate, multifocal degeneration of skeletal muscle.[84] 1469

20.3.1.5.2

Pathophysiology

The mechanism whereby tremetol causes the aforementioned lesions and signs remains unknown.

20.3.1.5.3

Diagnosis and Treatment

Diagnosis of tremetol toxicity is based on observation of the described clinical signs and concurrent clinicopathologic abnormalities. Additionally, evidence that the affected horses have been exposed to white snakeroot should be present, and when available, necropsy findings should be compatible with those described for tremetol toxicity. Isolation of tremetol from suspect samples has not been reported, and attempts at recovering the substance from blood, urine, liver, kidney, and stomach and cecal contents from affected horses have been unsuccessful.[84]

Treatment is symptomatic. The primary goal of therapy is promptly removing the horse from exposure to the plant and providing supportive care. One should attempt to evacuate the gastrointestinal tract of the horse with laxatives such as mineral oil. Activated charcoal also has been suggested as being beneficial in removing the toxin.[85] Based on observed histopathologic abnormalities, volume diuresis of affected animals seems appropriate, and one should attempt to maintain normal acid-base and serum electrolyte concentrations. One should provide all affected horses and herdmates with adequate and suitable forage and ample fresh water.

20.3.1.6

Yellow Star Thistle *(Centaurea solstitialis)* and Russian Knapweed *(Centaurea repens)*

Both yellow star thistle and Russian knapweed cause nigropallidal encephalomalacia in horses. These plants are found scattered over much of the western United States and are most abundant in nonirrigated pastures during the dry seasons of summer and fall. Both plants have a minimal moisture requirement and so may be the only green plants remaining in a dry season. Consequently, most poisonings occur during the summer or fall months.[86–88]

Horses apparently reject the plants when more suitable vegetation is available, for the disease does not occur in horses grazing improved pastures or grassland range.[88] However, some horses are reported to develop a craving for the plant and selectively seek it out.[86] Horses may eat the weeds, occasionally or frequently, without becoming ill, and continuous and protracted exposure to the plants is necessary for toxicosis to develop under experimental conditions. Feeding trials have shown that horses must consume an amount of weed equivalent to 59% to 200% of their body weight of yellow star thistle and 59% to 63% of their body weight of Russian knapweed for 3 to 11 weeks of continuous feeding before clinical signs develop. The plants retain their toxicity when dried and incorporated into hay. All ages may be affected, but in general, younger horses seem more prone to the disease. One study reported a median age of about 2 years in affected horses.[88] Horses appear to be the only animals that develop nigropallidal encephalomalacia when exposed to these plants.

20.3.1.6.1 Clinical Signs

The onset of signs is always sudden, beginning with variable degrees of impairment of eating and drinking. Coordinated movements of prehension, mastication, and deglutition are often lacking. Affected horses are unable to chew adequately and propel the food to the back of the mouth. Some horses may show only faulty prehension, whereas others are unable to eat at all. Most horses, however, appear to be able to swallow if feed or water gains access to the posterior pharynx. More severely affected horses may attempt to drink by immersing their muzzle deeply into the water in an attempt to force water into the posterior pharynx.[86,88–90]

Hypertonicity of the facial muscles is a characteristic sign, particularly when feed is offered.[86] The horse often holds the mouth partially opened with the lips retracted, resulting in a fixed facial expression. The tongue may protrude from the mouth, and many horses display constant chewing movements.[86,90]

Other characteristic signs include weight loss, mild to moderate depression, and yawning. Most horses can be roused readily from somnolence by mild stimulation. Few animals may show aimless, slow walking or circling early in the disease course. The gait is usually normal, but occasional deficits are apparent, including stiffness, slowness, ataxia, tetraparesis, and conscious proprioceptive deficits.[86,90] In cases of prolonged exposure, a wobbly, shuffling gait may occur because of weakness. Sensation and reflexes appear normal, and the animals are afebrile.[90]

Horses less severely affected may adopt unusual means of eating by scooping feed into the mouth. These animals may survive for months, but complete recovery has not been observed in confirmed cases of the disease. In some instances, however, residual signs may become almost undetectable.[88] Death of affected horses is from starvation and dehydration.

20.3.1.6.2 Pathophysiology

The pathogenesis of the lesions is unknown, but these plants have been postulated possibly to contain a specifically toxic substance or to lack some nutritional component necessary for the health and well-being of the horse.[89,90] Several sesquiterpene lactones and polyacetylenes have been isolated from these plants, but their significance remains undetermined.[91]

20.3.1.6.3 Diagnosis and Treatment

The antemortem diagnosis of nigropallidal encephalomalacia is based largely on observation of clinical signs and prolonged exposure of the horse to the plants by grazing or by severely contaminated hay. If available, magnetic resonance imaging can identify characteristic lesions on T1-weighted, T2-weighted, and proton density images. These lesions do not contrast enhance after gadolinium- 1469
diethylenetriaminopentaacetic acid administration.[92] Characteristic necropsy findings include bilaterally 1470
symmetric softening and necrosis in areas of the globus pallidus and substantia nigra. These areas are usually sharply defined and may be cavitary.[86,90]

No known treatment exists for affected horses. Prevention requires keeping horses from the plant and providing adequate, suitable forage.

20.3.1.7 Milk Vetch and Timber Milk Vetch (*Astragalus* species)

Most of the variants of *Astragalus miser* are referred to as timber milk vetch or milk vetch. These plants are found primarily in the western United States from northern Mexico to Canada, and are essentially a cause of toxicosis to ruminants. Horses are reported to be poisoned by this group of plants, but there are no reports of the lesions.[59]

The disease in ruminants is characterized primarily by general depression, mental dullness, incoordination, and eventual hindlimb paralysis. Respiratory distress, cyanosis, and acute collapse also may occur. Acute and chronic forms of the syndrome are reported.[59]

The toxic principle, referred to as miserotoxin, is a β-d-glycoside of 3-nitro-1-propanol, which is metabolized in the intestinal tract to the highly toxic compound 3-nitro-1-propanol. Miserotoxin is broken down into inorganic nitrite and a three-carbon side chain. The nitrite is responsible for producing methemoglobinemia in animals but is not the primary cause of death.[59]

No specific antidote is recommended. Poisoning is prevented by controlling the plants with herbicides and preventing livestock from grazing the plant.

20.3.1.8 Mushroom *(Amanita verna)*

One report describes fatal intoxication of a horse by ingestion of toadstools *(Amanita verna)*.[93] Mushrooms are apparently unpalatable to livestock species, but the described horse also suffered from meningioangiomatosis, a rare benign tumor of the meninges and brain. The authors speculate that the presence of the tumor may have resulted in abnormal mentation and altered the normal eating behavior of the horse, resulting in mushroom consumption.

20.3.1.8.1 Clinical Signs

The described horse had acute onset of depression, head pressing, ataxia, and repeated recumbency with difficulty in rising. Clinical signs of shock, including hypothermia, poor capillary perfusion, and weak pulse also were apparent. The horse was euthanized because of continued deterioration and lack of response to supportive therapy.

20.3.1.8.2 Pathophysiology

Amanita mushrooms contain a number of biologically active cyclic peptides including amatoxins, phallotoxins, phallolysin, and antaminide. Some of these peptides affect actin polymerization and cause hepatocytes to lose their cytoskeletal organization and cellular attachments, resulting in hepatocellular dissociation and necrosis. Amanitins are peptides that inhibit RNA polymerase II within the nucleus, thereby preventing DNA transcription and subsequent protein synthesis. The end result is acute submassive hepatic necrosis, which was present in the described horse.

20.3.1.8.3 Diagnosis and Treatment

Diagnosis in the described horse was based on histologic findings of submassive hepatic necrosis, acute onset of clinical signs, and presence of partially digested mushrooms in stomach contents. No specific therapy is recommended, although prompt evacuation of the gastrointestinal tract coupled with supportive care would seem prudent. The quantity of mushrooms ingested appears to be the primary prognostic indicator. If sufficient amounts of toxin are absorbed, prognosis is grave and often leads to hepatic coma in other species.

20.3.2 MEDICATIONS

20.3.2.1 Piperazine

Piperazine has been used widely as an equine anthelmintic, particularly because of its efficacy against ascarids. Numerous derivatives, principally salts of piperazine, have been developed, and these compounds have a wide margin of safety in all animals. Chemically, piperazine is a diethylenediamine that is freely soluble in water and glycerol. Piperazine is a strong base and therefore readily absorbs water and carbon dioxide.[77]

Piperazine and its salts are absorbed readily from the anterior gastrointestinal tract. Following absorption, piperazine is metabolized partially in tissues, but approximately 30% to 40% is excreted in urine. Urinary excretion is usually complete within 24 hours. Piperazine is reported to be virtually nontoxic under ordinary circumstances for adult horses and foals.[77]

Reports of toxicity in horses are rare, but the amount of compound necessary to produce clinical signs of toxicity apparently varies among the different piperazine salts. Foals treated with six times the normal dosage of piperazine adipate failed to show any ill effects. However, foals and adult horses treated with 6 times the normal dosage of piperazine citrate[94] and piperazine monohydrochloride[74] showed clinical signs of toxicity. Toxicity apparently results from the inadvertent overdosage of certain piperazine salts.

20.3.2.1.1 Clinical Signs

The clinical signs of piperazine toxicity are primarily those of depression and incoordination. Horses given excessive amounts of piperazine citrate began to show clinical signs over 12 to 48 hours following ingestion. The horses were depressed and incoordinated. Walking produced a moderate incoordination in
all legs, and when standing, affected horses would sway as if their sense of balance were affected 1470
adversely. Hyperesthesia to touch but not to sound was apparent. Other findings included dilated pupils 1471
that responded slowly to light, gross muscle tremors, and constipation. All laboratory values measured were within normal limits. These included a hemogram and serum electrolyte and muscle enzyme concentrations. Appetite initially was depressed in affected horses but returned to normal with recovery.[95]

The one horse experimentally intoxicated with piperazine monohydrochloride began showing signs of CNS depression 6 hours after treatment. By 24 hours after treatment, the horse was unsteady and reluctant to move. By 4 days after treatment, the horse stood quietly in a normal stance. Anorexia was notable during the entire posttreatment period, and the horse died on the eleventh day following treatment.[74]

20.3.2.1.2

Pathophysiology

The mechanism whereby piperazine produces its toxic effects in horses has not been elucidated. Piperazine and its derivatives have an anticholinergic action at the myoneural junction in ascarids. The resulting neuromuscular blockade produces a narcotizing or paralytic effect on the worm.[77] Whether this same mechanism is responsible for the toxic effects observed in horses remains to be proved.

20.3.2.1.3

Diagnosis and Treatment

Diagnosis of piperazine toxicity depends on observation of clinical signs and a history of inadvertent overdosage. No laboratory values appear to be altered in affected horses, but because the drug is excreted in the urine, measurement of urinary piperazine concentrations would seem valuable. One should attempt to measure piperazine concentration in the urine early in the disease course because urinary excretion is practically complete within 24 hours following ingestion.

No treatment other than supportive care is indicated. All horses intoxicated with piperazine citrate made a complete recovery within 2 to 3 days. The one horse that died following piperazine monohydrochloride administration was not treated, and necropsy abnormalities were only related to debilitation from prolonged anorexia.[74]

20.3.2.2

Reserpine

Reserpine is the most widely used and studied pure alkaloid prepared from the plant *Rauwolfia serpentina* and other *Rauwolfia* species.[7] The drug has found little application in clinical veterinary medicine but has been used in horses when a period of prolonged tranquilization lasting several days was desired.[96,97] The therapeutic and toxic dosages of reserpine are close in horses, which increases the likelihood of toxicosis even under the most judicious circumstances. An effective parenteral dose of 1 to 4 mg per 450 kg body mass has been suggested, but 5 to 10 mg per 450 kg has resulted in signs of toxicity.[97]

Reserpine is absorbed readily from the oral and intramuscular routes, and peak blood levels in human beings occur in 1 to 2 hours. The compound is distributed widely into a variety of tissues, including the brain, liver, spleen, kidneys, and adipose tissue. The alkaloid also localizes in the adrenergic neurons. Reserpine is metabolized in the liver and gastrointestinal tract, and approximately 6% of the dose is excreted in the urine within the first 24 hours. Up to 60% of a dose is excreted in the feces within 96 hours.[7]

20.3.2.2.1

Clinical signs

Signs of toxicosis in horses can occur rapidly, within 3 to 6 hours following intravenous administration.[97,98] Initial signs include marked depression, generalized profuse sweating, and flatulence. Horses may exhibit sporadic episodes of violent, coliclike behavior followed by abrupt recumbency and somnolence. Additional signs noted early in the disease course are increased gastrointestinal sounds and diarrhea, muscle trembling, sinus bradycardia, and second-degree atrioventricular blockade. Affected horses also have miosis and ptosis of the upper eyelids, and males develop paraphimosis.[98] Signs of tranquilization

persist in affected horses until norepinephrine stores are replenished.[96] In horses experimentally intoxicated with reserpine, clinical signs had abated within 60 hours of exposure.[98]

20.3.2.2.2

Pathophysiology

Reserpine is a sympatholytic agent that acts at the presynaptic nerve terminal of postganglionic adrenergic neurons to cause a depletion of norepinephrine. Reserpine impairs the magnesium- and ATP-dependent uptake mechanism whereby norepinephrine is accumulated and stored in intraneuronal vesicles within the terminal sympathetic nerve endings. As a result, norepinephrine is released from granular storage sites into the neuronal cytoplasm, where it is metabolized by cytoplasmic monamine oxidase. Reserpine interferes with catecholamine synthesis by blocking dopamine uptake into storage vesicles, where it is enzymatically converted to norepinephrine. Reserpine also crosses the blood-brain barrier, where it causes the brain neurons to become depleted of serotonin, dopamine, and norepinephrine.[7,96]

The end result is that norepinephrine is no longer available to cross the synaptic cleft and excite the postsynaptic membrane receptor. This transient deficiency of an adrenergic neurotransmitter allows a physiologic state to develop whereby profound parasympathetic tone predominates. Reserpine binding at the presynaptic neuron site is reversible. The prolonged effects result from the high lipid solubility of the drug, which allows it to persist in the body.[7,97]

20.3.2.2.3

Diagnosis and Treatment

One can perform qualitative analysis for reserpine on serum and urine samples, but testing is not easily available at most commercial laboratories. Thin-layer or high-performance liquid chromatography is used to identify the drug, which can be detected in serum up to 5 days following a 2- to 4-mg intravenous dose.[96]

No specific antidote is available.[7] Treatment of affected horses is mostly symptomatic, but pressor agents 1471
such as methamphetamine have been recommended.[97] One should use such agents only in horses that are 1472
volume-loaded, so as to maintain fluid, acid-base, and electrolyte indexes in a normal range.

20.3.2.3

Iron

Iron toxicosis in horses usually results from iatrogenic overdose of injected or oral products given to foals or from accidental consumption of iron-containing supplements. Supplemental iron is available in injectable and oral formulations, and presently more than 120 iron preparations are on the market.[15] Iron dextrin, iron polysaccharide, iron sorbitol, and ferric ammonium citrate are available injectable preparations. Oral formulations include iron salts such as ferris sulfate, citrate, or ammonium citrate; ferrous sulfate, chloride, glutamate, lactate, fumarate, or carbonate; or ferric phosphate with sodium citrate. Chelated iron compounds are about one fourth as toxic as other compounds.

The toxicity of iron is least by the oral route, with intramuscular and intravenous routes being increasingly more toxic. Because most animals do not have a mechanism for iron excretion, the toxicity of iron depends on the amount of iron already present in the body.

20.3.2.3.1

Clinical Signs

In animals, two syndromes of iron toxicosis are reported. A peracute syndrome is represented by sudden death within a few minutes to hours after injection. This syndrome may resemble an anaphylactic reaction, but the triggering mechanism is unknown. A subacute reaction characterized by progressive depression, icterus, and disorientation leading to coma and death seems to be the more typical syndrome seen in horses.[15,99,100]

20.3.2.3.2

Pathophysiology

Experimentally, 5% to 10% of oral iron is absorbed in the small intestine, primarily from the duodenum and jejunum, by a rate-limited mucosal transfer system. The ferrous forms are absorbed to a greater extent than the ferric forms, but both can be absorbed if they are in the ionized state. Phosphates reduce the absorption of iron, and a high-sugar diet increases absorption. Once absorbed, iron is bound in serum by transferrin.[15]

Toxic doses of orally administered iron overwhelm the mechanism controlling absorption of iron from the intestine, resulting in massive iron absorption. Toxicity occurs when serum iron levels exceed the iron-binding capacity of transferrin. Free circulating iron then damages blood vessels, may cause erosion and ulceration of the stomach and intestine, causes hepatocellular necrosis and fatty degeneration of the myocardium, and can produce cerebral edema.[7,15] In horses, hepatic failure appears to be the cause of death.[99]

At the cellular level, excessive iron causes extensive peroxidation of lipids in biologic membranes. A resulting decline in the ratio of unsaturated to saturated fatty acids leads to increased membrane rigidity, reduction of membrane potential, and increased permeability to various ions, leading to rupture of the membrane. The intracellular organelles adversely affected include the mitochondria and the lysosomal and sarcoplasmic membranes.[101] Elevated serum iron also inhibits the thrombin-induced conversion of fibrinogen to fibrin, thereby adversely affecting coagulation and enhancing any hemorrhagic process.[100] Histologically, affected livers are characterized by small size and have prominent bile duct proliferation, periportal fibrosis, and hepatocellular necrosis.[7]

20.3.2.3.3

Diagnosis

Measurement of serum iron concentration is the best method of confirming a diagnosis of iron toxicity.[15] In addition, a history of iron administration coupled with clinical signs and laboratory evidence of hepatocellular damage and cardiovascular collapse is highly suggestive of toxicity.

Abnormal laboratory findings include prolonged partial thromboplastin time (PTT) and prothrombin time (PT), high concentrations of aromatic amino acids (tyrosine, phenylalanine, tryptophan, methionine), elevated plasma ammonia concentration, and increased activities of the liver-derived enzymes alkaline phosphatase and GGT. In addition, a high ratio of aromatic to branched-chain amino acids and an elevated total serum bilirubin content often are found.[99]

20.3.2.3.4

Treatment

Treatment of peracute iron toxicosis is usually unrewarding. Once clinical signs become evident, major organ damage is usually present. No specific treatment for horses affected with iron toxicity is known. Treatment of affected dogs has included supportive therapy with glucose and norepinephrine, and magnesium oxide given orally to help complex the ingested iron. Experimentally, a specific chelator of ferric iron, deferoxamine (Desferal, Ciba-Geigy Corp., Summit, New Jersey) has been used at 0.75 mg/kg/min intravenously to chelate the circulating iron in dogs. One should give this drug slowly by intravenous drip because it can cause a sharp decline in blood pressure. Plasma extenders and intravenous fluids also have been used to counteract cardiovascular shock present in some dogs.[15]

In cases of human toxicosis, gastric lavage, chelating agents, and cathartics (sodium sulfate and magnesium sulfate) have been used. The use of oral bicarbonate solutions to decrease iron absorption is controversial, and activated charcoal is given orally to absorb the iron-deferoxamine complex, even though charcoal does not effectively bind free iron.[7]

The chelator of choice in human toxicosis is deferoxamine. The drug is produced by the bacteria *Streptomyces pilosis* and is a specific chelator of ferric iron. One gives deferoxamine intravenously for maximum effect; the drug has a plasma half-life of about 1 hour. Deferoxamine is detoxified by the liver, but the iron-deferoxamine complex is excreted via the kidneys.[7] 1472

1473

20.3.2.4

Carbon Tetrachloride

No current indication exists for carbon tetrachloride therapy in horses; therefore toxicosis results from accidental exposure to the substance. This product currently is used in the industrial manufacture of aerosol propellants, solvents, and fluorocarbon refrigerants. Carbon tetrachloride is a clear, highly volatile but nonflammable liquid that has an odor similar to that of ether and is well absorbed by the lungs and gastrointestinal tract and is concentrated in fat stores in the body.[7]

20.3.2.4.1

Clinical Signs

In animals, death following exposure to carbon tetrachloride occurs peracutely, that is, within 24 hours, as a result of anesthetic depression and severe pulmonary edema or 3 to 7 days later as a result of hepatic and renal failure. The latter syndrome is most typical of farm animals exposed to carbon tetrachloride. The peracute syndrome is characterized by immediate onset of staggering and falling, with progressive narcosis, collapse, convulsions, and death following. The more typical syndrome is characterized by anorexia, depression, weakness, jaundice, and diarrhea of several days' duration. In sheep, death usually is preceded by coma. Affected animals occasionally exhibit other signs of hepatic failure, such as photosensitization, and they are reported to be more sensitive to various environmental stressors.[102] Because carbon tetrachloride is also a potent renal tubular toxin, affected animals can exhibit signs suggestive of acute renal failure (see Toxicoses Causing Signs Relating to the Urinary System).

20.3.2.4.2

Pathophysiology

Carbon tetrachloride causes acute fatty degeneration of the liver by blocking the formation and release of low-density lipoproteins. Carbon tetrachloride also induces hepatic necrosis, but the exact mechanism whereby this occurs has not been elucidated fully. Cleavage of the carbon-chloride bond, which is thought to proceed via the microsomal cytochrome P-450 reductase and NADPH-dependent reductive pathways, produces trichloromethyl and monoatomic chlorine-free radicals. These radicals lead to lipid peroxidation, and energy processes and protein synthesis within the endoplasmic reticulum subsequently are disrupted. In addition to the lipid peroxidation, binding of these radicals to cell organelles contributes to the hepatic damage.[7]

Carbon tetrachloride also produces acute tubular necrosis primarily of the proximal tubules and the loop of Henle in the kidney.[7] Inhalation of carbon tetrachloride causes immediate, acute CNS depression and diffuse pulmonary edema.[7,102]

20.3.2.4.3

Diagnosis

One should suspect a diagnosis of carbon tetrachloride toxicity when horses show clinical signs and laboratory evidence of acute hepatorenal disease and exposure to the toxin is known to have occurred. Laboratory findings suggesting acute hepatic dysfunction include elevations in serum activities of the liver enzymes sorbitol dehydrogenase, AST, and isoenzyme 5 of LDH.[103] Increases in plasma bile acid concentration and plasma bilirubin also are apparent.[104]

Laboratory findings suggesting renal tubular damage include elevated BUN and creatinine concentrations, along with abnormal urine findings of proteinuria, casts, and occasionally blood cells. Affected horses may be expected to lose their urine concentrating ability, and urinary activity of renal tubular enzymes such as GGT and LDH should be increased early in the course. As a result of renal dysfunction, other homeostatic mechanisms are disturbed, which can lead to changes in fluid balance, acid-base disturbances, and serum electrolyte abnormalities.

20.3.2.4.4

Treatment

No specific antidote is available for carbon tetrachloride toxicity. One should initiate supportive therapy for acute hepatic and renal dysfunction (see Chapter 14 and Chapter 17.4)

20.3.2.5

Propylene Glycol

Propylene glycol is used commercially as a diluent for injectable drugs and as a glucose precursor in the treatment of hypoglycemia in ruminants. Horses may become intoxicated by the inadvertent use of propylene glycol if it is mistaken for a similar appearing liquid paraffin preparation. Reports of toxicosis in horses are rare.[105,106]

Propylene glycol has a low oral toxicity in human beings. Approximately 45% of the absorbed dose is excreted unchanged via the kidney, whereas the remainder is metabolized by hepatic alcohol dehydrogenase to acetate, pyruvate, and lactate.[7]

20.3.2.5.1

Clinical Signs

Adverse signs occur within 10 to 30 minutes following a toxic dose of propylene glycol. Initial findings include salivation and profuse sweating, ataxia, depression, and tachypnea. Additional signs can include cyanosis, seizures, and coma.[105] Diarrhea also has been reported in one horse experimentally given a large dose of propylene glycol.[106] Death has occurred 1 to 3 days following ingestion of excessive amounts of the product.[105,106]

20.3.2.5.2

Pathophysiology

Propylene glycol is metabolized by hepatic alcohol dehydrogenase to form acetate, lactate, and pyruvate. Following a large exposure, excessive amounts of these products accumulate, resulting in severe systemic lactic acidosis.[7] The clinical signs and toxicologic findings result from the effects of this severe acidemia on various body organs and tissues.

The acute oral LD_{50} for horses has not been established, but the doses for rats, rabbits, and dogs are 32, 18, and 9 ml/kg, respectively. One 450-kg horse died following intubation with 3.8 L (7.6 ml/kg) of propylene glycol,[105] but other horses have survived this dose. Toxic signs were reported in horses receiving 1.9 to 7.6 L of propylene glycol, but the only death occurred in the horse getting 7.6 L.[106] 1473

1474

20.3.2.5.3

Diagnosis and Treatment

One can confirm exposure to propylene glycol by chemical analysis of serum and tissues and by use of gas chromatography with flame ionization. Necropsy findings associated with propylene glycol toxicosis may be minimal.[105] The horse given 7.6 L exhibited sloughing of the gastric mucosa, diffuse enterocolitis, renal congestion, and brain edema.[106] Histopathologic findings typically include hepatic necrosis, renal tubular necrosis and infarcts, myocardial perivascular edema, and pulmonary edema.[105,106]

Because no specific antidote is available, treatment of propylene glycol toxicosis aims at alleviating the severe acidemia that develops and providing supportive care for the other organs and tissues that may become compromised. One should give sodium bicarbonate solutions to treat the acidosis. Where possible, one should monitor blood pH and adjust bicarbonate administration according to need. One should give fluids intravenously to aid diuresis and to maintain normal fluid volume. One should evaluate pulmonary and renal function thoroughly in affected horses and should take precautions to prevent further pulmonary edema from developing. Such precautions may require the use of diuretics and careful monitoring of the fluid administration rate.

One should maintain serum electrolyte concentrations in normal ranges, and oxygen therapy may be beneficial in horses exhibiting tachypnea and cyanosis. Activated charcoal has been recommended in treating human toxicosis.[7]

20.3.3 MISCELLANEOUS AGENTS

20.3.3.1 Triclopyr

Triclopyr is a herbicide used to control hardwood species on road rights-of-way, industrial sites, and forest planting sites. Horses may become exposed to the herbicide by grazing areas that have been treated previously with the product. Spontaneously occurring instances of triclopyr toxicity were not found in the literature.

An experimental study has been conducted to determine the toxic level of triclopyr to ponies. Ponies given 60 mg/kg/day for 4 days did not show any clinical sign of illness. Ponies given 300 mg/kg/day for 4 days did develop clinical signs. This study indicated that the toxic dosage in ponies was 5 times the estimated maximal intake for the highest recommended usage rate as a herbicide.[107] Therefore poisoning from the proper use of this herbicide is unlikely.

20.3.3.1.1 Clinical Signs

Initial signs of depression and decreased gastrointestinal motility were first noticed on the fourth day of the trial. Additional signs that developed were ataxia, weakness, muscle tremors, increased respiratory rate, cyanotic mucous membranes, and normal to slightly elevated body temperature. Some ponies became recumbent as clinical signs progressed. Two ponies died on the fifth and sixth days of the trial, and two other ponies were euthanized on the fifth day. The remaining two ponies were only mildly affected and recovered.

No significant changes were apparent in clinical chemistry values. Gross necropsy lesions consisted of pale livers and pale swollen kidneys, and a few horses had excessive intestinal fluid contents. Microscopic changes were mild and were those of nonspecific hepatosis and nephrosis.[107]

20.3.3.1.2 Pathophysiology

The mechanism whereby triclopyr produces clinical disease in horses has not been elucidated.

20.3.3.1.3 Diagnosis and Treatment

Toxicosis caused by triclopyr appears highly unlikely under natural circumstances.[107,108] Diagnosis of suspect cases is based on clinical signs and a history of exposure to the herbicide. No specific antidote is available. Affected individuals require supportive and symptomatic care.

20.3.3.2 Aflatoxin

Aflatoxicosis is apparently a rarely documented disorder of horses, as evidenced by the paucity of clinical cases reported in the literature.[109–111] In reported instances, toxicosis developed in horses being fed contaminated feedstuffs, but horses also have been affected experimentally by forced feeding of aflatoxin-contaminated material.[112,113]

Aflatoxins are toxic metabolites produced by the fungi *Aspergillus flavus* and *A. parasiticus*. These molds are ubiquitous in nature and normally can be found in stored feeds. The molds are not inherently toxigenic, but under environmental conditions of adequate temperature and humidity, the molds can grow rapidly and produce large amounts of aflatoxin. Many feedstuffs can support the growth of these molds, but cereal grains, cottonseed meal and cake, and peanuts seem to be affected most commonly.[38]

These molds produce five major aflatoxins: B1 and B2, which fluoresce blue under long-wave ultraviolet light; G1 and G2, which fluoresce green; and M1 aflatoxin, which is present in milk. Of these, B1 is the most important because of its toxicity and because it occurs most abundantly under natural conditions.[38]

Aflatoxins are a group of polycyclic, unsaturated compounds that have a coumarin nucleus coupled to a reactive bifuran system and a pentenone or lactone. These toxins are insoluble in water and are heat resistant; they are absorbed rapidly from the gastrointestinal tract and bound to serum albumin. Most of the toxins are removed from the bloodstream in the liver, where aflatoxins bind to macromolecules such as DNA, endoplasmic steroid-binding sites, and certain enzymes within the hepatocytes. In the liver a variety of metabolites are produced at rates that vary among species. The metabolites may be lipid-soluble or water- 1474
soluble conjugates and are excreted in bile. At least some of the metabolites undergo an enterohepatic cycle 1475
of absorption and excretion. The aflatoxins and their metabolites are excreted in urine and feces, and complete elimination may take several days. The aflatoxins are not known to be stored in any particular tissue.[38]

Acute and chronic aflatoxicoses are reported in a variety of animal species, including human beings. However, clinical reports of equine disease are concerned primarily with acute intoxication. The acute oral LD_{50} of aflatoxin B1 in horses is reported to be greater than 2 mg/kg and for foals is 2.0 mg/kg. One author reported signs of toxic hepatopathy and gastrointestinal upset in horses that consumed feed containing 2 to 50 ppb of aflatoxin B1. Toxicity of aflatoxins also is reported to be enhanced by riboflavin, exposure to light, and a diet low in protein, choline, and vitamin B_{12}.[38]

20.3.3.2.1 Clinical Signs

Clinical signs associated with acute aflatoxicosis include anorexia, elevated temperature, increased heart and respiratory rates, ataxia, depression, lethargy, convulsions, icterus, colic and abdominal straining, bloody feces, and death. These signs were exhibited by horses experimentally intoxicated with aflatoxin at dosages of 2 to 5 mg/kg. Onset of signs began as early as 4 hours after dosing, and deaths occurred from 68 hours to 32 days after intoxication.[110,112,113] An additional sign noted in a naturally occurring instance of toxicosis was subcutaneous hemorrhages.[110]

The feed concentration of aflatoxin B1 necessary to cause signs of chronic aflatoxicosis in horses has not been established, and reports of chronic aflatoxicosis were not found in the literature. Signs of chronic aflatoxicosis in other species have included reduced feed efficiency, rough hair coats, anemia, anorexia, depression, mild jaundice, and occasionally abortion.[38] One should note that experimental trials have indicated that some horses refuse mold-contaminated grain and that well-fleshed animals may be at lesser risk of developing aflatoxicosis than unthrifty animals.[110,112]

20.3.3.2.2 Pathophysiology

The hepatic cytotoxicity of aflatoxins is thought to be related to their binding to intracellular macromolecules. Aflatoxin B1 binds to nuclear DNA to inhibit RNA synthesis, which subsequently inhibits synthesis of intracellular enzymes and other proteins. Aflatoxin also binds to endoplasmic steroidal ribosome-binding sites, resulting in ribosomal disaggregation. Metabolites of aflatoxin B1 also can bind to cellular macromolecules, and most of the cytotoxicity of aflatoxin B1 appears result from binding of certain of these metabolites rather than from aflatoxin B1 itself. This impairment of protein synthesis and the related ability to mobilize fats is thought to cause the early lesions of hepatic necrosis and fatty degeneration of the liver in aflatoxicosis.[15]

The possibility of other mechanisms being responsible for the other signs and lesions noted with aflatoxicosis has been suggested. Aflatoxins are known to be carcinogenic, they can be immunosuppressive, and they also can inhibit synthesis of clotting proteins. The mechanisms whereby these changes take place have not been well described.[38]

20.3.3.2.3 Diagnosis and Treatment

Definitive diagnosis of aflatoxicosis can be difficult because of the nonspecificity of many clinical signs and because the disease can mimic many other conditions. Experimentally intoxicated horses have elevations in serum concentrations of AST, alanine aminotransferase, GGT, iditol dehydrogenase, and arginase.[110,112,113] Other laboratory abnormalities have included hypoglycemia, hyperlipidemia, lymphopenia, and elevated PT.[109,110,113]

Gross necropsy lesions typically consist of variable degrees of hepatic degeneration and necrosis, visceral petechial hemorrhages, and hemorrhagic enteritis.[109,110,113] Other lesions noted at necropsy include encephalomalacia of the cerebral hemispheres, myocardial degeneration, fatty infiltration of the kidney, and subcutaneous and intramuscular hemorrhage.[109,110] Histopathologic abnormalities may include fatty degeneration and necrosis of hepatocytes, bile duct hyperplasia, periportal fibrosis, and inflammatory cell infiltration into the liver. Renal lesions have included lipid accumulation in the tubular epithelial cells of the proximal tubules and protein precipitation in the tubular lumen.[109,113]

Although metabolites of *Aspergillus* species fluoresce under ultraviolet light, the presence of fluorescence in suspect feed samples is not pathognomonic for aflatoxin. One can assay aflatoxin definitively in feed samples by a minicolumn technique using thin-layer chromatography.[110] One also can quantitate aflatoxin in animal tissues.[109,113] Mold culture is nondiagnostic.[38]

Treatment is largely symptomatic and must include removal of the offending feed material, if it still is being fed. An easily digested, low-fat diet containing appropriate protein has been recommended. Multiple vitamin supplementation might be beneficial, and one should initiate treatment of specific organ dysfunction. In acutely intoxicated horses, charcoal administered orally has been recommended.[38] Prevention of the condition requires storing feeds in a suitable environment that discourages mold growth and the feeding of noncontaminated feedstuffs.

20.3.3.3

Leukoencephalomalacia

Equine leukoencephalomalacia, a sporadically occurring disease of horses, ponies, donkeys, and mules, has a worldwide distribution. The disease is usually seasonal, with most cases occurring from late fall through early spring, and most outbreaks have been associated with a dry growing period followed by a wet period. [114,115]

1475

1476

This malady is caused by the mycotoxin fumonisin B1, a metabolite of *Fusarium moniliforme*. Equidae become affected usually by ingesting *F. moniliforme*– infected corn, but the problem also has been associated with the consumption of commercially prepared diets.[114–117] Infected kernels often have a pink to reddish-brown discoloration, and damaged kernels and cob parts have a much greater concentration of fumonisin B1 than do undamaged kernels.[115,117] Feeds containing less than 10 ppm fumonisin B1 have not been associated with disease, but concentrations of greater than 10 ppm can be lethal to horses.[118]

20.3.3.3.1

Clinical Signs

Two clinical syndromes are associated with fumonisin B1 intoxication. The more common is the classic neurotoxic syndrome, but hepatotoxicosis also occurs in some horses. Older animals may be more susceptible than younger animals, and clinical signs become evident approximately 3 to 4 weeks following daily ingestion of contaminated feed. Onset of signs is typically abrupt and death usually occurs within 2 to 3 days.[114,115] Occasionally, horses are found dead with no premonitory signs.[114]

The neurologic syndrome is characterized initially by incoordination, aimless walking, intermittent anorexia, lethargy, depression, blindness, and head pressing. These signs may be followed by hyperexcitability, belligerence, extreme agitation, profuse sweating, and delirium.[114,115] Recumbency and clonic-tetanic convulsions may occur before death. Recovery from acute episodes has been reported, but some horses retain neurologic deficits.[115]

Clinical signs associated with the hepatotoxic syndrome are swelling of the lips and nose, somnolence, severe icterus and petechiae of mucous membranes, abdominal breathing, and cyanosis. Affected horses also had acute onset of clinical signs with death occurring within a few hours to days.[114,115]

20.3.3.3.2

Pathophysiology

The gross lesions typical of equine leukoencephalomalacia include liquefactive necrosis and degeneration of the cerebral hemispheres, but degenerative changes also can occur in the brainstem, cerebellum, and spinal cord.[114–117] Necrotic areas can vary in size, and regions adjacent to the necrosis are often edematous and rarefied.[115,116]

Gross hepatic lesions in affected horses generally are not pronounced. The liver may be slightly swollen, have a yellowish-brown discoloration, and contain irregular foci or nodules scattered throughout the parenchyma. Histologic abnormalities noted in the liver may include centrilobular necrosis and fibrosis, fatty infiltration of hepatocytes, portal fibrosis, biliary stasis, and bile duct proliferation.[114–116]

The mechanism whereby these changes occur has not been elucidated. The following have been suggested: the brain lesions may be induced by smaller quantities of infected corn ingested during a long period, and ingestion of higher quantities may produce fatal hepatotoxicosis in a shorter time.[115,119]

Several metabolites of *F. moniliforme* have been identified in feeds associated with outbreaks of equine leukoencephalomalacia. These include fusarin C, moniliformin, fusaric acid, 2-methoxy-4-ethylphenol, fumonisin B1, and fumonisin B2.[116,117] Toxicity information about fumonisin B2 is unknown, but moniliformin, fusaric acid, and 2-methoxy-4-ethylphenol do not produce leukoencephalomalacia when injected intravenously into donkeys. Their role in the pathogenesis of the liver lesions in equine leukoencephalomalacia is likewise unknown. However, the neurologic and hepatotoxic syndromes can be produced by oral and intravenous administration of fumonisin B1.[116]

20.3.3.3.3 Diagnosis and Treatment

The diagnosis of equine leukoencephalomalacia has been based mostly on observation of clinical signs coupled with a history of exposure to moldy corn. Typical postmortem lesions, when available, confirm the diagnosis.

Clinicopathologic abnormalities are nonspecific and usually indicate some degree of liver dysfunction. Increased serum concentrations of bilirubin, AST, GGT, and LDH have been reported.[114,116,119] Cerebrospinal fluid abnormalities can include increased protein and total nucleated cell counts and an increased concentration of myelin basic protein.[115,119]

With the recent identification of fumonisin B1 as the causative agent, however, analytic methods have been developed to assay this toxic metabolite in feed material. One can analyze suspect feed samples for fumonisin B1 by thin-layer chromatography, high-performance liquid chromatography, or gas chromatography/mass spectroscopy. Feed containing greater than 10 ppm fumonisin B1 is not safe to feed to horses.[118] Because the disease requires a fairly prolonged exposure to infected corn, one should submit an appropriate feed sample for analysis. Feed currently being ingested may not be contaminated with the mold.

Treatment of equine leukoencephalomalacia is largely supportive because no specific antidote is available for fumonisin B1. One should sedate horses that are hyperexcitable to minimize injury to themselves and their handlers. One should initiate supportive therapy for hepatic dysfunction if liver damage is evident, and some horses may require forced feeding and watering if they become unable to eat and drink. One may give mannitol or DMSO to aid resolution of cerebral edema, and one may give laxatives and activated charcoal to eliminate toxins already in the digestive tract, but their usefulness is probably minimal because this disease is not an acute intoxication. Contaminated feed should be removed immediately from all exposed horses, and pastured horses should be moved to pastures without access to corn. Prevention aims 1476
to provide suitable feed material to horses and to store grains, particularly corn, under conditions that 1477
discourage mold growth.

20.3.3.4 Trichothecenes

The trichothecenes are a group of compounds elaborated primarily by *F. tricinctum* and other *Fusarium* species. Only four of approximately 40 trichothecene derivatives have been found to occur naturally in

feedstuffs. These four include T-2 toxin, deoxynivalenol, diacetoxyscirpenol, and nivalenol.[120,121] Of these, only one reported episode of T-2 intoxication in horses was found in the literature.[121]

In the reported outbreak, horses showed clinical signs and laboratory abnormalities similar to those of equine leukoencephalomalacia caused by fumonisin B1. Gross lesions in necropsied horses were also similar to those of equine leukoencephalomalacia. *F. tricinctum* was isolated from all suspect feed samples, and T-2 toxin was detected in varying concentrations in all examined feed samples. Other *Fusarium* metabolites detected in this outbreak included HT-2, verrucarin A and J and roridin A. The toxicity of these metabolites in farm animals is not yet determined.[121]

20.3.3.5

Lead

Lead is reported to be one of the more common toxicants found in veterinary practice. Materials that can serve as a source of lead toxicity to animals include lead-based paints, putty and caulking materials, used crankcase oil, greases, linoleum, leaded gasoline, solid lead solder, roofing materials, asphalt, and industrial effluents contaminating streams or forage. Discarded automobile batteries and water from lead plumbing also might serve as a source of toxicity.[65,86]

Acute and chronic forms of toxicosis can occur depending on the amount of lead ingested and the time frame in which ingestion occurs. Lead toxicosis in horses is usually chronic and is associated with some type of forage contamination.[122,123] Foliage near lead smelters often contains excessive lead, and grasses located near busy highways have been reported to contain high lead concentrations.[86,123] Horses appear to be much more sensitive than cattle to prolonged, low-dose exposure to lead, yet they are much less sensitive than cattle to short-term exposure of large doses.[65,122] The acute oral lethal dose of lead acetate in horses is 500 to 750 g total dose, but chronic toxicosis can arise when 1 to 7 mg/kg/day is ingested over a period of days, weeks, or months.[65]

Numerous factors can influence the toxicity of lead in horses. Young animals and malnourished animals are reported to be more susceptible than older animals; solid lead is not as toxic as the more soluble salts, which are absorbed more readily; and concurrent exposure to lead and cadmium results in increased severity of clinical signs of lead poisoning. In addition, lead may interact with other minerals to affect toxicity. High levels of dietary calcium cause decreased gastrointestinal absorption of lead.[65,86,123]

20.3.3.5.1

Clinical Signs

The clinical signs of lead toxicity in horses are caused primarily by peripheral nerve dysfunction. The motor nerves are at greater risk, with minimal sensory perception loss in affected horses. Initially, affected horses may appear weak or have slight incoordination. Depression and weight loss become apparent and worsen over the disease course. Laryngeal and pharyngeal paralysis, dysphagia, dysphonia, and proprioceptive deficits occur. As the disease progresses, horses may exhibit flaccidity of the rectal sphincter, paresis of the lower lip, and difficulty in prehension, mastication, and deglutition. Aspiration pneumonia resulting from dysphagia and regurgitation of food is common, and fine muscle tremors may occur intermittently. Terminally, horses may show severe incoordination, anorexia, emaciation, and almost complete pharyngeal and esophageal paralysis with inability to swallow food or water. Seizures also may occur terminally. Colic and diarrhea may be apparent, but they are not common signs.[86,122,123] Progression of these disease signs may require weeks.

Dietary lead crosses the placental barrier, and mares chronically exposed to lead in late pregnancy may deliver premature or small, weak foals. These foals are at greater risk of developing secondary disease complications.[122]

20.3.3.5.2 Pathophysiology

Lead enters the body primarily through ingestion. Inorganic lead cannot readily penetrate the skin, but organic forms such as tetraethyl lead and tetramethyl lead are absorbed through the skin. However, exposure of horses to organic lead compounds would seem to be a rare occurrence. Metallic lead shot or bullets lodged in tissues do not dissolve because tissue pH is too high.[65]

Metallic lead and lead sulfide are less absorbed than the acetate, carbonate, hydroxide, oxide, and phosphate salts. Only 1% to 2% of ingested lead is absorbed, but if sufficient quantities of soluble salts are ingested, a significant amount of lead can cross into blood. Even though intestinal absorption is inefficient, increases in blood lead concentrations occur within 3 hours of dosing.[65,86]

Once absorbed, a large portion of lead is carried on erythrocyte membranes where it is bound irreversibly to erythrocyte proteins. Much of the remaining lead becomes bound to albumin, and only a small proportion of the absorbed lead is actually free in serum. Unbound lead is in equilibrium with lead bound to erythrocytes and albumin, and distribution to various tissues takes place from the unbound fraction.

Much of the blood lead is removed in the liver. Within the liver, cellular trapping of lead is thought to occur by lead binding to cytoplasmic proteins called metallothioneins. Lead also accumulates within the 1477
renal cortex, where it becomes trapped as intranuclear lead proteinate inclusions in tubular epithelial cells. 1478
Unbound lead is excreted into milk, and it readily passes membrane barriers such as the placenta and the blood-brain barrier to become distributed in many body tissues.[65]

Unbound lead becomes immobilized and bound to bone substance, particularly in the physeal region, by an unknown mechanism. However, bone is considered to be the “sink” for lead and eventually may contain greater than 90% of the total body burden of lead. Deposition of lead into bone is a slow, gradual process, entailing redistribution of lead from other soft tissues. In this manner, bone serves as a detoxification mechanism under conditions of chronic exposure to small concentrations. Bone cannot hold an infinite amount of lead, however, and when saturation occurs, signs of toxicosis may appear suddenly because of rising blood and soft tissue concentrations following continued exposure.[65]

Bile and feces are thought to be the primary pathways of excretion of lead, and feces may contain unabsorbed lead and lead that has undergone enterohepatic circulation. Gastrointestinal secretions, including pancreatic secretions, also might be involved in elimination of lead from the body.[65,86]

The mechanism of action of lead at the cellular level is still under scrutiny. The known toxic effects of lead include inhibition of sulfhydryl groups of enzymes essential to cellular metabolism and inhibition of heme synthesis. Lead also is known to cause a decrease in local concentrations of the essential trace metals copper, iron, and zinc. These metals have important functions in mitochondrial enzymes, and interference by lead of these may affect cellular respiration, oxidative phosphorylation, and the ATP synthetase complex adversely.[65]

The peripheral neuropathy associated with lead toxicosis in horses is thought to be caused by peripheral nerve segmental demyelination, which impedes nerve impulse conduction and contributes to the clinical signs observed. The metabolic inhibitory effects of lead are speculated to cause the demyelination.[65,122]

Lead is known to damage the blood-brain barrier and capillary endothelial cells, resulting in cerebral edema and hemorrhage. Additionally, the damaged blood-brain barrier may allow cytotoxic solutes normally excluded from the brain to enter the brain substance.[65] Whether these mechanisms have any appreciable effect on the development of clinical signs observed in the horse is unknown.

Inhibition of heme synthesis is an important aspect of lead toxicosis in several animal species. This pathologic mechanism also occurs in the horse, but its significance to the overall disease course is limited. The result of heme metabolism interference and altered function of other erythrocyte proteins is a shortened erythrocyte half-life that can produce a normochromic, normocytic anemia, which is generally marginal in affected horses (PCV of 25% to 30%).[122,123] The anemia also may be accompanied by nucleated red blood cells and Howell-Jolly bodies in peripheral blood.[123]

Two enzymes in the heme synthesis pathway that are particularly susceptible to lead are δ-aminolevulinic acid dehydratase (ALA dehydratase) and ferrochelatase. Inhibition of ALA dehydratase results in reduced levels of porphobilinogen in erythrocytes and an accumulation of ALA dehydratase, which is excreted in urine. Interference with ALA dehydratase also may be partly responsible for brain damage associated with lead toxicity in some species. Inhibition of ferrochelatase limits the formation of heme from protoporphyrin, resulting in an accumulation of unmetabolized porphyrins. These include protoporphyrin I, which is retained in the erythrocyte; uroporphyrins, which are excreted in urine; and coproporphyrins, which are excreted in feces. Lead also interferes with pyrimidine-specific 5′-nucleotidase activity, resulting in basophilic stippling of affected erythrocytes.[86]

Another important implication of lead toxicity is the suggestion that lead may be immunosuppressive via interference with cell-mediated immune responses.[65,86] The mechanism of this effect is unknown, and its significance to equine lead toxicosis in unclear.

20.3.3.5.3 Diagnosis and Treatment

Confirmation of suspected lead poisoning often is based on determination of blood or tissue lead concentrations. Blood levels of 0.35 ppm or greater are diagnostic if horses are showing clinical signs, but blood lead concentrations do not reflect the severity of poisoning.[122,123] Lead concentrations greater than 4 ppm in liver, 5 ppm in kidney, and 30 ppm in bone are considered diagnostic of lead intoxication in horses.[65]

In instances of chronic toxicity, however, blood lead values may be within a normal range. In such instances, diagnosis of toxicity may be aided by administration of calcium disodium EDTA, which chelates lead in bone stores and increases the lead concentration in plasma. The soluble lead complexes then are excreted in urine, with a resultant manyfold increase in urinary lead concentration within a few hours of EDTA administration.[65,86,121] The recommended dose of calcium disodium EDTA is 75 mg/kg intravenously.[86]

Clinicopathologic aberrations include increased concentrations of erythrocyte aminolevulinic acid and erythrocyte porphyrins and decreased activity of erythrocyte ALA dehydratase. Increased amounts of coproporphyrins, uroporphyrins, and aminolevulinic acid are found in urine, but measurement of erythrocytic ALA dehydratase is considered more diagnostic than measuring urinary ALA dehydratase content.[65,86,122] Increased blood concentration of zinc protoporphyrin also has been documented in an affected horse.[124] 1478

1479

Hematologic abnormalities in affected horses can include a marginal anemia frequently accompanied by metarubricytes and Howell-Jolly bodies in peripheral blood.[86,123] Anisocytosis, poikilocytosis, hypochromasia, polychromasia, and basophilic stippling also can occur. These changes are suggestive but not pathognomonic of lead toxicity in horses.[86] One also can measure the concentration of lead in soil and in forages. Poisoning in horses has been reported when grazed forage contained greater than 300 ppm lead.[86,122]

Treatment of affected horses should include immediate elimination of the lead source, if possible, and prompt initiation of chelation therapy. Calcium disodium EDTA is the chelator of choice; it chelates osseous lead but not tissue-bound lead. The chelated lead then becomes soluble and is excreted by the kidney. The unsaturated bone stores then reequilibrate with the lead in soft tissues. One can give calcium disodium EDTA by slow intravenous infusion at a dosage of 75 mg/kg body mass daily for 3 to 5 days. One may follow a 2-day nontreatment period to allow reequilibration of soft tissue and bone lead by an additional 5-day treatment regimen if needed. An alternative dosage schedule is 110 mg/kg intravenously twice daily for 2 days. Following a 2-day nontreatment period, one may repeat this same regimen. One should base the decision to continue therapy with EDTA on posttreatment blood lead concentrations and renal function tests.[86]

Additional therapy should include fluid and nutritional support. Although thiamine administration has been advocated along with chelation therapy in ruminant lead toxicosis,[86] its efficacy in treating horses with lead poisoning has not been investigated. Dietary calcium supplementation may have some beneficial effect by helping to reduce further gastrointestinal absorption of lead.

Methods aimed at reducing exposure to lead and preventing intoxication include appropriate cutting and disposal of contaminated forage, tilling or burning the stubble, and addition of lime to the soil.[122] Use of alfalfa as a roughage might also be beneficial, possibly because of the high calcium content in alfalfa because intoxication is more difficult to produce experimentally in horses when alfalfa is being fed and because increased dietary calcium decreases the gastrointestinal absorption of lead.[86,122]

20.4 Toxicoses Causing Signs Relating to the Cardiovascular System

Toxicoses affecting the heart are relatively uncommon. Far more frequent are manifestations associated with hemolysis and anemia or the development of abnormalities.

20.4.1 PLANTS

20.4.1.1 Red Maple *(Acer rubrum)*

Intoxication of the horse by leaves of the red maple tree is a seasonal disorder that occurs during the summer and fall months, primarily in the eastern United States.[125,126] Fresh leaves present no problem to the horse, but wilted or dried leaves are toxic, and overnight freezing and storage of dried leaves for 30 days does not alter their toxicity.[127] Experimentally, dried leaves are toxic when administered at a dose of 1.5 mg/kg body mass.[126,127] The toxin present in red maple leaves is unknown, but the clinical syndrome produced is one of acute hemolytic anemia with methemoglobinemia and Heinz body production.[125–128] Red maple toxicity has been recognized in horses[128] and Grevy's zebras,[129] and horses electively ingest the leaves when other suitable forage is available.

20.4.1.1.1 Clinical Signs

Signs of toxicity generally commence within 48 hours of ingestion. Affected horses show acute onset of lethargy, anorexia, weakness, and depression. Increased heart and respiratory rates are typical, and the animals are afebrile. Two outstanding characteristics of most affected horses are the obvious presence of icterus or brown discoloration of mucous membranes, and a brownish discoloration of blood and urine. Many horses may appear cyanotic, and petechiation of mucous membranes has been reported. Signs of secondary acute renal failure also have been documented.[128] Death, when it occurs, generally happens 3 to 7 days following ingestion.[125–128] The mortality in naturally occurring and experimental cases is approximately 60%.[130]

The aforementioned signs are representative of naturally occurring instances of toxicity. In an experimental study, however, two patterns of toxicity were recognized. One group of ponies given dried leaves accumulated before September 15 exhibited signs of the typical hemolytic syndrome and died 3 to 5 days later. Ponies given leaves collected after September 15 died within 18 hours of dosing and exhibited clinical signs only of cyanosis and depression.[127] The reason(s) for this disparity of signs was not offered.

20.4.1.1.2 Pathophysiology

Although the toxin in wilted or dried red maple leaves has not been identified, it produces an acute hemolytic anemia with methemoglobinemia and Heinz body production in affected horses. The mechanism of erythrocyte damage has not been determined, but these hematologic abnormalities are characteristic of an oxidant.[126–128]

Heinz bodies are intracellular precipitates of oxidized hemoglobin that result from oxidant injury to erythrocytes. They damage the erythrocyte membrane and produce intravascular and extravascular hemolysis. Intravascular hemolysis results when erythrocyte membrane functions involving active and 1479
passive ion transport become impaired. The hyperpermeability changes that then occur alter the osmotic 1480
gradient of the erythrocyte and cause rupture of the affected red blood cell. Extravascular hemolysis occurs when the red blood cell remains intact, but the damaged erythrocyte is removed from circulation by cells of the reticuloendothelial system.[125,126,128]

Methemoglobin is formed when hemoglobin is oxidized from the ferrous to the ferric form of iron. A certain amount of direct oxidation of hemoglobin to methemoglobin occurs naturally, but erythrocytes are able to reduce methemoglobin back to hemoglobin. Excessive production of methemoglobin occurs under conditions of excessive oxidative stress or when methemoglobin reduction is impaired.[125,127] Although methemoglobin itself does not produce hemolysis, it is incapable of transporting oxygen and therefore contributes to hypoxia. When present in sufficient quantities, methemoglobin imparts a brown discoloration to peripheral blood and mucous membranes.

20.4.1.1.3 Diagnosis and Treatment

Red maple leaf toxicosis occurs under rather specific conditions but is characterized by an acute onset of hemolytic anemia with methemoglobinemia and Heinz body production. The typical clinical signs and conditions supporting red maple leaf intoxication should be in evidence before making a diagnosis. Because the toxic principle is yet unidentified, no specific assay of feed or tissue specimens is available.

Hematologic abnormalities noted in affected horses include moderate to severe anemia (PCV often <10% in severely affected horses), hemoglobinemia, methemoglobinemia, Heinz bodies, anisocytosis, hyperbilirubinemia, and increased erythrocyte fragility. Blood chemistry analysis may reveal depletion of erythrocyte-reduced glutathione and increased serum concentrations of LDH, creatine phosphokinase, AST, and sorbitol dehydrogenase.[125–128] Transient hypercalcemia has been recorded in some horses,[125] and one can expect increases in BUN and creatinine concentrations in horses undergoing significant renal insult secondary to hemolysis.[128] Urine analysis may indicate varying degrees of hemoglobinuria, hematuria, bilirubinuria, and proteinuria.[125–127]

Treatment of affected horses is primarily symptomatic. Exposure to red maple leaves should be eliminated immediately, and one should maintain affected horses in a quiet, calm environment. Oxygen therapy may be beneficial in selected cases, and one can administer blood transfusions to severely affected individuals.

Balanced, polyionic fluid administration is important to maintain renal function and to aid in diuresis because affected horses may be at great risk of developing hemoglobin nephrosis and acute renal failure. One should monitor blood electrolyte and acid-base parameters and correct abnormalities as needed. One should treat acute renal failure appropriately if it develops.

Other symptomatic therapies suggested include nasogastric intubation with activated charcoal to aid in binding toxin; dexamethasone to aid in stabilizing red blood cell membranes and decrease phagocytosis of damaged red blood cells; and ascorbic acid (30 mg/kg) given in intravenous fluids twice daily potentially to reduce oxidative damage to red blood cells. Whether dexamethasone increases the risk of laminitis in affected horses is unknown, and the efficacy of ascorbic acid is questionable.[130]

Prevention of the disease is accomplished by preventing exposure of horses to leaves from red maple trees.

20.4.1.2 Onion (*Allium* Species)

Onion toxicosis in horses is a rare event and occurs when horses are fed large amounts of culled onions (from commercial onion farms) or when forced to eat wild onions because of inadequate available forage. Horses appear to avoid these plants when suitable forage is available.[131,132] The toxic principle in onions, *n*-propyl

disulfide, only affects circulating erythrocytes, in which it causes oxidant injury to the red blood cell with resultant Heinz body formation and subsequent hemolytic anemia. Severely affected horses can succumb to onion toxicosis because of severe anemia or secondary renal failure caused by hemoglobin nephropathy.

The clinical signs, laboratory values, and pathogenesis of the anemia are all similar to those of red maple leaf toxicosis, with the exception that methemoglobin formation does not seem to be nearly as pronounced in onion toxicity as in the former. Horses dying from onion toxicosis may have an onion odor of the carcass noticeable at necropsy.[131]

Affected horses may recover from onion toxicity if they are removed from the onion source soon enough and the anemia is not pronounced. Treatment is largely symptomatic and should include removal of the onion source and provision of adequate, suitable forage. Hematinics are of little value, but oxygen therapy and blood transfusions may be indicated in more severely affected animals.

Maintenance of renal function is of primary concern because affected horses are at risk of developing secondary hemoglobin nephropathy. One should give balanced, polyionic fluids to promote diuresis and should correct electrolyte and acid-base abnormalities. One should use diuretics with caution, but they may be of value in the volume-loaded horse.

20.4.2 MEDICATIONS

20.4.2.1 Heparin

Heparin is an anionic sulfated glycosaminoglycan polysaccharide found normally in mast cells. Heparin is 1480
commercially available as a calcium or sodium salt and is prepared from bovine lung tissue or porcine 1481
intestinal mucosa.[7] Its use in human beings and animals is primarily as an anticoagulant, and in horses heparin has been used as adjunct therapy to treat acute laminitis, septic peritonitis, and disseminated intravascular coagulation and in horses at risk of developing thrombosis. Heparin also has been used to prevent peritoneal fibrin deposition following abdominal surgery and in attempts to prevent disseminated intravascular coagulation in horses suffering from various systemic diseases.[133–135]

Heparin is strongly acidic and is not absorbed from the gastrointestinal tract. Intramuscular injection often leads to painful, large hematomas at the injection site, so administration is limited to the intravenous and subcutaneous routes.[7,136] Heparin is bound primarily to low-density lipoproteins, globulins, and fibrinogen and is metabolized in the liver by heparinase. In human beings the inactive metabolic products are excreted in urine along with a small fraction of unchanged drug. Heparin apparently is removed from the circulation primarily by the reticuloendothelial system and localizes on arterial and venous endothelium.[7] The plasma half-life of heparin is approximately 1½ hours.[136]

20.4.2.1.1 Clinical Signs

One adverse effect of heparin overdose is hemorrhage because heparin acts as an anticoagulant, but the primary problem associated with heparin therapy in the horse is that of induced reduction of red blood cell mass.[133–135] In experimental studies, dosages of 160 units per kilogram of body mass or greater given subcutaneously twice a day resulted in reduction of the measured circulating red blood cell mass and an increase in measured mean corpuscular volume. The red blood cell mass was reduced as much as 57% in

some horses. A dosage of 40 units per kilogram twice daily had no effect on measured blood parameters.[133] In reports of clinical cases, a dosage of 80 units per kilogram subcutanously twice daily also resulted in reduced PCV and increased mean corpuscular volume.[134]

In affected horses the PCV begins to decrease by 12 to 24 hours after initiation of a toxic dose and appears to remain depressed while the horse remains on heparin therapy. The PCV begins to increase by 24 hours after cessation of heparin therapy and approaches baseline values in 72 hours.[133,137] One anecdotal report indicated that horses maintained on heparin therapy also would exhibit a rebound in PCV in several days, even though heparin administration was continued.[138] Other hematologic abnormalities that may be apparent in affected horses include an increase in serum bilirubin concentration[137] and decreased serum concentrations of hemoglobin and platelets. These hematologic discrepancies have been induced in horses given heparin at a dosage that maintained the activated PTT within a therapeutic range of 1.5 to 2 times the normal mean.[133]

20.4.2.1.2 Pathophysiology

Heparin by itself is inactive and produces its anticoagulant action by combining with antithrombin III, an endogenous α_2-globulin that must be present in adequate amounts for the process to proceed. The heparin–antithrombin III complex greatly accelerates the antagonistic action of antithrombin III on thrombin, thereby restricting the conversion of fibrinogen to fibrin. This complex is also inhibitory to kallikrein and to the activated forms of clotting factors IX, X, XI, and XII.[136] In addition, heparin acts as an opsonin and may augment certain phagocytic activities of the reticuloendothelial system.[133,137]

The mechanism whereby heparin causes a reduction in circulating red blood cell mass is still under scrutiny. Initially, heparin was suggested to cause extravascular hemolysis by enhanced phagocytosis of red blood cells by the reticuloendothelial system.[133,137] More recent evidence, however, strongly suggests that the deleterious effects of heparin on formed blood elements are largely artifactual and that the measured abnormalities result from erythrocyte agglutination.[134,135] Further investigation is required to determine if this agglutination also occurs in vivo in heparinized horses.

20.4.2.1.3 Diagnosis and Treatment

The rapid onset of dramatic reduction in PCV in horses treated with heparin implies acute hemorrhage or the previously described adverse reaction of heparin on the formed blood elements of the horse. The specific antidote for heparin is protamine sulfate, which one can give at a dose not to exceed 1 mg for every 90 to 100 units of heparin administered.[136,139] One also can give whole, fresh blood or plasma transfusions to reverse or antagonize the anticoagulant effect.[136]

The foregoing treatments are not likely to be required except in instances of hemorrhage caused by heparin overdose. Removal of heparin from the treatment regimen is usually all that is necessary to stop the decline in PCV. Normal numbers of circulating erythrocytes should reappear by approximately 72 hours after cessation of heparin therapy, if this adverse reaction to heparin is the cause of the lowered PCV.

20.4.2.2 Coumarin Derivatives

Coumarin is normally present in some species of sweet clover and has no anticoagulant action. However, coumarin derivatives are used widely as anticoagulants, with bishydroxycoumarin (dicumarol) and 3-(α-acetonylbenzyl)-4-hydroxycoumarin (warfarin sodium) being the first oral anticoagulants developed from coumarin.[140] These first-generation compounds are used therapeutically as anticoagulants and as rodenticides. In horses, warfarin has been used therapeutically to treat thrombotic disorders such as thrombophlebitis and more recently to treat navicular disease.[141,142] Horses may exhibit signs of toxicity 1481
while being medicated with warfarin if a therapeutic concentration is exceeded. Rarely are horses exposed to 1482
warfarin or other coumarin derivatives used as rodenticides around buildings or feed storage areas. Second-generation anticoagulant rodenticides (brodifacoum and bromodiolone) have been developed because of acquired rodent resistance to the first-generation compounds. Because no indications exist for human or veterinary medicinal use of brodifacoum, toxicity associated with this compound is caused by accidental ingestion.[143]

20.4.2.2.1 Clinical Signs

The clinical signs of toxicity noted with first- and second-generation anticoagulant rodenticides are largely those of a hemorrhagic diathesis. Onset of signs is usually acute and may include hematoma formation, epistaxis, anemia, weakness, pale mucous membranes, or ecchymoses of mucous membranes. Hematuria and melena can occur, and hemorrhage into various body compartments may result in secondary signs caused by malfunction of the involved organ or tissue. Occasionally, affected animals may be found dead.[15] Multiple fractional doses of first-generation compounds given over several days may be more toxic to horses than a single larger dose.[141] Brodifacoum, however, differs from warfarin in that a single oral dose has the potential of causing illness and may even be lethal (estimated LD_{50} of 1 to 2 kg per adult horse).[143,144]

The onset of clinical signs for first-generation compounds is delayed from the time of ingestion. In an experimental model the hypothrombogenic effect of warfarin anticoagulation was noticed 60 hours following an acute dose.[145] This effect persisted for approximately 30 hours. The effect of brodifacoum, however, is much longer and may persist for weeks, despite its half-life of 1.22 days.[143] In an experimental study, horses given a single dose of brodifacoum (0.125 mg/kg body mass) showed increased PTT at 24 hours and one-stage PT at 48 hours after exposure. These values returned to pretreatment levels by day 12. However, two horses required 23 days for clotting time to return to normal. In these horses, peak plasma concentration of brodifacoum occurred 2 to 3 hours after oral administration. Additionally, four of the six experimental horses showed clinical signs of depression, anorexia and weight loss.[144]

20.4.2.2.2 Pathophysiology

Warfarin is absorbed readily from the gastrointestinal tract but also may be administered intravenously for therapeutic purposes.[140,141] Once absorbed, warfarin is highly bound (>90%) to plasma proteins and some is stored in the liver.[140,141,145] The degree of brodifacoum protein binding in horses is not known but may be similar.[143] Warfarin is hydroxylated by hepatic enzymes to inactive compounds that are eliminated by

the kidney. The metabolites have no anticoagulant effect,[140] and the biologic half-life of warfarin in the horse is approximately 13 hours.[145] Coumarins also cross the placenta and are secreted in milk.[140]

Protein binding of warfarin is reversible, and the protein-bound, pharmacologically inactive warfarin serves as a reservoir. The unbound portion remains fairly constant in plasma.[140,141]

A number of factors can influence the amount of unbound free warfarin in serum. Protein-bound drugs such as phenylbutazone, chloral hydrate, and sulfonamides may enhance the toxicity of warfarin by displacing warfarin from protein-binding sites. This allows a greater proportion of the drug to be in the free form and thus able to exert its pharmacologic effect.[15,140] Corticosteroids and thyroxine may lower the therapeutic dose of warfarin by increasing clotting factor catabolism and receptor site affinity.[141]

Certain physiologic factors also may enhance the toxicity of warfarin. Hypoalbuminemia may result in fewer binding sites available, thereby increasing the amount of free drug. Hepatic dysfunction may impede metabolism of warfarin, and reduced amounts of vitamin K in the diet may predispose to toxicity.[140]

Some drugs reduce the therapeutic response to a given dose of warfarin. Barbiturates, rifampin, and chloramphenicol induce hepatic microsomal enzyme activity, thereby accelerating metabolism of warfarin. If these drugs are withdrawn during warfarin therapy, toxicosis may result.[140,141] Likewise, excessive dietary intake of vitamin K (such as alfalfa) or vitamin K administration can reduce or inhibit the anticoagulant effects of warfarin.[141]

Warfarin acts as an anticoagulant by inhibiting production of the vitamin K–dependent clotting factors II, VII, IX, and X. Vitamin K is a co-factor in the synthesis of clotting factors II, VII, IX, and X and also acts on all clotting factor precursors to convert glutamyl residues to α-carboxyglutamyl residues. During this carboxylation process, vitamin K_1 is converted to vitamin K_1 2,3-epoxide, an inactive metabolite. This epoxide returns to active vitamin K_1 by action of the microsomal enzyme vitamin K_1 epoxide reductase. The coumarin anticoagulants inhibit vitamin K_1 epoxide reductase, thereby creating a vitamin K_1 deficiency. The result is decreased production and subsequent deficiency of the vitamin K–dependent clotting factors.[7] The delayed onset of action of the coumarin derivative anticoagulants results from this impediment to clotting factor synthesis rather than from a direct effect on the clotting mechanism per se.

The various blood clotting factors have different plasma half-lives. Factor VII has a shorter half-life than the other clotting factors, so the earliest laboratory indication of warfarin toxicity is a prolonged PT. As the other clotting factors become depleted, activated PTT also increases as toxicity continues.[141] One should 1482
monitor horses given warfarin therapeutically for clotting abnormalities. Prolongation of PT by 1.5 to 2 1483
times baseline has been suggested as the effective range of anticoagulation. However, some horses maintained in this range may show signs of hemorrhage.[142]

20.4.2.2.3 Diagnosis and Treatment

The diagnosis of warfarin or other coumarin derivative anticoagulant intoxication is based on evidence of exposure to the drug, presence of a bleeding diathesis, and prolongation of PT with or without prolonged activated PTT. Because warfarin only affects certain clotting factors, other elements of the clotting profile are not affected. The platelet count, fibrinogen concentration, fibrin degradation product concentration, and antithrombin III activity remain within their respective normal ranges of activity.[141,142]

One also can evaluate tissue concentration of warfarin on postmortem specimens. One can submit liver, kidney, spleen, stomach and intestinal contents, feces, and unclotted blood for evaluation. One should freeze specimens for transportation to the laboratory.[15,145] Certain laboratories can evaluate serum for brodifacoum content.[143]

In horses intoxicated by warfarin, discontinuance of warfarin therapy or removal of the product from the environment of the horse is of primary importance. Vitamin K_1 is the specific antidote for coumarin derivatives and should be given at a dosage of 300 to 500 mg subcutaneously every 4 to 6 hours until PT returns to the baseline value. Thereafter, one should monitor PT daily for 3 to 4 days to ensure stability. The subcutaneous route of vitamin K_1 administration is preferable because of the possibility of adverse reactions if the product is given intravenously or intramuscularly. Intravenous injection of vitamin K_1 may result in transient restlessness, tachypnea, tachycardia, sweating, and anaphylactic reactions.[146,147] Intramuscular administration of vitamin K_1 results in erratic response times and therefore may be inappropriate for a hemorrhaging patient.[146] Alternative doses for vitamin K_1 administration are 0.3 to 0.5 mg/kg intravenously, and a dosage of greater than 0.5 mg/kg intravenously has been suggested to inhibit coumarin activity for several days.[141] If one chooses the intravenous route, one should dilute vitamin K_1 in 5% dextrose or saline and give it slowly.[15]

In horses intoxicated with brodifacoum, treatment with vitamin K_1 may be required for 3 to 5 weeks or until serum brodifacoum concentration decreases to less than 30 ng/ml and coagulation status is normal 2 to 3 days following the last dose of vitamin K_1. Affected horses were given vitamin K_1 (2.5 mg/kg) subcutaneously every 12 hours for 36 hours and then orally twice daily for the duration of treatment.[143]

If bleeding is serious, fresh blood or fresh plasma given intravenously may be necessary to control hemorrhage and to help correct hypovolemia. Other supportive measures such as bandaging and keeping the animal in a quiet environment may be helpful. Alfalfa hay added to the diet may provide a natural source of vitamin K_1.[143] One should treat organ dysfunction induced by hemorrhage appropriately. The prognosis for horses intoxicated with first-generation compounds is good if the disorder is recognized early and appropriate therapy is instituted. The prognosis for brodifacoum toxicosis is much more guarded because of the prolonged and severe course of clinical signs with this substance.

Prevention of warfarin toxicosis should aim to minimize exposure of horses to the product and to monitor the therapeutic use of the drug in the horse carefully. Contraindications to its use include any clinical or laboratory suggestion of hepatic disease, hypoproteinemia, or other condition that might increase the risk of toxicity. One should evalute the concurrent use of other medications because they may affect the potential for toxicosis to develop, and one should reevaluate the dosage of warfarin administered if other concurrent medications are changed. Additionally, one should minimize the potential for traumatic injury in horses undergoing warfarin therapy.

20.4.2.3 Dimethyl Sulfoxide

Dimethyl sulfoxide is a by-product of the papermaking industry and is a colorless liquid originally used as an industrial solvent. The chemical is a polar compound that readily mixes with ethyl alcohol and many organic solvents, is extremely hygroscopic, and can absorb more than 70% of its weight of water from air. Dimethyl

sulfoxide possesses some antimicrobial and antifungal activity, but its primary medical use has been as an antiinflammatory agent and as a transdermal transport agent.[148] More recently, DMSO has found use as a diuretic and has shown promising results when used to treat acute cranial and spinal cord trauma.[148,149]

The systemic toxicity of DMSO is considered to be low, and its greatest toxic potential appears to result from its combination with other toxic agents.[150] However, in an experimental study, rapid infusion of DMSO in 20% and 40% concentrations caused hemolysis, hemoglobinuria, diarrhea, muscle tremors, and signs of colic in some horses.[151] The LD_{50} of DMSO has not been established for horses but ranges from 2.5 to 9.0 g/kg as a single intravenous dose in a number of animal species.[150] A dose of 1 g/kg intravenously has been suggested for use in horses. One should dilute this dose to a 10% to 20% solution and administer it slowly intravenously.[149,150]

Dimethyl sulfoxide produces hemolysis when given intravenously in concentrations of 20% to 50% or greater.[148–150] If hemolysis is severe, affected horses may be at increased risk of developing hemoglobin 1483
nephrosis. Concentrations of 10% or less are considered suitable for intravenous injection in horses. 1484
[148,149,151] Additionally, increased white blood cell adherence and fibrinogen precipitation have been reported when concentrations greater than 50% were administered.[148]

Dimethyl sulfoxide is a mild cholinesterase inhibitor, and its concurrent use with organophosphates or other cholinesterase inhibitors is not recommended.[148,150] Dimethyl sulfoxide also is known to induce histamine release from mast cells, but the significance of this phenomenon is uncertain.[150]

Skin reactions to topically applied DMSO can occur. Varying degrees of erythema, pruritus, drying, hardening, and desquamation of normal skin may be evident. These reactions are usually self-limiting and typically diminish with repeated applications.[150]

The greatest risk of toxicity resulting from DMSO is probably a consequence of its concomitant use with other toxic or potentially toxic agents. Dimethyl sulfoxide may aid transport of a variety of toxic compounds across skin, thereby inducing toxicosis from the transported agent. For example, mercury toxicity has been reported in a horse that had a blister from DMSO and mercury applied topically to a leg.[152] In such instances, one should treat the specific toxic reaction(s) appropriately. No specific antidote is recognized for DMSO, other than its judicious and conscientious use when being administered to horses. One should heed the aforementioned precautions when administering the drug.

20.4.2.4 Phenothiazine

Phenothiazine is an anthelmintic that has a narrow spectrum of activity in horses. Phenothiazine is active only against strongyles, is moderately effective in removing large strongyles, but is more effective against small strongyles.[153] This drug rarely is used as an equine anthelmintic because of its side effects and because safer and more efficacious anthelmintics with broader spectra of activity have been developed.

20.4.2.4.1 Clinical Signs

Phenothiazine administration has resulted in acute and unpredictable signs of toxicity in horses. Debilitated, weak, and anemic animals are reported to be more susceptible to toxicosis, yet toxic reactions

have been seen at normal therapeutic doses.[77,153] Fifteen grams may be toxic to horses, and 30 g may be lethal.[15] The common signs of toxicity reported are hemolytic anemia with subsequent hemoglobinuria and icterus, anorexia, weakness, CNS disturbances, and photosensitization.[77,153]

20.4.2.4.2 Pathophysiology

Phenothiazine is absorbed from the intestinal tract after being converted to phenothiazine sulfoxide by cellular enzymes of the intestinal epithelium. Once absorbed, phenothiazine is oxidized further in the liver to leukophenothiazone and leukothionol. These two substances then are excreted primarily in urine.[77]

Phenothiazine acts as an oxidant to red blood cells, resulting in the production of Heinz body anemia. For a detailed description of the pathogenesis of this condition, see Red Maple *(Acer rubrum)*.

Photosensitization may not be a problem in horses intoxicated by phenothiazine. However, in other species, photosensitization can occur because of abnormal accumulation of phenothiazine sulfoxide. Normally, this product is converted to phenothiazone by the liver. When high doses of phenothiazine are given or if liver dysfunction impairs the conversion of phenothiazine sulfoxide to phenothiazone, the sulfoxide diffuses into the general circulation and ultimately into the aqueous humor of the eye. On exposure to ultraviolet light, the phenothiazine sulfoxide produces photosensitization in unpigmented skin and a photosensitive keratitis. The keratitis may be manifested by corneal ulceration and blindness.[77]

The mechanism whereby phenothiazine may induce CNS derangements has not been elucidated.

20.4.2.4.3 Diagnosis and Treatment

Diagnosis of phenothiazine toxicity is based primarily on history of exposure to the drug and compatible clinical signs. No specific antidote is available, so symptomatic therapy is indicated. One should treat Heinz body anemia as previously described. One can prevent photosensitization by keeping treated animals out of direct sunlight for 2 to 3 days following therapy. One should not give phenothiazine to debilitated, weak animals and those with evidence of liver disease.

20.4.2.5 Digoxin

Digoxin has been used to treat congestive heart failure in many species, including horses. However, reports of digoxin toxicity in horses are rare. The margin between therapeutic and toxic doses in many species is narrow, and wide variations in individual tolerance to the drug occur. Therefore signs of toxicity may develop in horses given a normal dose of digoxin.[154]

20.4.2.5.1 Clinical Signs

The clinical signs reported in one instance of digoxin intoxication were anorexia, depression that became more pronounced over time, muscle tremors, and colic. Cardiac abnormalities included a slower, irregular pulse rate and electrocardiographic findings of a prolonged PQ interval with increased duration (widening) of the P wave. The horse also was hyponatremic and hypochloremic.[154]

Signs of toxicity reported in other species, including human beings, are anorexia, vomiting, salivation, diarrhea, abdominal pain, depression, skin rashes, neurologic signs, nausea, and various cardiac arrhythmias.[154,155] The most frequently encountered arrhythmias include incomplete or complete heart block, junctional escape rhythms and ventricular premature beats, ventricular bigeminy, and paroxysmal ventricular or atrial tachycardia with block. Death, when it occurs, is caused by cardiac arrhythmias.[155] 1484

1485

20.4.2.5.2 Pathophysiology

One can administer digoxin intravenously or orally, but the latter is preferred in the horse. Intravenous administration of the drug results in an initial high serum concentration and is an unsatisfactory means of providing long-term therapy. Absorption of digoxin is rapid and occurs largely in the small intestine, but the bioavailability of the drug is low (approximately 20%), and considerable variation in absorption occurs among horses.[155,156] Following absorption, digoxin is bound primarily to serum albumin, but again individual variation in the amount of protein binding in normal horses is considerable.[157] The biologic half-life of digoxin in the horse is reported to range from 17 to 23 hours,[156,158] and elimination is largely through urinary excretion of unchanged drug.[157]

The suggested therapeutic range for digoxin in the horse is a serum concentration of 0.5 to 2.0 ng/ml. This concentration has been achieved by administering an oral dose of 35 μg/kg every 24 hours. However, one must remember that no dosage regimen is absolute because of the extreme individual variation in absorption and protein binding of the drug. Repeated clinical monitoring of treated horses is imperative, with dosage adjustments based on clinical improvement, development of early signs of toxicosis, and assay of plasma digoxin concentration.[156]

Digoxin acts as a positive ionotrope and a negative chronotrope. The cellular mechanisms of inotropic action of digoxin still are being evaluated, but digoxin is known to inhibit the Na^+,K^+-ATPase–dependent transport system. This results in an intracellular loss of potassium and an intracellular elevation of sodium and calcium. The resting membrane potential therefore is reduced, making the cardiac cells more excitable. Another hypothesis is that the increased intracellular sodium concentration augments transmembrane exchange of intracellular sodium for extracellular calcium. The increased calcium delivered to the contractile proteins may be partially responsible for the positive inotropic effect.[155]

Digoxin acts as a negative chronotrope by decreasing sinus rate and slowing conduction of the atrioventricular impulse. These effects result from increased vagal tone and secondary hemodynamic improvement in digitalized animals. The increased vagal tone has been attributed to at least three mechanisms: (1) direct stimulation of vagal centers in the brain, (2) sensitization of baroreceptors in the carotid sinus to blood pressure, and (3) enhanced pacemaker response to acetylcholine at the myocardial level. The circulatory improvement following digitalization tends to remove the stimuli responsible for reflex sinus tachycardia, a compensatory effort in many instances of congestive heart failure. As a result the sinus rate can return to normal.[155]

Toxic effects of digoxin on cardiac muscle occur when the aforementioned mechanisms proceed beyond a beneficial level. Increased cardiac automaticity and excitability, coupled with excessive refractoriness at the atrioventricular node and decreased refractoriness of the atria and ventricles, can lead to extrasystoles and tachyarrhythmias. These dysrhythmias can be severe enough to result in cardiac failure and death.[7]

Many factors may enhance digoxin toxicity in human beings. Diseases such as renal failure, hypothyroidism, myocardial infarction, and myocarditis can have an additive effect on toxicity. Certain drugs—including quinidine, verapamil, amiodarone, spironolactone, and indomethacin—act to increase serum digoxin levels, and abnormal electrolyte concentrations can enhance digoxin toxicity. Hypokalemia, hyperkalemia, hypomagnesemia, hypernatremia, and alkalosis can contribute to digoxin toxicity.[7]

The mechanisms responsible for the noncardiac signs of digoxin toxicity have not been elucidated.

20.4.2.5.3

Diagnosis and Treatment

Diagnosis of digoxin toxicity may be difficult to differentiate from continuing cardiac compromise. If compatible clinical and electrocardiographic findings of toxicity are present, measurement of serum digoxin concentration should verify the diagnosis. However, some horses may exhibit signs of toxicity even though the serum concentration is within the suggested nontoxic range of 0.5 to 2.0 ng/ml.

Treatment of digoxin toxicosis should begin with drug withdrawal. One should evaluate serum electrolyte concentrations and acid-base status and correct abnormalities.[7,155] Oral charcoal administration has been advocated in instances of human toxicosis,[7] but its efficacy in equine poisoning remains undetermined. For horses that require digoxin therapy, one should start at a low dose and increase the dosage as needed over time.

20.4.2.6

Bicarbonate

Sodium bicarbonate is one of the most common alkalizing agents used in animals, including horses. Sodium bicarbonate is indicated specifically to treat acute, severe metabolic acidosis because of its rapid effect on blood pH when given intravenously.[159] Sodium bicarbonate also has been used in performance horses to treat exertional myopathies and in attempts to prevent rhabdomyolysis. More recently, sodium bicarbonate administration in performance horses has been investigated because of its suggested role in limiting or preventing systemic lactic acidosis, thereby enhancing the performance level of the horse.[160,161] The adverse effects of bicarbonate administration occur when it is given too rapidly or in excessive quantities or when it is given in the presence of certain other systemic abnormalities.

20.4.2.6.1

Clinical Signs

Animals, including horses, that suffer from an acute overdose of bicarbonate may exhibit signs of delirium, depression, and coma. Rapidly induced alkalosis also has been associated with cardiac dysrhythmias.[159] 1485

1486

Horses such as endurance horses or racehorses that are volume depleted and have sustained excessive electrolyte loss through sweat often have clinicopathologic changes of hypokalemia, hypochloremia, hypocalcemia, and metabolic alkalosis. When such horses are given bicarbonate, dramatic deleterious effects occur. These animals may exhibit signs of muscle fasciculation, synchronous diaphragmatic flutter, bruxism, and decreased respiratory rate. One also may note clinical evidence of further dehydration, such as increased capillary refill time, delayed jugular distensibility, diminished skin turgor, and decreased arterial pulse.[161]

20.4.2.6.2

Pathophysiology

The rapid administration or overdose of sodium bicarbonate has been associated with extracellular hyperosmolality, intracranial hemorrhage, and CSF acidosis. Hyperosmolality results from hypernatremia because sodium bicarbonate dissociates into sodium ions and bicarbonate ions. An abrupt increase in serum osmolality can lead to intracranial hemorrhage as intracellular water moves into the extracellular space. This extracellular fluid accumulation may result in engorgement of perivascular spaces, with subsequent tearing of bridge veins and resultant hemorrhage. The CSF acidosis results from the rapid diffusion of generated carbon dioxide into the CSF. Carbon dioxide enters the CSF almost instantaneously, establishing new steady-state levels within minutes. Bicarbonate ion, however, is slow to enter the CSF and requires hours to days to achieve new steady-state levels. With sodium bicarbonate administration, the increasing amount of carbon dioxide generated readily enters the CSF disproportionately more than does the bicarbonate ion. As a consequence the CSF becomes acidic.[162] These mechanisms, individually or collectively, are thought to be responsible for development of the clinical signs observed with rapid or excessive administration of sodium bicarbonate solution.

Another effect of alkalosis is a shift to the left of the oxyhemoglobin dissociation curve. This left shift indicates an increased affinity of hemoglobin for oxygen, with a resultant decrease in the amount of oxygen available for cellular use. This change in hemoglobin affinity for oxygen has been associated with cardiac dysrhythmias following rapidly induced alkalosis.[159]

Horses undergoing extensive exercise or horses that are treated with furosemide (primarily as prerace medication for exercise-induced pulmonary hemorrhage) are at risk of developing hypochloremic, hypokalemic metabolic alkalosis. When sodium bicarbonate is given to these volume-depleted horses with electrolyte loss and concurrent metabolic alkalosis, another deleterious series of events can result. Further reduction of the circulating fluid volume may occur, along with development of serum hyperosmolality, electrolyte abnormalities of hypernatremia, hypokalemia, hypochloremia, and hypocalcemia, and further development of metabolic alkalosis.[161]

Excess sodium bicarbonate produces hyperosmolality caused by hypernatremia because sodium bicarbonate dissociates into sodium and bicarbonate ions. The hypokalemia is explained partially by the intracellular shift of potassium in response to metabolic alkalosis, and the bicarbonate ion adds further to the alkalosis already present. Furosemide administration causes urinary loss of potassium, chloride, and calcium, and sweating also can result in significant loss of chloride and calcium. Additionally, rapid intravenous infusion of 5% sodium bicarbonate in normal horses results in hypochloremia.[163]

The muscle fasciculations and diaphragmatic flutter noted in some horses likely result from hypocalcemia.[161] The total serum calcium concentration may be within a normal range, but alkalosis causes a reduction in the amount of circulating ionized calcium. Because ionized calcium is responsible for neuromuscular function, reduction in this fraction can cause clinical signs of hypocalcemia.

20.4.2.6.3

Diagnosis and Treatment

One should monitor horses being treated with sodium bicarbonate solutions closely for clinical signs of alkalosis. Blood pH obviously is elevated, but rapid infusion of sodium bicarbonate or excessive use in horses already sustaining fluid and electrolyte loss can result in a number of clinicopathologic alterations.

Affected horses typically exhibit increases in PCV, total serum protein, and serum bicarbonate and sodium concentrations. Additional findings of hypokalemia, hypochloremia, and hypocalcemia are usually present.

Treatment of affected horses involves cessation of bicarbonate administration and correction of the alkalosis and electrolyte abnormalities. Potassium chloride administration is indicated in horses with hypokalemic, hypochloremic metabolic alkalosis, and is much more effective in correcting these electrolyte abnormalities than is sodium chloride. Potassium chloride also has been shown to cause a prompt, significant decline in venous blood pH in these horses.[161]

Apparently, one should not use hypertonic sodium bicarbonate solutions in dehydrated horses. The concurrent use of furosemide and sodium bicarbonate also appears to be contraindicated or at best must be used with extreme caution and close observation with laboratory assessment. One should not mix sodium bicarbonate with fluids containing calcium because insoluble complexes may form. The use of sodium bicarbonate orally in horses subjected to short-term, intense exercise is still controversial.

20.4.3 MISCELLANEOUS AGENTS

20.4.3.1 Nitrates and Nitrites

Nitrates are an important component in the naturally occurring nitrogen cycle and as such are present in soils, 1486
groundwater, forages, row crops, weeds, animal tissues, and excreta. Nitrates also are used widely in 1487
fertilizers. Toxicity problems can arise when animals consume plants, feed, or water containing excessive amounts of nitrates or when they ingest nitrate fertilizers or residues. Nitrates naturally undergo microbial decomposition to nitrites, so nitrite toxicity can occur when animals ingest feed or water in which the nitrates have decomposed to yield large amounts of nitrites. This decomposition can occur in moist haystacks, water troughs, farm ponds, silages, and pig swills. Nitrite also is administered intravenously to treat cyanide poisoning, and overzealous use of this therapy can result in toxicity.[42]

The primary exposure to nitrate or nitrite for most animals is the plants they consume. Many plants and forages are known to be nitrate accumulators, and a number of factors influence the uptake of nitrates in plants. Nitrate concentration by plants is enhanced by low soil pH; low soil molybdenum, sulfur, or phosphorus content; low soil temperature; drought; soil aeration; decreased light; and use of phenoxyacetic acid herbicides such as 2,4-dichlorophenoxyacetic acid. Nitrate and nitrite accumulation in ponds and groundwater is caused by water runoff from nitrate-rich soils or by direct contamination with nitrates and nitrites.[15,42] Nitrates and nitrites are water soluble and are carried easily from feedlots, pigpens, and fertilized areas into the soil and subsequently into plants, wells, and ponds.

The most important aspect of nitrates is their ease of microbial conversion to nitrites. Nitrite is responsible for the primary signs associated with toxicity in nitrate poisoning.

20.4.3.1.1 Clinical Signs

Although apparently rare, horses are reported to be susceptible to nitrate intoxication. Experimentally, an oral dose of 1 g/kg potassium nitrate caused illness but not death in horses. However, nitrates have been associated with death of horses under field conditions.[42]

In monogastric animals, nitrate ingestion is reported to produce gastrointestinal irritation with resulting emesis or enteritis. Salivation, diarrhea, colic, and frequent urination may be evident if the nitrate is concentrated enough. Because no mechanism are known whereby these animals can rapidly reduce nitrate to nitrite, they are generally much more tolerant of nitrate than are ruminants.[15]

Signs of acute poisoning with nitrites usually commence within 30 minutes to 4 hours following ingestion of high-nitrite feed or water. The most characteristic signs are those referable to respiratory insufficiency and include dyspnea, cyanosis, rapid and weak pulse, and anxiety. Exertion may exacerbate these signs and induce muscle tremors and collapse. The horse may have terminal clonic convulsions. The blood of affected animals is usually brown or chocolate-colored and imparts a cyanotic appearance to mucous membranes. Death may occur within several hours or be delayed until 12 to 24 hours after ingestion.[15,42]

20.4.3.1.2

Pathophysiology

Nitrites are absorbed rapidly from the gastrointestinal tract into the bloodstream. The nitrite ion acts directly on vascular smooth muscle to cause relaxation, and easily enters erythrocytes in exchange for chloride ion. Nitrite also can pass the placenta to enter fetal erythrocytes, which are especially sensitive to nitrite. The biologic half-life of blood nitrate in horses is 4.8 hours. Only small amounts of nitrate or nitrite are bound to plasma proteins.[42,164]

Nitrite causes acute poisoning by two mechanisms. The primary action of nitrite is to interact with hemoglobin to form methemoglobin. One molecule of nitrite interacts with two molecules of hemoglobin, causing the oxidation of normal ferrous hemoglobin to ferric hemoglobin, which is called methemoglobin. Methemoglobin is incapable of transporting oxygen to tissues, and if sufficient quantities are formed, severe oxygen deficiency can occur. Clinical signs become evident when methemoglobin levels approach 30% to 40%, and death occurs when 80% to 90% of hemoglobin is oxidized to methemoglobin.[15,42] However, death can occur in active animals with only 50% to 60% methemoglobin.[42]

Normally, methemoglobin is converted back to ferrous hemoglobin by two reducing enzyme systems: nicotinamide adenine dinucleotide–dependent diaphorase I and nicotinamide adenine dinucleotide phosphate–dependent diaphorase II. This conversion occurs slowly, and in instances of nitrate toxicity, methemoglobin formation far exceeds the ability of these enzyme systems to regenerate hemoglobin.[42]

The second action of nitrite is to cause direct relaxation of smooth muscle, particularly vascular smooth muscle. The mechanism by which this occurs is unknown, but the physiologic changes brought about by the vasodilating action of nitrite include pulmonary arterial, central venous, and systemic arterial hypotension and decreased cardiac output. These changes may contribute to tissue anoxia and act to enhance tissue oxygen starvation already initiated by methemoglobin.[42]

20.4.3.1.3

Diagnosis and Treatment

The diagnosis of nitrate or nitrite toxicity is based on compatible clinical signs; methemoglobinemia; history of exposure to nitrate- or nitrite-containing plants, water, or fertilizers; and nitrate quantitation in blood. One should perform serum nitrate and methemoglobin determinations quickly following collection because these are not stable in refrigerated, heparinized blood for more than a few hours. However, blood mixed with a phosphate buffer preserves the methemoglobin and allows shipment to a diagnostic 1487

laboratory. One can analyze forage, hay, and water samples for nitrate or nitrite content, as well as other body fluids such as urine, aqueous humor, and intestinal contents.[15]

Treatment aims to reduce methemoglobin back to hemoglobin. Mildly affected animals may recover spontaneously if the toxic source is removed and if they are given sufficient time for normal methemoglobin reduction processes to occur. One may use methylene blue to treat more severely affected horses at a suggested dose of 4.4 mg/kg intravenously given slowly as a 1% solution in isotonic saline. One can repeat the dose in 30 minutes if clinical response is unsatisfactory. One should exercise caution with this product, however, because excess methylene blue may directly oxidize hemoglobin to methemoglobin. Methylene blue is converted to leukomethylene blue by an $NADPH_2$-dependent system. Leukomethylene then reduces methemoglobin to hemoglobin. In this reaction, leukomethylene blue is oxidized back to methylene blue but can be reconverted to leukomethylene blue as long as sufficient $NADPH_2$ is available. If this $NADPH_2$ system becomes saturated with methylene blue, excess methylene blue may oxidize hemoglobin directly to more methemoglobin.[42]

Other nonspecific therapies one may use include blood transfusion, oxygen therapy, and laxatives such as mineral oil to aid evacuation of the gastrointestinal tract.[42]

20.4.3.2 Cyanide

Hydrogen cyanide, cyanide, hydrocyanic acid, and *prussic acid* are terms relating to the same toxic substance. Horses become exposed primarily through ingestion of certain plants that contain cyanogenic glycosides, but compounds containing cyanide also are used as fumigants, rodenticides, and fertilizers.[15,42]

A number of plants or plant parts may accumulate large quantities of cyanide or cyanogenic glycosides, and a more complete description of them can be found elsewhere.[165] When these cyanogenic glycosides undergo hydrolysis, free HCN is formed. Plant cells contain degradative enzymes that can hydrolyze these glycosides, but under natural conditions the enzymes are kept separated spatially from the glycosides in intact cells. Damage to the plant cells by wilting, freezing, or stunting allows enzymatic degradation of the glycoside.[15] Rapid hydrolysis and release of HCN occurs only when the plant cell structure is disrupted. When the glycoside is exposed to an acid medium, or when maceration of the plant occurs within the intestinal tract, hydrolysis and subsequent formation of HCN also occurs.

A number of factors can influence the toxic potential of cyanogenic plants. Because plant cyanogenic glycosides and degradative enzymes are controlled genetically by a dominant gene, selectively breeding plants with low cyanogenic potential is possible. Therefore, species and varieties of forage affect cyanogenic content. High-nitrogen fertilization, nitrogen and phosphorus imbalance in soil, and drought conditions also can influence cyanide potential in plants.[15]

Most of the cyanogenic activity in the plant is located in the leaves and seeds, and immature and rapidly growing plants have the greatest potential for high glycoside levels. Conditions that damage the plant, such as drought, wilting, or freezing, may allow for more rapid combination of glycoside and enzyme, thereby enhancing plant toxicity. Other factors that may affect toxicity are the size of the animal, speed of ingestion, the type of food ingested along with the cyanogen, and the presence of active degradative enzymes in the plant and in the digestive tract of the horse.[15]

20.4.3.2.1

Clinical Signs

Because cyanide is such a potent, rapidly acting poison, affected animals commonly are found dead. On observation, clinical signs may range from mild tachypnea and anxiousness to severe panting, gasping, and behavioral excitement. Salivation, lacrimation, muscle tremors, defecation, urination, and mydriasis may be evident. These signs are followed by prostration, clonic convulsions, and death. The mucous membranes typically have a bright red appearance, and blood color is a bright cherry red. Clinical signs may last from only several minutes to a few hours, but horses that survive longer than 90 to 120 minutes following exposure usually survive.[6,15,42,165]

20.4.3.2.2

Pathophysiology

HCN is absorbed rapidly from the gastrointestinal tract or from the lungs. Following absorption, endogenous thiosulfate combines with the cyanide ion to form thiocyanate, which is relatively harmless. This reaction occurs in the liver and other tissues, and the generated thiocyanate is excreted in urine. Another inherent detoxification mechanism involves inactivation of HCN in the bloodstream by combining with the ferric iron of methemoglobin. However, because asmall amount of methemoglobin normally is present in blood and endogenous stores of thiosulfate can be depleted rapidly, these two endogenous mechanisms of detoxification are overcome rapidly in cases of clinical toxicity.[15]

Excess cyanide ion reacts readily with the trivalent (ferric) iron of cytochrome oxidase to form a stable cyanide–cytochrome oxidase complex. When iron is maintained in the ferric form, electron transport can no longer occur, and the chain of cellular respiration is brought to a halt. As a consequence, hemoglobin is unable to release its oxygen to the electron transport system, and cellular hypoxia results. This action occurs despite a large concentration of oxygen in the bloodstream. Cytochrome oxidase is most concentrated in tissues that have a high oxidative metabolic rate, such as the CNS and cardiac muscle. All tissues can be affected from this lack of usable oxygen, but death primarily is caused by anoxia in the brain.[15,42] 1488

1489

The acute oral LD_{50} of HCN is 2.0 to 2.3 mg/kg, and rapid intake of plant material equivalent to about 4 mg/kg is thought to be a lethal amount.[42]

20.4.3.2.3

Diagnosis and Treatment

One should consider cyanide poisoning when animals consuming cyanogenic plants are affected with acute signs of oxygen starvation and bright red blood. Chemical confirmation can be accomplished, and one may submit samples of forage, blood, liver, muscle, brain, and heart. One should quick-freeze all samples as soon as possible, and ship them frozen.[15,42] Plant materials containing greater than 200 ppm HCN, and concentrations in brain and ventricular myocardium greater than 100 µg/100 g wet tissue are considered significant.[42]

Treatment aims at splitting the cyanide–cytochrome oxidase complex, with subsequent removal of the cyanide complex, and augmenting available thiosulfate in the bloodstream. Sodium nitrite displaces the cyanide molecule from the cytochrome enzyme and changes some of the hemoglobin to methemoglobin, which then competes with cytochrome oxidase for the cyanide ion. In this process, methemoglobin and the

cyanide ion form cyanomethemoglobin, and cytochrome oxidase subsequently is regenerated. One should use sodium nitrite cautiously because of the possible danger of producing nitrite toxicosis, but it can be administered intravenously at doses ranging from 6 mg/kg, given as a 20% solution,[157] to 15 to 25 mg/kg.[42]

Sodium thiosulfate reacts with the cyanide ion in the blood or liberated from cyanomethemoglobin and forms thiocyanate, which is essentially harmless and is excreted in urine. One also can give sodium thiosulfate intravenously at doses ranging from 60 to 660 mg/kg, as a 20% solution,[6] to 1.25 g/kg. Additional recommended therapies include large doses of hydroxycobalamin (vitamin B_{12}) and mineral oil. The cobalt in the vitamin B_{12} preparation may bind additional cyanide in the circulation, and mineral oil aids evacuation of the gastrointestinal tract. Animals that survive 24 hours usually do not require further treatment.[42]

20.4.3.3 Sodium Fluoroacetate (1080)

Sodium fluoroacetate and fluoroacetamide are highly toxic to many animal species. They are used as rodenticides and in predator control, and because of their toxicity are available only from licensed exterminators. The compounds are odorless, tasteless, and water soluble and are typically incorporated into baits composed of carrot chunks, bread, bran, or meats. In the United States, these compounds are mixed with a black dye before being placed in baits. Horses may become intoxicated by inadvertent exposure to these baits.[15,65]

20.4.3.3.1 Clinical Signs

Sodium fluoroacetate causes signs primarily related to cardiac dysfunction in herbivores. The onset of signs usually occurs from 30 minutes to 2 hours following ingestion. When signs begin, their onset is usually acute and follow a rapid, usually violent course. Significant cardiac arrhythmias with rapid, weak pulse and eventual ventricular fibrillation are typical findings. Horses may exhibit staggering, trembling, restlessness, urination, and defecation. Moaning and bruxism may occur along with profuse sweating and signs of colic. Terminal convulsions also may occur. Ventricular fibrillation is the cause of death, and some horses may be found dead with no outward signs of struggle.[15,65]

20.4.3.3.2 Pathophysiology

Fluoroacetate is absorbed readily from the gastrointestinal tract, lungs, or open wounds, but not through intact skin. Following absorption, fluoroacetate is distributed throughout the body and does not accumulate in any specific tissue. The acute oral LD_{50} of fluoroacetate in horses is 0.35 to 0.55 mg/kg.[65]

Following entry into cells, fluoroacetate can replace acetyl coenzyme A, combining with oxaloacetate to form fluorocitrate. Fluorocitrate then competes with citrate for the active site of aconitase, a Krebs cycle enzyme, and also inhibits succinate dehydrogenase, which catalyzes succinate metabolism. The inhibition of these two enzymes and the subsequent accumulation of citrate block the Krebs cycle leads to decreased glucose metabolism, energy stores, and cellular respiration. These actions occur in all cells, but organs with high metabolic rates (such as brain and heart) are affected most severely.[7,15,65]

The short latent period between ingestion and onset of signs is because fluoroacetate must be converted to the more toxic fluorocitrate. The accumulation of toxic levels of fluorocitrate therefore requires some time. [15]

20.4.3.3.3 Diagnosis and Treatment

Diagnosis of fluoroacetate toxicity must rely heavily on history of exposure, compatible clinical signs, and absence of other pathologic findings. Laboratory detection of these compounds can be difficult, but specimens can be subjected to analysis by gas-liquid and high-performance liquid chromatography.[7,15] Fluoride ion–specific electrodes also can detect the compound in suspect samples. Suspect baits, stomach contents, liver, and kidney are the best samples to submit for evaluation.[15,65] Significantly increased kidney citrate levels suggests 1080 toxicity.[65]

Laboratory abnormalities in affected animals might include hyperglycemia and lactic acidemia.[15] However, these findings are inconclusive and accompany many disease states in the horse.

No specific antidote is available. Therapy is largely supportive and apparently unrewarding in horses already showing signs of toxicity. One may attempt intestinal decontamination using orally administered mineral oil and activated charcoal. If hypocalcemia develops, one may administer calcium gluconate or 1489
calcium chloride. Glycerol monoacetate at 0.1 to 0.5 mg/kg intramuscularly with hourly repeat treatments 1490
has been suggested but may not be effective after onset of clinical signs.[15,24]

20.5 Toxicoses Causing Signs Relating to the Epithelium, Skeletal System, and General Body Condition

Toxicoses causing these clinical signs can be among the most difficult to diagnose. Signs are often mild-moderate and quite nonspecific. In some cases the history is nonspecific and the possibility of exposure to a toxin is difficult to evaluate.

20.5.1 PLANTS

20.5.1.1 Black Walnut *(Juglans nigra)*

Shavings and aqueous extracts from black walnut trees are responsible for a toxic syndrome in horses characterized by acute onset of laminitis and variable degrees of limb edema.[166–168]

20.5.1.1.1 Clinical Signs

Horses begin showing signs of toxicity within 10 to 12 hours of being bedded with black walnut shavings. The primary signs are those of laminitis and include reluctance to move, shifting weight from limb to limb, increased digital pulse and temperature of the hoof, and positive response to hoof testers. The laminitis can vary from mild to severe.[166–168] Another characteristic finding is that of limb edema, which can become pronounced. Additional signs noted may include increased respiratory rate with flared nostrils, anorexia

and lethargy, and abdominal pain.[167] Horses removed from the bedding after clinical signs have developed have a good prognosis for full recovery.[166,167]

20.5.1.1.2

Pathophysiology

The toxic principle involved in this toxicosis is yet unidentified. Earlier, juglone, a naphthoquinone found in roots, bark, and nuts of black walnut trees, was suggested to be the causative agent.[166–168] Further work has shown, however, that an aqueous soluble toxin other than juglone that is found in the heartwood is more likely to be responsible for generation of clinical signs.[168] The mechanism of action of this soluble toxin has not been elucidated fully, but it has been shown reversibly to enhance vasoconstriction of isolated digital vessels in vitro induced by administration of epinephrine potentiated with hydrocortisone.[169]

20.5.1.1.3

Diagnosis and Treatment

Diagnosis of black walnut– induced laminitis is based primarily on known exposure to shavings containing the plant and subsequent development of clinical signs. The treatment of laminitis is covered elsewhere, but horses have a good prognosis for recovery if they are removed from the offending bedding. Black walnut shavings should not be used as bedding for horses.

20.5.1.2

Wild Jasmine *(Cestrum diurnum)*

Cestrum diurnum (wild jasmine, day cestrum, day-blooming jessamine, king-of-the-day, Chinese inkberry) is a tropical to subtropical plant native to the West Indies that has been introduced and cultivated widely as an ornamental in southern parts of the United States, including Florida, Texas, and California. The plant grows rapidly from seeds, and birds may contribute to spread of the plant because of their appetite for ripe berries that contain seeds. The plant is naturalized in Hawaii and India also and tends to multiply along fence rows, roadsides, and in neglected pastures and fields. Horses show signs of disease following ingestion of the plant for several weeks to months.[170]

20.5.1.2.1

Clinical Signs

Affected horses show signs primarily of weight loss and lameness. Weight loss occurs over several weeks to months in spite of normal appetite. Lameness is usually of increasing severity and may begin with signs of generalized stiffness. Eventually, the fetlock joints may become overextended and horses may exhibit kyphosis. The flexor tendons and particularly the suspensory ligament become sensitive to palpation. The lameness can become so severe as to require euthanasia.[170] Signs of renal failure also may become evident in isolated cases.

20.5.1.2.2

Pathophysiology

Cestrum diurnum and certain other members of the Solanaceae family contain a potent steroid glycoside with vitamin D–like activity. The toxic agent is a 1,25-dihydroxycholecalciferol (1,25[OH]2D_3) glycoside found in the leaves of the plant.[171,172] Normally, vitamin D_3 is acquired from the diet or is produced in the

skin by a reaction dependent on ultraviolet light. Vitamin D_3 is hydroxylated in the liver to yield 25-hydroxycholecalciferol, which subsequently is hydroxylated in the kidney to $1,25(OH)2D_3$. This compound is the most active form of the vitamin and acts to increase calcium absorption and stimulate production of calcium-binding protein in the intestine.[171]

The normal rate of production of $1,25(OH)2D_3$ is regulated by a negative feedback mechanism. Calcium or phosphorus deprivation stimulates the production of $1,25(OH)2D_3$, and a decreased rate of production occurs when calcium or phosphorus is present in adequate amounts.[171]

This natural feedback mechanism is bypassed when $1,25(OH)2D_3$ is supplied exogenously, as in the case of ingestion of *C. diurnum*. As a consequence, excessive calcium-binding protein is synthesized in the intestine, and excessive amounts of calcium and phosphorus are absorbed. If the calcium load exceeds the capacity of the kidney to excrete it, soft tissue mineralization (dystrophic calcification) and osteopetrosis occur.[171] In horses ingesting toxic amounts of *C. diurnum,* calcification of the flexor tendons, suspensory
ligament, and other elastic tissues appears to predominate over deposition of calcium into other soft 1490
tissues. Osteopetrosis is thought to result from sustained hypercalcemia and secondary elevation of 1491
calcitonin.[170]

20.5.1.2.3 Diagnosis and Treatment

One should suspect a diagnosis of toxicosis when horses exhibit signs of weight loss and lameness and they have known prolonged access to *C. diurnum*. Affected horses typically are hypercalcemic, but serum phosphorus concentration is usually within a normal range. Renal dysfunction, if present, may be characterized by elevations in BUN and creatinine concentrations. Urine analysis may indicate an increased fractional excretion of sodium, potassium, and phosphorus, along with other laboratory findings associated with renal failure.

No treatment for vitamin D toxicosis in known. Horses should be denied access to *C. diurnum* plants.

20.5.1.3 Hairy Vetch *(Vicia villosa)*

One report of toxicosis suspected to result from ingestion of hairy vetch is described.[173] The affected horse was a 1-year-old crossbred female presented for euthanasia because of severe weight loss and bilateral corneal ulceration with perforation.

The clinical signs reported were weight loss despite good appetite, fluctuating body temperature, subcutaneous swelling that started around the lips and spread to involve the rest of the body, and bilateral corneal ulceration with eventual perforation.

The only recorded abnormal laboratory findings consisted of elevated serum concentrations of LDH and AST measured 2 weeks after onset of clinical signs. Histologic lesions consisted of multifocal to diffuse granulomatous inflammation of the heart, lungs, kidneys, skin, lymph nodes, ileum, colon, skeletal muscle, and choroid.

The toxic substance has not been identified, and no specific therapy has been recommended. A similar toxic condition occasionally occurs in cattle grazing hairy vetch, with most cases of toxicosis occurring between April and July.

20.5.1.4

Photosensitizing Plants

Many plants can cause photosensitive reactions in horses. Some plants contain photodynamic substances that are absorbed from the gastrointestinal tract intact or in a form metabolically altered into an active compound (primary photosensitizing plants). Other plants may cause photodermatitis following liver dysfunction, in which the photodynamic toxin is a metabolite normally excreted in bile (secondary photosensitivity). Because of hepatic damage induced by the plant, these metabolites enter the circulation and subsequent interaction with light results in clinical manifestation of disease. Box 20-1 lists plants[6,165,174] known to induce photosensitization in herbivores.

20.5.1.4.1

Clinical Signs

1491

Signs of photosensitization are similar, regardless of the cause, and vary in degree. Factors that influence 1492 the severity of signs include the amount of reactive pigment present in the skin at a given time, the degree of exposure to light of appropriate wavelength, and the severity of hepatic damage, if hepatogenous photosensitization is the cause.[174]

20.5.1.4.1.1

BOX 20-1 PLANTS INDUCING PHOTOSENSITIZATION IN HERBIVORES

20.5.1.4.1.1.1

Primary Photosensitizers

Ammi majus (bishop's weed): Contains furocoumarins

Avena fatua (oatgrass)

Brassica (rape)

Cooperia pedunculata

Cymopterus watsonii (spring parsley): Contains furocoumarins

Erodium (trefoil)

Fagopyrum sagittatum (buckwheat): Contains the naphthodi-anthrone derivative fagopyrin

Hypericum perforatum (St. John's wort, Klamath weed): Contains the naphthodianthrone derivative hypericin

Perennial ryegrass

Ricinus communis (castor bean)

Rutaceae

Trifolium (clover)

Umbelliferae

20.5.1.4.1.1.2 Secondary or Hepatogenous Photosensitizers

Agave lecheguilla (lecheguilla)

Blue-green algae

Brachiaria brizantha

Brassia hyssopifolia

Brassica napus (cultivated rape)

Holocalyx glaziovii

Lantana spp.

Lippia rehmanni

Myoporum laetum (ngaio)

Narthecium ossifragum (bog asaphodel)

Nolina texana (sacahuiste)

Panicum spp. (panic grass, kleingrass)

Pithomyces chartarum and *Pithomyces minutissima*

Senecio spp. (ragwort, groundsel)

Tetradymia canescens (gray horsebrush)

Tetradymia glabrata (spineless horsebrush)

Tribulus terrestris (puncture vine)

20.5.1.4.1.1.3 Other Photosensitizers

Avena (oats)

Euphorbia maculata (milk purslane)

Kochia scoparia (summer cyprus, fireweed)

Medicago (alfalfa)

Polygonum spp. (smartweed)

Sorghum vulgare (Sudan grass)

Trifolium (clover)

Vicia spp. (vetches)

Restlessness and discomfort are usually the first signs one notes. Erythema may be apparent, followed by edema of affected areas. Blister formation and subsequent serum exudation and scab formation occur as the condition progresses. Affected sites are usually painful to touch, and animals often attempt to protect themselves from direct sunlight.[6,174]

The light-colored or nonpigmented areas of skin are affected most severely, particularly those areas involving the face, nose, back, escutcheon, and coronary band. Severely affected animals also may have involvement of pigmented areas of skin, and secondary self-trauma and bacterial infection may arise from the attempts of the animal at rubbing the affected areas. Horses may lose patches of skin that slough in large, leathery plaques.[6,174]

20.5.1.4.2 Pathophysiology

Plants causing primary photosensitization contain a photodynamic agent that is absorbed from the gastrointestinal tract intact or that is later metabolically altered into an active compound. Secondary photosensitizing plants induce hepatic damage of sufficient magnitude to inhibit adequate clearance of photodynamic agents. Normally, these photodynamic toxins are metabolites excreted in bile. When the liver is damaged sufficiently or bile flow is hindered, these metabolites enter the circulation. Phylloerythrin, a normal chlorophyll breakdown product, is considered the only important photodynamic substance in instances of secondary photosensitization.[15] These photodynamic agents then are circulated throughout the body, eventually reaching the dermal capillaries.

Interaction of long-wave ultraviolet light with these photodynamic agents circulating in the skin capillaries results in chemical excitement of these substances. As a consequence, free radicals form that are highly inflammatory and cause degradation of cell phospholipid membranes, polypeptide proteins, and nucleic acids.[6,175] These processes disrupt the cells and ultimately result in the dermal lesions noted with this toxicity. One should remember that drugs and diseases that cause liver damage also potentially can cause photosensitivity.

20.5.1.4.3 Diagnosis and Treatment

Clinical signs of photosensitivity are fairly typical and seldom are confused with other afflictions of skin. When clinical signs become evident, one should evaluate the horse thoroughly for evidence of hepatopathy because primary and secondary photosensitivity produce the same clinical signs. If hepatic disease is present, one should ascertain the cause and institute appropriate therapy.

One can identify primary photodynamic agents with several biologic assay systems. A mouse assay system and a microbial assay using *Candida albicans* are available for this purpose.[6]

Specific therapy for photodermatitis is not available. Horses should be removed from direct sunlight until skin lesions are healed and the offending plant is removed from the environment. One may use various topical agents to help skin healing. One should treat superficial bacterial dermatitis with appropriate antibiotics, and nonsteroidal antiinflammatory therapy may be beneficial during initial stages of the disease process.

20.5.1.5 Pyrrolizidine Alkaloids

Pyrrolizidine alkaloid toxicity results from consumption of plants that contain various pyrrolizidine alkaloids. Horses can become intoxicated by ingestion of fresh plants and dried plants incorporated into hay. As with many toxic plants, though, these plants are frequently unpalatable to most horses, yet certain conditions may render them more appetizing. This toxicity is characterized by a chronic, progressive disorder manifested by signs of liver failure. The more common plants that cause toxicosis in horses include *Senecio jacobaea* (tansy ragwort), *S. vulgaris, S. longilobus* (groundsel), *Amsinckia intermedia* (fiddleneck), *Crotalaria* species (rattlebox), *Echium plantagineum* (Viper's buglos), *Heliotropium europaeum* (common heliotrope), and *Cynoglossum officinale* (houndstongue).[176,177]

20.5.1.5.1 Clinical Signs

Signs of pyrrolizidine alkaloid intoxication in horses are essentially those of liver failure. The more frequent signs noted include weight loss of weeks to months in duration, icterus, and behavioral abnormalities. The behavioral changes indicate hepatoencephalopathy and may include aimless pacing or wandering, ataxia, licking inanimate objects, blindness, head pressing, and uncharacteristic aggression. Convulsions and coma may precede death. Clinical signs of abnormal behavior usually are a terminal event in the disease process and typically have an acute onset.[177,178] Other signs less frequently reported include diarrhea, photosensitization of nonpigmented areas of skin, hemoglobinuria, and inspiratory dyspnea.[177,179] Abortion and poor exercise tolerance (reduced athletic performance) also have been observed in horses following ingestion of sublethal amounts.[180] Because toxicity of these plants is related to liver dysfunction, clinical signs of disease may not become apparent for weeks to months following ingestion.

20.5.1.5.2 Pathophysiology

A number of pyrrolizidine alkaloids are present in various plant species, and some plants may contain
multiple alkaloids. These substances are absorbed from the gastrointestinal tract and carried to the liver 1492
where they are metabolized by hepatic microsomal enzymes to pyrroles. These pyrroles then can cross- 1493
link double-stranded DNA and bind to proteins and nucleic acid within hepatocytes.[176,177]

The cross-linking of DNA has an antimitotic effect on hepatocytes. The hepatocytes are unable to divide and subsequently become megalocytes. As these cells die, they are replaced by fibrous tissue rather than normal hepatocytes. Binding of protein and nucleic acid results in inhibition of cytoplasmic protein synthesis. These changes may lead to more rapid death of hepatocytes and cause centrilobular necrosis. Eventually, liver function begins to fail because of progressive hepatocellular death and subsequent fibrosis.[176,177] As the disease progresses, generalized fibrosis develops. Once connective tissue bridges form between portal areas, the disease is fatal.[176]

Variation in the dosage and frequency of administration of alkaloids results in a wide spectrum of hepatic lesions. Acute toxicosis resulting from massive doses is more likely to produce centrilobular necrosis with hemorrhage. Chronic doses tend to produce hepatocellular death in the portal areas, along with megalocytosis, fibrosis, biliary hyperplasia, and occlusion of hepatic veins.[176,177] Liver failure is thought to be ultimately responsible for the clinical signs observed in pyrrolizidine alkaloid toxicosis.

The toxic dose of dried *Senecio* is estimated to be 5% of the body weight of the horse. This amount does not need to be ingested all at once, however, because the effects are cumulative. The total dose of alkaloids consumed determines the toxic effect, regardless of the amount of time in which the alkaloids were consumed.[176,177]

20.5.1.5.3 Diagnosis and Treatment

Most cases of pyrrolizidine alkaloid toxicosis are diagnosed based on history, compatible clinical signs, serum liver enzyme activities, and liver biopsy findings. When active hepatocellular damage is occurring early in the disease process, sorbitol dehydrogenase and LDH usually are elevated, but they often decline to normal values by the time the horse is showing clinical signs. Serum GGT, alkaline phosphatase, and AST activities tend to be elevated throughout the disease course. Serum concentration of bile acids also is reported to be elevated in affected horses. Serum bilirubin concentration tends to be elevated in later stages of disease, and hypoglycemia and hypoalbuminemia rarely are seen except in cases of severe hepatic disease.[176,177,179,180]

Other diagnostic aids that may be useful from a diagnostic and prognostic standpoint include measurement of the ratio of branched-chain amino acids to aromatic amino acids in serum and liver biopsy. The branched-chain amino acids isoleucine, leucine, and valine are catabolized primarily in muscle, and the aromatic amino acids phenylalanine and tyrosine are catabolized mainly in the liver. The ratio of the sums of these amino acids (branched-chain to aromatic) has been shown to decrease progressively from normal in horses affected with pyrrolizidine alkaloid toxicosis. If the ratio is below normal range and the horses are exposed continually to alkaloid-containing plants, they have a poor chance of survival. Some affected horses also showed a dramatic decrease in this ratio just before death.[181] Liver biopsy findings of a triad of fibrosis, bile duct proliferation, and megalocytosis are highly suggestive of pyrrolizidine alkaloid toxicosis. Liver biopsy samples also can help in establishing prognosis because the presence of advanced or generalized hepatic fibrosis warrants a grave prognosis.[176,177]

One may analyze feed samples for pyrrolizidine alkaloid content, but the process is often time-consuming and expensive.[176]

No specific treatment for pyrrolizidine alkaloid toxicity exists. Affected horses may survive if they are denied further exposure to alkaloid-containing plants and are fed a suitable diet. However, some horses still may show signs of liver disease even though they have not had exposure to the plant for some time. Specific treatment of acute and chronic liver failure is discussed elsewhere.

Prevention is accomplished by keeping horses away from pasture or feed contaminated with pyrrolizidine alkaloid–containing plants.

20.5.1.6 Tall Fescue *(Festuca arundinacea)*

The causative agent of the disorder associated with grazing tall fescue is *Neotyphodium coenophialum*[182] (formerly identified as *Acremonium coenophialum*), a fungal endophyte that grows within the stem, leaf sheaths, and seeds of tall fescue.[183,184] This endophyte is highly indigenous to many areas of the United States and may contaminate as much as 90% of fescue pastures in certain geographic areas.[183]

20.5.1.6.1

Clinical Signs

Horses grazing or being fed tall fescue hay preparations may develop a condition termed *summer slump* or *summer syndrome*.[6,185] The disorder is characterized by anorexia, weight loss, poor hair quality, pyrexia, and hypersalivation. Additionally, mares may sustain a variety of pregnancy- and reproductive-related disorders. Typical findings include the presence of a thick, tough placenta, prolonged gestation, abortion, birth of dead or weak foals, and high perinatal foal mortality.[186] Mares frequently are affected also with agalactia, retained placenta, and rebreeding difficulties.[6,175,183]

20.5.1.6.2

Pathophysiology

The fungus produces multiple toxins, including peramines, lolines, and ergopeptine alkaloids. Peramines have no apparent effect on animal health, but the lolines (*N*-acetyl loline and *N*-formyl loline) present in *Neotyphodium* are pyrrolizidine alkaloids. However, the hepatotoxicity characteristic of pyrrolizidine alkaloids has not been observed with tall fescue toxicosis in any species.[184] 1493

1494

The ergopeptine alkaloids appear to be responsible for most of the abnormalities associated with fescue toxicosis. Ergotamine, ergosine, ergovaline, ergoine, ergocristine, ergocryptine, and ergocornine have been isolated, but ergovaline and ergosine are most prominent. Ergovaline is thought to account for 84% to 97% of the ergopeptine concentration of infected tall fescue. The concentration of ergot alkaloids in tall fescue tends to increase with nitrogen fertilization and drought stress, and toxicity varies from season to season and year to year depending on the percentage of endophyte present, drought stress, nitrogen fertilization, and probably other factors.[184]

Agalactia occurs for a variety of reasons. First, ergopeptines are dopamine D_2-receptor agonists, and dopamine is thought to be the major inhibitor of prolactin secretion in the body. Second, ergot alkaloids inhibit adrenocorticotropic hormone secretion, resulting in reduced fetal cortisol concentration that subsequently causes reduced progesterone secretion by the placenta. Third, these alkaloids decrease tissue binding of estradiol, which can lead to an elevated serum concentration of estradiol-17β[184] (normally, serum estradiol concentrations decline near parturition). The interaction of appropriate levels of prolactin, progesterone, and estradiol-17β plays a major role in preparing the mammary gland for lactation. The combination of reduced concentrations of prolactin and progesterone and elevated concentration of estradiol-17β likely is the major cause of the agalactia and impaired udder development in affected mares.

The gestation period may be prolonged because ergopeptines have been hypothesized to block corticotropin-releasing hormone activity in the foal, which results in a lack of fetal production of adrenocorticotropic hormone and cortisol. Because increased fetal cortisol concentration acts to signal the mare for parturition, lack of fetal production of corticotropin-releasing hormone, adrenocorticotropic hormone, and cortisol may contribute to extended gestation periods in affected mares.[184]

The placental abnormalities frequently noted have been suspected to be associated with vasoconstriction. Edema, fibrosis, and mucoid degeneration of arteries in placentae from affected mares have been observed.[185] These changes were thought to be consistent with anoxia, which was hypothesized to be associated with vasoconstriction. Ergovaline and *N*-acetyl loline, which are present in infected fescue, have vasoconstrictive properties.[184]

Ergot alkaloids also may have a negative effect on fertilized ovum implantation in the endometrium, resulting in reduced reproductive efficiency of affected mares. In the mare the effects of ergopeptines on implantation are inconclusive, but ergocryptine, ergocornine, ergosine, and ergovaline are capable of interrupting early pregnancy in the rat.[184]

Foals born alive to affected mares may be hypothyroid, although the mechanism responsible for this is unknown.[186] High perinatal foal mortality probably also is influenced by agalactia and poor colostral antibody production by the mare, resulting in failure of passive transfer with associated septicemia and failure of the foal to thrive.[184]

20.5.1.6.3 Diagnosis and Treatment

Diagnosis is often empiric, based on clinical signs and access to fescue pasture or hay during late gestation. Affected mares typically have reduced serum concentrations of prolactin and progesterone, and elevated levels of estradiol-17β. Reduced serum concentrations of triiodothyronine, adrenocorticotropic hormone, cortisol, and total progestogens may be present in affected foals. One also may evaluate hay and pasture samples for the presence of endophytes and ergovaline.[184]

Treatment of gravid mares past their foaling date should include removal from fescue as quickly as possible. Domperidone given orally once daily at 1.1 mg/kg during the last 15 days of gestation may be efficacious in helping establish udder development and lactation. One may give postfoaling mares domperidone (1.1 mg/kg orally) twice daily for several days to try to stimulate milk production.

Prevention requires removing mares from fescue pasture or hay during late gestation. In one study, fescue removed from the diet at 300 days of gestation was not associated with any problems in mares.[185] Thus the most critical time for exposure to infected fescue in pregnant mares seems to be during the last 30 days of pregnancy. One should consult local or regional authorities for current methods of managing infected pastures.

20.5.1.7 Hoary Alyssum *(Berteroa incana)*

Toxicosis in horses related to ingestion of hoary alyssum was first reported in 1992.[187,188] This plant is a member of the Cruciferae (mustard) family and can behave as an annual, biannual, or perennial. Hoary alyssum grows primarily in the northeastern and north central United States and Canada but also is reported in the states of Oklahoma, Washington, and California and in Europe. The plant tends to flourish under conditions of drought, frost, and overgrazing, and in areas of poor soil.[188,189] Toxicity has been reported in horses grazing contaminated pasture, eating plant-contaminated hay, and being fed oats containing hoary alyssum seed.[187–190] Reported cases are more prevalent during summer months after ingestion of recently cut hay, but toxicosis has occurred from feeding hay stored for 9 months.[188]

20.5.1.7.1 Clinical Signs

Not all horses exposed to hoary alyssum develop clinical signs of toxicosis. An estimated 45% of horses 1494
exposed to the plant under field conditions did not develop any signs of illness. However, the most 1495
common clinical signs observed under field and experimental conditions were varying degrees of fever,

edema of one to four limbs, and laminitis. Horses affected with laminitis rarely are reported to develop rotation of the distal phalanges. These signs typically commence within 24 hours of ingestion and in most cases subside within 2 to 4 days following removal of the source.[188] Other signs noted have been lethargy, short-term diarrhea, and abdominal discomfort.[189] Early parturition and abortion are rare occurrences in pregnant mares.[187,189] Rarely, individual horses are affected more severely and exhibit clinical signs of endotoxemia, hypovolemic shock, acute renal failure, and ventral rotation of the distal phalanges. Death can occur in these horses.[188,190]

Pregnant mares may be more susceptible to toxicity and develop more severe clinical signs, however. In one report, 23 of 29 broodmares developed signs of fever, tachycardia, tachypnea, distal limb edema, and mild to severe laminitis.[189] Fifteen of these mares subsequently developed moderate to profuse bloody diarrhea, dehydration, abdominal pain, hematuria, and oliguria. Four of these mares were euthanized, and two had necropsy findings of hemoperitoneum, hemothorax, and ventral rotation of distal phalanges. Three of the mares aborted spontaneously, but no abnormalities were noted in the placentae or fetuses.

20.5.1.7.2 Pathophysiology

The toxic agent in hoary alyssum remains unknown,[188] as does the mechanism of action of the toxic substance(s). However, red blood cell destruction appears to occur via hemolysis or some other mechanism.[188,189] No laboratory abnormalities have been noted in an experimental feeding trial and in most field cases.[188] However, laboratory findings in more severely affected horses include significant red blood cell hemolysis; elevations in serum concentrations of creatinine, urea nitrogen, phosphorus, alkaline phosphatase, aspartate transaminase, CK, sorbitol dehydrogenase, and total bilirubin; neutopenia; proteinuria; hematuria; hemoglobinuria; and occult blood in feces and gastric fluid.[188–190] Which of these abnormalities are the direct result of toxin and which result from physiologic deterioration of various organs is unknown.

20.5.1.7.3 Diagnosis and Treatment

One should suspect a diagnosis based on history of exposure to the plant and clinical signs. No specific therapy is indicated, but horses immediately should be denied access to the plant, and all contaminated hay and grain should be removed. One should initiate symptomatic treatment with fluids, nonsteroidal antiinflammatory medications, and gastrointestinal tract evacuation. Activated charcoal (1 to 3 g/kg administered via nasogastric tube) has been suggested to help prevent absorption of the toxin.[190] One should use intravenously administered DMSO with caution because it has potential to cause intravascular hemolysis, thereby compounding the red blood cell destruction caused by the toxin.[188,190] Most horses recover uneventfully in 2 to 4 days following removal of the plant and supportive care.

20.5.2 MEDICATION (IODINE)

Iodine toxicosis or iodism is a rarely reported cause of toxicosis in horses. When iodism occurs, it most likely is caused by iatrogenic administration of iodine-containing substances. Many rations contain iodine in the form of various iodized salts, and sodium iodide and potassium iodide, along with the organic iodide compound ethylenediamine dihydroiodide, are used to treat various medical conditions.[24,191]

20.5.2.1
Clinical Signs

Nonpruritic generalized alopecia and diffuse scaliness of the skin were reported in a horse given 45 g of ethylenediamine dihydroiodide twice daily for 14 days.[192] Other reported clinical signs include goiter following excessive iodine intake, increased secretions of the respiratory tract, nasal discharge, intermittent nonproductive cough, and excessive lacrimation.[15,24,192] Pregnant mares receiving excessive amounts of iodine may produce weak foals with enlarged thyroid glands. Such foals have a high mortality rate.[24]

20.5.2.2
Pathophysiology

Organic and inorganic forms of iodine are absorbed rapidly and almost completely from the gastrointestinal tract in the ionic form and are distributed throughout the body. Iodine is excreted primarily in the urine, but smaller amounts are present in feces, sweat, and milk.[15,191] The only known metabolic role of iodine is involvement in synthesis of the thyroid hormones thyroxine and triiodothyronine.[15]

Oral iodine salts, whether organic or inorganic, taken in higher doses stimulate nerve receptors in the stomach wall. Subsequently, the vagus nerve becomes stimulated and causes reflex secretion by cells in the upper respiratory tract.[15,193] Excessive iodine intake causes thyroidal organic iodine formation to increase to a maximal amount, and then a sharp decline in organic iodine formation occurs. Excessive iodine also inhibits release of organic iodine from the thyroid gland if the gland is stimulated by thyroid-stimulating hormone. The net results are clinical signs of increased amount and viscosity of respiratory tract secretions and occasional goiter development.[193] The mechanism underlying the development of the dermal lesions associated with iodism is unknown.[192]

20.5.2.3
Diagnosis and Treatment

Diagnosis of iodism is based on a history of exposure to high levels of iodine for a prolonged time coupled 1495
with compatible clinical signs of nasal discharge and excessive lacrimation, intermittent nonproductive 1496
cough, and nonpruritic generalized alopecia and scaling. One can measure serum iodine concentrations, which are elevated in cases of iodism, but blood levels decrease rapidly to near background levels within a few days if iodine exposure ceases.[15] Serum concentrations of thyroxine and triiodothyronine may be below normal values in affected horses.[192]

Treatment consists in removing the source of the iodine. Because iodine is mobilized rapidly and excreted from tissues, clinical signs usually subside rapidly when excessive iodine is removed.[15,191,192]

20.5.3
MISCELLANEOUS AGENTS

20.5.3.1
Snake Venom

The venomous snakes in North America belong to the families Crotalidae (pit vipers), Elapidae (cobra), and Viperidae (true vipers). Most poisonous snakebites reported in human beings are inflicted by members of the Crotalidae family, and the same is probably true for horses as well. Of this family, *Crotalus* (rattlesnakes),

Agkistrodon (copperhead, cottonmouth), and *Sistrurus* (pigmy rattlesnake, massasauga) are the three genera most commonly involved. The eastern coral snake *(Micrurus fulvius)* and the Arizona coral snake *(Micruroides euryxanthus)* are two members of the Elapidae family indigenous to the United States, but they account for only about 3% of poisonous bites reported in human beings.[6,7] No documentation of coral snakebite affecting horses could be found in the literature.

Venom injected into prey is an aid to digestion and greatly reduces the time for complete digestion to occur in the snake. The amount of venom injected at a given time is under voluntary control, and larger amounts are injected into larger prey or when the snake strikes for defensive purposes. Not all bites result in envenomation, and rattlesnakes are estimated to fail to inject venom in up to 20% of bites.[6,7]

Snake venom is a highly complex mixture of enzymes, lipids, biogenic amines, free amino acids, metal ions, proteins, and polypeptides. Most snake venoms contain up to 25 different fractions, yet many of them are not yet identified. Venom composition and toxic properties vary among *Crotalus* species and between individuals within the same species. Factors influencing venom composition include age, time from last feeding, and seasonal influences related to changes in feeding patterns or physiologic responses such as hibernation. The LD_{50} in mice exposed to venom of *Crotalus* species ranges from 0.23 mg/kg for the Mojave rattlesnake (*C. scutulatus*) to 3.77 mg/kg for the red diamond rattlesnake (*C. ruber ruber*). The LD_{50} for mice for the copperhead (*Agkistrodon contortrix*) and cottonmouth (*A. piscivorus*) is 10.92 mg/kg and 4.17 mg/kg, respectively.[7] This large variation in dose and chemical composition of venom accounts for the extreme amount of variation in the physiologic responses of animals to these substances.

20.5.3.1.1 Clinical Signs

Snake bites in horses are most common on or near the muzzle, but bites also may occur on the limbs or other parts of the body. The classic signs noted in most horses are acute onset of swelling and edema at the bite site. The muzzle and nasal passages may become swollen to the extent that respiration can become extremely labored, necessitating a tracheotomy. Epistaxis also may be apparent. Initially, one may note fang marks, but they soon disappear with the onset of extensive swelling. Skin discoloration at the injection site is a common occurrence with many rattlesnakes but rarely occurs with copperhead and Mojave rattlesnake bites.[6] Varying degrees of necrosis of local tissue may occur, as well as secondary bacterial infections at the wound site. In the author's experience, bites involving the distal extremities of horses frequently have a prolonged convalescent period that may be accompanied by residual lameness.

Systemic manifestations of snake envenomation may be apparent when venom is injected intravascularly or perivascularly. In a retrospective study of rattlesnake venom poisoning in 32 horses, manifestations included fever, tachycardia, tachypnea, caridac arrhythmia, hemolytic anemia, thrombocytopenia, hemorrhage, thrombosis of venipuncture sites, colic, diarrhea, and prehensile and masticatory dysfunction. Chronic problems included cardiac disease, pneumonia, laminitis, pharyngeal paralysis, and wound complications. The most common chronic problem observed in these horses was cardiac disease.[194] Labored respiration may result from pulmonary edema caused by passive congestion following vascular hypotension or precipitation of pulmonary emboli. Muscle fasciculation may be evident.[6] The venom of the Mojave rattlesnake produces respiratory paralysis that may result in death in human beings.[7] Overall mortality rate in 32 horses acutely affected with bites of prairie rattlesnake was 25%.[194]

The venom of coral snakes produces neurologic signs in affected human beings, with death occurring within 24 hours as a result of respiratory depression, hypotension, and cardiovascular collapse.[7] However, the coral snake requires prolonged contact (30 seconds or greater) to work the venom into the skin of its prey. Therefore for horses to become exposed to coral snake venom except under extremely unusual circumstances seems improbable.

20.5.3.1.2

Pathophysiology

1496

1497

The venoms of Crotalidae are rich in enzymes. Proteases cause severe tissue damage by digesting tissue proteins and peptides, and hyaluronidase allows rapid spread of venom through tissue by hydrolyzing connective tissue hyaluronic acid. l-Amino acid oxidase, l-arginine ester hydrolases, and 5′-nucleotidase also may contribute to tissue destruction. Phospholipases A, B, C, and D hydrolyze lipids and cause hemolysis by destroying lecithin in the red blood cell membranes. They also disrupt neurotransmission at the presynaptic and postsynaptic junctions. Other enzymes present in crotalid venom include ribonuclease, deoxyribonuclease, transaminase, phosphomonoesterase, phosphodiesterase, ATPase, DNAase, alkaline phosphatase, acid phosphatase, and endonuclease.[7]

Crotalid venom contains a number of polypeptides in addition to the enzymes. These polypeptides are low-molecular-weight proteins that are 5 to 20 times more lethal than crude venom in animal models, and they do not have enzymatic activity. They are present in higher concentrations in cobra venom than in rattlesnake venom and are mainly responsible for blood dyscrasias and coagulopathies. Small peptides are partly responsible for the generation of disseminated intravascular coagulation, and a venom fraction of the timber rattlesnake (*Crotalus horridus horridus)* causes platelet aggregation with resultant thrombocytopenia. Additionally, the venoms of the Mojave and Southern Pacific rattlesnakes contain a direct cardiotoxin.[7]

Rattlesnake venom contains substances with anticoagulant, procoagulant, and plasminogen-induced fibrinogenolytic properties. The coagulopathy that occurs in a given instance varies and depends on the content of the various venom components and on the dose of venom injected. The anticoagulant activity of crotalid venom appears to result from reversible binding of venom to prothrombin. Thrombinlike enzymes produce hypofibrinogenemia and increased concentration of fibrin degradation products. They are also capable of directly converting fibrinogen to fibrin, which may result in excessive fibrin formation and rapid disseminated intravascular coagulation. The fibrinolytic characteristics of crotalid venom occur directly or indirectly through the activation of endogenous plasminogen.[6,7]

20.5.3.1.3

Diagnosis and Treatment

Diagnosis of snakebite usually depends on clinical signs and accessibility to poisonous snakes. Laboratory abnormalities that may be present in affected horses include thrombocytopenia, hypofibrinogenemia, anemia, prolonged PT and PTT, hematuria, proteinuria, and myoglobinuria.[6,7]

Affected horses should be kept calm and quiet. Incision over the fang marks and suction are rarely indicated and probably of minimal value except in the immediate time frame of the bite, because the venom is absorbed almost immediately into the surrounding tissues. Tracheotomy is indicated in those horses that develop excessive edema and swelling of the head and external nares to the point that respiration becomes impaired. Topical cold therapy may have some beneficial effect if applied early and

for short periods. Prolonged or excessive cold application, however, may enhance further tissue necrosis. Antivenom therapy commonly is used in instances of human snakebite but often is considered unnecessary in horses because of the low mortality rate, financial considerations, and availability of other therapies. An exception may be the valuable animal or foals.

One should initiate tetanus prophylaxis and systemic antibiotic therapy. One should use broad-spectrum antimicrobials because gram-positive and gram-negative organisms are found in the mouth of North American pit vipers. The most common organisms isolated include *Proteus vulgaris, Escherichia coli, Corynebacterium, Streptococcus,* and Enterobacteriaceae.[7]

One should not use NSAIDs during the early stages of the bite wound because they may enhance the thrombocytopenia frequently induced by snake venom. One may use NSAIDs in the later stages of the disease to help reduce pain, swelling, and inflammation. One should use corticosteroids with caution because they may diminish the clearance of fibrin degradation products from the peripheral vasculature by the reticuloendothelial system, and they may increase susceptibility to wound infection at the site. Corticosteroids may be beneficial, however, in treating severe hypotensive shock in young animals or in patients with intravenous envenomation. Heparin therapy also has been suggested to be helpful in instances of thrombus formation.[6]

One should treat animals affected with systemic hypotension and cardiac dysrhythmias appropriately. Treatment may include the administration of intravenous fluids and plasma and the use of specific antiarrhythmic medications.

20.5.3.2 Fluoride

Fluoride toxicosis in horses is apparently an rare event.[195] Although acute and chronic fluoride toxicosis have been described in various animals, chronic fluorosis appears more common. Common sources of fluoride in chronic fluorosis include forages subjected to airborne contamination from nearby industrial plants such as aluminum smelters, steel mills, or fertilizer plants that heat fluorine-containing materials and discharge fluorides; drinking water containing excessive fluoride; feed supplements and vitamin and mineral additives with high fluoride concentration; and vegetation grown on soils containing high fluoride levels.[15]

Animals normally ingest small amounts of fluoride throughout their lives, and it accumulates in the body as
long as constant or increasing amounts are ingested. Chronic toxicosis can result from prolonged ingestion of 1497
sufficiently high levels. The long-term dietary tolerance for fluoride in the horse is reported to be 40 to 60 1498
ppm dietary fluoride.

Fluoride is absorbed almost totally from the gastrointestinal tract. Once absorbed, approximately half is excreted rapidly in urine, with the remaining half being stored in bone and teeth. Fluoride accumulates in calcified tissues, but once exposure ceases, bone fluoride is depleted slowly over months to years.

20.5.3.2.1 Clinical Signs

Chronic fluorosis in the horse is a rare event. In one suspected case the affected horse exhibited chronic weight loss of months' duration, poor growth, difficulty in mastication, and deformed, discolored, and absent deciduous incisors. The horse also was missing some deciduous premolars and molars.[195] Classic dental abnor-malities reported in other species include mottled, hypoplastic enamel and brown

discoloration with uneven wear of teeth.[15] Additional signs associated with chronic fluorosis in other animals include hyperostosis, enlargement and roughening of involved bones, intermittent lameness and generalized stiffness, dry and roughened hair coat, and decreased weight and milk production.[195] Because of the insidious nature of chronic fluorosis, one must remember that a time lag may occur between ingestion of excessive fluoride and the appearance of clinical signs.

20.5.3.2.2 Pathophysiology

Excessive fluoride produces dental abnormalities by affecting the teeth during development. The primary effect of fluorine is thought to be a delaying and alteration of normal mineralization of the preenamel, predentine, and precementum. High fluoride levels appear to cause specific ameloblastic and odontoblastic damage. The matrix laid down by these damaged cells fails to accept minerals normally, resulting in faulty mineralization of the tooth bud. Once the tooth is formed fully, the ameloblasts have lost their constructive ability and the enamel lesions cannot be repaired. However, odontoblasts can produce secondary dentine to compensate for deficiencies brought about by excessive fluoride.[15] The brown to black discoloration of affected teeth results from oxidation of organic material in the teeth.

The pathogenesis of bone lesions associated with fluoride toxicosis is still undecided. One theory is that high fluoride levels lead to inadequate matrix and defective, irregular mineralization of bone. Another theory is that hydroxyl radicals in the hydroxyapatite crystal structure are replaced by fluoride ions, resulting in a decrease in crystal lattice dimensions. The pathologic results of skeletal fluorosis include dissociation of normal sequences of osteogenesis, production of abnormal bone, accelerated remodeling of bone, and occasional accelerated bone resorption.[15]

20.5.3.2.3 Diagnosis and Treatment

Diagnosis of chronic fluorosis is based primarily on clinical findings and history of possible exposure to fluorides. One usually confirms fluorosis by analysis of skeletal or dental tissues for fluoride content and evaluation of fluoride concentration in urine. One also should analyze water and feed consumed by the animals for fluoride content.

Treatment of chronic fluorosis aims mainly at dietary restriction of fluoride-containing substances. Aluminum sulfate, aluminum chloride, calcium aluminate, calcium carbonate, and defluorinated phosphate have been used to reduce the toxic effects of fluoride, but no substance completely prevents the toxic effects of ingesting excessive amounts of fluorides.

20.5.3.3 Zinc

Zinc intoxication is a problem of young, growing horses. Sources of excessive zinc are usually soil and forage contamination from nearby smelters and following topdressing of pastures with zinc oxide.[196,197] Classic signs of zinc toxicity also have been produced by experimental feeding of excess zinc to young foals.[198,199] Skeletally mature horses do not appear to be susceptible to the effects of zinc-contaminated pastures.[199]

20.5.3.3.1 Clinical Signs

Typical signs associated with zinc toxicity include swelling at the physeal region of long bones, gradual onset of lameness and stiffness that may become so severe that affected animals are reluctant to rise from lateral recumbency, swollen joints resulting from synovial effusion, unthriftiness, and weight loss despite normal appetite.[196–198] Anemia also may develop in more chronically affected individuals.[198] The joint swellings in affected horses are typical of those of osteochondrosis desiccans, and severe generalized osteochondrosis also develops in zinc-intoxicated horses.[196,197,199]

20.5.3.3.2 Pathophysiology

Zinc toxicity in horses actually appears to be a manifestation of copper deficiency and the subsequent development of hypocupremic-induced articular cartilage disease.[196,199] Copper is an essential co-factor for lysyl oxidase, an enzyme involved in the formation of collagen cross-links. Copper deficiency interferes with collagen metabolism and results in production of weak connective tissue. This allows articular cartilage fractures and growth physeal fractures to occur in the zone of hypertrophic cells, producing the clinical syndrome of osteochondrosis desiccans.

The mechanism of zinc-induced copper deficiency is not understood totally. Experimentally intoxicated foals at necropsy had high hepatic copper content despite low serum copper concentration, suggesting that the hepatic copper was not readily available for production of ceruloplasmin or could not be mobilized rapidly enough for use by other tissues.[199] Excess zinc stimulates production of metallothionein, an
intestinal cell protein that binds to excess zinc, copper, and other divalent metal ions and facilitates their 1498
excretion in bile, feces, and saliva. Copper has a higher affinity for metallothionein than does zinc, and 1499
increased production of metallothionein, with subsequent binding to copper, may lead to copper deficiency via increased copper excretion.[200]

20.5.3.3.3 Diagnosis and Treatment

Once signs of osteochondrosis develop, one should treat the condition appropriately. Diagnosis of zinc toxicity may be difficult in that zinc is excreted rapidly following absorption, and blood and tissue zinc concentrations tend to decline quickly to normal levels with cessation of intake. One can measure liver, kidney, and serum zinc concentrations, but fecal samples collected from affected horses may be more suitable. One also can evaluate feed and water supplies for zinc content.[201]

Treatment of affected horses aims to restore proper copper concentration in the diet and to remove the source of excess zinc. Diets containing 7.7 mg copper per kilogram and 250 mg zinc per kilogram of dry weight were sufficient to maintain normal serum copper and zinc concentrations and did not induce disease in treated foals. Diets containing 1000 mg/kg or greater of zinc caused hypocupremia and subsequent osteochondrosis desiccans when fed to foals over a period of several weeks.[199] Osteochondrosis desiccans is treated surgically.

20.5.3.4
Selenium

Selenium toxicity in horses usually results from prolonged ingestion of plants containing excessive amounts of selenium. Intoxication can result from horses foraging on soil with high levels of selenium and from ingestion of selenium-accumulating plants growing on soils with minimal amounts of selenium.[201–204] Acute toxicosis also can occur through inadvertent overdose of selenium supplements added to rations or given by parenteral injection.[205] The acute single oral toxic dose of selenium given as sodium selenite lies between 3.3 and 6 mg/kg for the horse.[201,206]

20.5.3.4.1
Clinical Signs

Three different syndromes are attributed to selenium intoxication: acute toxicity and two chronic forms described as “blind staggers” and “alkali disease.” Signs of acute toxicity develop within 6 hours of ingestion and include sweating, diarrhea, tachycardia, tachypnea, mild pyrexia, lethargy, and mild to severe colic. Death may occur within 24 hours, and some horses exhibit a dumb attitude before death. Head pressing before death is suggested as a classic sign of acute selenosis.[201,206]

Chronic selenium intoxication described as blind staggers results from frequent ingestion of plants over weeks to months. Signs associated with this syndrome include aimless wandering or circling, muscle weakness, incoordination, respiratory difficulty, and decreased vision. In classic cases, blindness eventually develops and is followed by paralysis and death.[207]

Alkali disease also occurs from ingestion of plants, and signs may develop within 3 weeks. Initially, lameness and swelling of the coronary band regions are apparent, along with anorexia and mild depression. These signs progress to transverse cracking of the hoof wall distal to the coronary band with associated lameness. The hooves eventually may be sloughed. Loss of hair from the mane and tail occurs because the hairs become brittle and are broken easily. Compromised reproductive function also may develop in affected horses.[201–205]

20.5.3.4.2
Pathophysiology

Selenium is absorbed readily from the gastrointestinal tract, but organic forms of selenium generally are retained in greater amounts than are inorganic forms. Elimination occurs rapidly through urine, sweat, feces, and exhaled air. One also must recognize hoof and hair as routes of excretion because excess selenium is deposited in these structures.[205] This latter fact has important diagnostic implications.

The mechanism whereby excess selenium produces these signs is not elucidated fully. Selenium functions in a number of enzymatic and physiologic processes. The toxic effects of selenium have been associated with its affinity for reacting with sulfur-containing amino acid residues such as cystine that are incorporated synthetically into biologically active glycoproteins and polypeptides. As a result, various selenosulfides are formed as a substitute for disulfide bonds.[208]

20.5.3.4.3

Diagnosis and Treatment

One can make a presumptive diagnosis of selenium intoxication based on typical clinical signs and history of possible exposure to selenium iatrogenically in the form of selenium supplementation or via ingestion of appropriate plants. One can attempt to make a definitive diagnosis by assaying serum, hair, and hoof material for selenium content. In acute fatal selenosis, serum selenium concentration may exceed 1 ppm.[201,206] A selenium concentration greater than 5 ppm in hair and hoof wall can be considered diagnostic of selenosis.[201,202,204] One also can measure selenium concentration in liver and kidney samples.

Treatment of affected horses involves removing the selenium source and symptomatic treatment of lesions and good nursing care. Oral dosing of naphthalene at 4.5 g/day for 5 days, waiting 5 days, and then repeating the dose for an additional 5 days has been suggested for treatment of adult horses.[201,202] Prevention of selenosis has been attempted by adding copper,[205] methionine,[209] or sodium arsenite[201,202] to the diet of at-risk animals.

20.5.3.5

Magnesium

Magnesium is an important cation involved in the regulation of many enzyme systems. Magnesium is found primarily intracellularly, with only about 1% of the total body content circulating in the vascular space. Of
this amount, approximately two thirds is unbound in the ionized or active form and one third is bound to 1499
plasma proteins.[210] Magnesium is absorbed primarily from the small intestine, with little or no absorption 1500
occurring in the large intestine. Absorption begins rapidly within 1 hour of ingestion, and the amount absorbed depends on the quantity presented to the intestine, intestinal transit time, interactions with other minerals, and integrity of the intestinal mucosa.[211,212] The serum concentration and total body content of magnesium are regulated primarily by renal filtration.[210] Because of this, hypermagnesemia is difficult to maintain when renal function is normal.

20.5.3.5.1

Clinical Signs

Magnesium toxicosis has not been reported following consumption of natural feedstuffs and occurs only from excessive administration of commercial products. Acute magnesium toxicosis results in signs of impaired motor function in horses, and respiratory paralysis, cyanosis, and cardiac arrest also can occur.[213] One report describes the clinical findings of magnesium toxicosis as a complication in two horses given magnesium sulfate orally for treatment of intestinal impactions.[214] These horses exhibited signs of muscle tremors followed by recumbency. They appeared to maintain normal consciousness but exhibited flaccid paralysis of the neck and limb muscles. Both horses were tachypneic and tachycardic while recumbent, but heart and respiratory rates returned to normal following treatment. Serum magnesium concentration was elevated (14.7 mg/dl and 15.8 mg/dl) in the affected horses at the time of recumbency. Resolution of clinical signs was rapid (within minutes to hours) in both horses following treatment.

20.5.3.5.2

Pathophysiology

When an action potential arrives at a neuromuscular terminal (effecting depolarization), Ca^{2+} enters the presynaptic nerve terminal, causing exocytosis of acetylcholine into the synaptic cleft. Magnesium acts as

a neuromuscular blocking agent by inhibiting this Ca^{2+} influx into the presynaptic nerve terminal, thereby preventing the release of acetylcholine into the synaptic cleft.[215] High concentrations of magnesium also are reported to reduce motor end plate sensitivity and decrease muscle membrane excitability, which also also can result in neuromuscular paralysis.[216] The tachycardia and tachypnea noted in the aforementioned horses was thought to result from secondary reflex responses to hypotension because magnesium infusion capable of causing recumbency in normal horses does not change heart rate or rhythm.

20.5.3.5.3

Diagnosis and Treatment

One can suspect a diagnosis of magnesium toxicosis based on clinical signs and history of recent magnesium administration. One can determine the serum magnesium concentration to confirm the diagnosis. Calcium solutions given intravenously should result in rapid improvement of clinical signs, but additional calcium administration over the course of several hours may be necessary for complete resolution of clinical signs. When possible, one should monitor serum magnesium and calcium concentrations in affected horses and use the results to guide further therapy.

20.5.3.6

Gangrenous Ergotism *(Claviceps purpurea)*

Claviceps purpurea is a fungal parasite that invades the developing ovary of the grass flower and cereal grains. This fungus commonly parasitizes rye, oats, wheat, and Kentucky bluegrass, which are associated most often with outbreaks of gangrenous ergotism. The fungus replaces the seed ovary with a dark brown to purple oblong body called a sclerotium. Sclerotia are slightly larger than the original whole grain seed, and their growth is promoted by warm, moist conditions. Horses rarely are affected with this condition in part because of the distasteful nature of affected feedstuffs and because most fungal elements are removed during commercial grain processing procedures.[15,175]

20.5.3.6.1

Clinical Signs

Signs of intoxication may become apparent if infected feeds are ingested over several days to weeks. Dry gangrene of the extremities is the classic sign associated with *C. purpurea* toxicosis and can affect the limbs, nose, ears, and tail. Early signs of toxicosis are lameness and cool extremities. The hindlimbs often are affected first, with swelling and tenderness in the fetlock area. The involved tissues become dark and discolored and a transverse line of demarcation may occur between normal skin and the distal parts of the limb. Eventually, the hoof and associated bones and tissue may slough. This same sequence can involve the nose, ears, and tail. Gangrenous signs may be preceded by colic and constipation or diarrhea. Subacute effects can include depression, partial anorexia, general unthriftiness, and increased pulse and respiratory rates.[15,175]

20.5.3.6.2

Pathophysiology

The major toxic alkaloids in ergot are divided into three groups: ergotamine, ergotoxine, and ergometrine. They are absorbed slowly and incompletely from the gastrointestinal tract, reaching peak plasma concentrations in approximately 2 hours. The liver is the primary site of metabolism, and approximately 90% of metabolites are excreted in bile. Small amounts of unmetabolized alkaloids are excreted in urine.

The total concentration and proportions of alkaloids present in ergot sclerotia may vary with species and environmental conditions.[15,175]

Ergotamine and ergotoxine are polypeptide derivatives of lysergic acid. The varied physiologic effects of ergot are caused primarily by mixtures of levoisomers of ergotamine, coupled with smaller amounts of acetylcholine, histamine, and tyramine.[15]

Ergotamine is a vasoactive substance that causes arterial and venous constriction. Ergotamine also may
damage capillary endothelium. The combined effects of vasoconstriction and endothelial damage produce 1500
increased blood pressure, decreased blood flow through the extremities, vascular stasis, thrombosis, and 1501
eventually gangrene.[15,175]

The ergotoxine group of alkaloids produce α-adrenergic blockade and antagonize 5-hydroxytryptamine. This produces an increase in blood pressure as a result of peripheral vasoconstriction, particularly in postcapillary vessels.[15]

20.5.3.6.3 Diagnosis and Treatment

Tentative diagnosis of ergotism is based on clinical signs and exclusion of other disease processes. An experienced person can readily identify ergot sclerotia in grains. However, once grinding of feed has occurred, one can recognize ergot only by microscopic examination or chemical analysis for ergot alkaloids. One can identify and quantitate ergot alkaloids by chromatographic methods, and one should obtain a sample of the individual grain components for analysis whenever possible.[15]

No specific treatment exists for gangrenous ergotism. The offending grain should be removed, and affected animals should be kept warm to avoid cold-induced vasoconstriction in the extremities. Supportive therapy in the form of antibiotics and analgesics may be indicated. The use of anti–α-adrenergic pharmaceuticals to effect vasodilation also may be helpful. Such agents might include acepromazine, isoxsuprine, phenoxybenzamine, or similar products.[15,175]

20.6 Toxicoses Causing Signs Relating to the Urinary System

Detection of renal disease can be difficult, regardless of cause. Whereas nephrotoxicity associated with equine administration of medications is well established and usually recognized, that linked to ingestion of plants is less commonly detected and reaching a definitive diagnosis is harder. Although heavy metals like cadmium and mercury have long been known for their nephrotoxic effects, clinical signs are nonspecific and the diagnosis will be made only if the clinician performs diagnostic tests to specifically rule these problems in or out.

20.6.1 PLANTS

20.6.1.1 Oxalate Toxicosis

The most common source of oxalates for livestock is plants, particularly those of the Chenopodiaceae family. These plants contain varied amounts of soluble oxalates, usually in the form of sodium or potassium salts. However, because plants containing oxalates are generally unpalatable to horses, plant-associated oxalate intoxication is rare. The following plants contain large amounts of soluble oxalates:

Amaranthus spp.	Pigweed
Beta vulgaris	Beet, mangold
Chenopodium album	Lambsquarters
Halogeton glomeratus	Halogeton
Oxalis spp.	Wood sorrel, soursob
Portulaca oleracea	Purslane
Rheum rhaponticum	Rhubarb
Rumex spp.	Sorrel, dock
Salsola kali	Russian thistle
Sarcobatus vermiculatus	Black greasewood

Of these, *Halogeton* and *Sarcobatus* seem to be the primary offenders in range animals in the western United States.[15]

Because oxalates accumulate in the plants throughout the growing season, the incidence of toxicosis may be highest in the fall and winter months.[217] The oxalate content is highest in the leaves, with a lesser amount in seeds and a minimal amount present in the stems. The nonfatal toxic dosage of sodium oxalate for adult horses is approximately 200 g/day for 8 days.[15]

20.6.1.1.1 Clinical Signs

Affected horses may begin to show signs of depression, mild to moderate colic, muscular weakness, and irregular gait within 2 to 6 hours of ingestion. Weakness may proceed to lateral recumbency, unconsciousness, and death in 10 to 12 hours. Some animals may exhibit convulsions before succumbing.[15] The observed clinical signs of acute toxicity are typical of those of hypocalcemia.

20.6.1.1.2 Pathophysiology

Oxalates combine with serum calcium ions to form insoluble calcium oxalate. The result is a functional hypocalcemia in acute cases, with associated signs of altered behavior and neuromuscular abnormalities.

More chronic ingestion of oxalates can result in renal failure. Insoluble calcium oxalate crystals can lodge in the renal tubules, producing tubular blockage and necrosis. Oxalates also may crystallize in the vasculature and infiltrate blood vessel walls, producing necrosis and hemorrhage.[15]

20.6.1.1.3 Diagnosis and Treatment

In instances of acute toxicosis, consistent clinicopathologic abnormalities include moderate to significant hypocalcemia and varied electrolyte alterations. In chronic toxicity, urinalysis may reveal the presence of characteristic calcium oxalate crystals on microscopic examination. Impending renal failure also is characterized by increases in BUN and creatinine concentrations.[15]

Treatment is usually of little value once clinical signs have appeared. One can administer calcium gluconate intravenously, but it usually provides only temporary relief of signs. Balanced electrolyte solutions are indicated to aid diuresis, and diuretics also may have benefit in the volume-loaded patient. Prevention primarily aims keeping horses from the plants by means of providing adequate suitable sources of feed.[15]

20.6.1.2 Rayless Goldenrod *(Isocoma wrightii)*

Ingestion of rayless goldenrod may produce renal tubular nephrosis and signs of renal failure, but tremetol is 1501
the most significant toxin present in the plant.[83,218] For a detailed discussion of tremetol toxicity, see the 1502
discussion of white snakeroot toxicity.

20.6.1.3 Sorghum

Ingestion of *Sorghum* species and certain hybrid Sudan grasses has been associated with the development of an ataxia-cystitis syndrome.[219,220] The toxicity occurs when horses graze the plants. More cases occur when the plant is young and rapidly growing, but mature and second-growth plants also have been incriminated. Horses being fed well-cured *Sorghum* species hay have not developed signs of toxicity. Occurrence of toxicity may increase during seasons of medium to high rainfall, but no cases have been recognized following the date of the first frost. Signs of toxicity may develop following a grazing period of 1 week to several months.[219]

20.6.1.3.1 Clinical Signs

The primary clinical signs are those of posterior ataxia and urinary incontinence or cystitis. The neurologic signs usually develop first and begin as posterior ataxia and incoordination. Affected horses may sway from side to side if forced to move, and signs tend to worsen on backing the animal. Occasionally the rearquarters may drop almost to the ground, and flaccid paralysis of the tail and the rear legs may develop within 24 hours of the onset of neurologic signs. Affected horses remain alert and afebrile and have a normal appetite and pulse and respiratory rates. Mares frequently exhibit continual opening and closing of the vulva and relaxation of the perineal muscles. Males typically have a relaxed and extended penis.[219,220]

Urinary incontinence exhibited by continual urine dribbling is prominent in both sexes, and urine scalding on dependent skin becomes pronounced. The urinary bladder typically is distended and atonic, resulting in moderate to severe cystitis. Urethritis and ureteritis also may develop, and in horses that die from the disease, ascending pyelonephritis is usually the cause of death. Other clinical signs include abortion and birth of foals with multiple arthrogryposis.[219,220]

20.6.1.3.2 Pathophysiology

The clinical signs result from axonal degeneration and demyelination of nerve fibers in the spinal cord, particularly in the lumbar and sacral segments. The toxic substance in *Sorghum* species responsible for causing this change is unknown. Most *Sorghum* species are cyanogenic plants and contain various amounts of HCN. Exposure to multiple sublethal doses of HCN has been suggested to induce axonal degeneration and demyelination.[219] Another hypothesis is that sorghum plants contain lathrogenic

precursors and that this toxicosis may be caused by the ingestion of lathrogenic nitriles present in rapidly growing plants.[15,220]

20.6.1.3.3 Diagnosis and Treatment

Diagnosis of sorghum ataxia-cystitis is based primarily on approriate clinical signs, history of grazing the plants, and exclusion of other known causes of posterior ataxia or paresis. No specific diagnostic tests are available. Cystitis and pyelonephritis are diagnosed by standard laboratory methods.

No specific treatment is available. One should remove affected horses from the offending feed immediately. Once the feed is removed, affected horses usually show gradual improvement over several weeks to months, but complete recovery may not occur. Supportive and symptomatic therapy should include appropriate antibiotic treatment of bacterial urinary tract infections and topical treatment of urine scald dermatitis. Periodic manual decompression of the urinary bladder may be helpful. Catheterization and frequent aspiration of bladder contents may be necessary to aid resolution of cystitis.

20.6.2 MEDICATIONS

20.6.2.1 Aminoglycosides

The aminoglycoside antibiotics commonly are used because of their wide spectrum of bactericidal activity against gram-negative organisms. However, these drugs have significant toxic potential. Toxicity in horses is manifested almost exclusively by nephrotoxicosis, but eighth cranial nerve dysfunction, neuromuscular blockade, and direct myocardial depression have been described in other species, including human beings.[221]

The development of toxicity depends on a number of variables. Of the group, streptomycin is least nephrotoxic; neomycin is most nephrotoxic; and gentamicin, kanamycin, and amikacin are intermediate in their ability to cause renal damage. Because the aminglycosides are eliminated primarily by the kidney, any cause of reduced renal function can result in increased serum concentration of the drug and increased potential for nephrotoxicity. Other factors that enhance the toxic potential of these agents include acidosis, dehydration, hypovolemia, endotoxemia, increased dose or frequency of administration of the drug, and prolonged use of the drug. The concurrent use of other potentially nephrotoxic drugs, such as NSAIDs, also may predispose to aminoglycoside nephrotoxicity.[221–223] Although foals have not been shown to be more sensitive than adults to aminoglycoside nephrotoxicity, one should monitor closely use of these products in young animals that have potential for sepsis, hypotension, or dehydration.[224]

20.6.2.1.1 Clinical Signs

The clinical signs of aminoglycoside nephrotoxicity are those of acute renal failure. One may note anorexia and depression while the horse is being medicated or shortly after treatment has stopped. Most cases of acute renal failure caused by aminoglycoside toxicity are nonoliguric, and polyuria is a frequently reported clinical finding. Chapter 17.4 discusses the clinical signs of acute renal failure. 1502

20.6.2.1.2

Pathophysiology

The aminoglycosides are highly polar cations that are poorly lipid soluble but highly water soluble. They are absorbed minimally from the intestinal tract, but rapid absorption occurs from intramuscular and subcutaneous sites of injection.[225,226] Distribution is essentially to the extracellular fluid space in the body, and high concentrations of drug occur only in the renal cortex and the endolymph and perilymph of the inner ear.[226] Binding to plasma proteins is minimal, and excretion occurs almost entirely by glomerular filtration of unchanged drug.

A small portion of filtered aminoglycoside binds to phospholipid receptors on the brush border of cells of the proximal convoluted tubules and pars recta. Subsequently, the drug is reabsorbed, primarily by pinocytosis, and accumulates in lysosomes and other subcellular compartments of proximal tubular cells. This net reabsorption results in high concentrations of aminoglycoside within the renal cortex.[226,227] Concentrated aminoglycoside within the renal cortex forms a poorly exchangeable drug pool, with a renal tissue half-life of several hundred hours. This contrasts to the serum half-life of aminoglycosides, which is several hours. Therefore an aminoglycoside may be excreted slowly in urine for weeks after dosage is discontinued, even if serum levels are undetectable.

Eventually, proximal tubular cell damage and death occur. The mechanisms resulting in cell death are understood poorly, but several have been hypothesized: binding of aminoglycosides to plasma phospholipids, inducing alterations in plasma membrane structure and function; altered phospholipid accumulation and metabolism, resulting in impairment of lysosomal degradation and phagocytosis of cellular debris; activation of cellular phospholipases; damage to mitochondrial respiration, leading to reduced production of cellular ATP; and altered Na^+,K^+-ATPase activity. Although all of these actions may occur, which mechanism is primary still is unclear. The ultimate step leading to cell death may involve changes in subcellular calcium homeostasis, but the precise mechanism is unknown.[227]

In addition to proximal tubular dysfunction, aminoglycoside toxicity also results in a decreased glomerular filtration rate. Proposed mechanisms for this phenomenon include release of vasoactive hormones causing alterations in renal blood flow; damage to proximal tubular cells leading to backleak of fluid and waste products across the damaged epithelium; and obstruction of individual nephrons causing increased hydrostatic pressure within the tubular lumen with subsequent reduction in the net ultrafiltration pressure within the glomerular capillaries.[227] With aminoglycoside nephrotoxicity, acute severe tubular necrosis rarely occurs, and impaired renal function is almost always reversible because of the capacity of the proximal tubular cells to regenerate.[226]

20.6.2.1.3

Diagnosis and Treatment

Aminoglycoside nephrotoxicity initially is manifested by evidence of proteinuria, hematuria, cylindruria, polyuria, and enzymuria. Under experimental conditions, a rise in the urinary GGT ratio was the earliest detectable laboratory change noted with gentamicin toxicity and preceded increases in urinary protein and fractional excretion of phosphate by about 48 hours.[228] Proteinuria and cylindruria may be present 3 to 6 days after initiation of treatment and may precede elevations in serum creatinine and urea nitrogen concentrations by several days.[221,223] From a practical standpoint, monitoring urine for the presence of

protein appears to be a sensitive means of detecting early drug toxicosis. If aminoglycoside toxicity results in acute renal failure, other clinicopathologic findings compatible with acute renal failure will be evident.

Therapeutic drug monitoring has been shown to be an effective means of decreasing the incidence of aminoglycoside nephrotoxicity in human patients. Measuring serum peak and trough concentrations of aminoglycosides allows use of individual dosage regimens, particularly in the high-risk patient. In human patients and foals, elevated trough values have been associated with an increased incidence of nephrotoxicity[229,230] and are more predictable indicators of toxicity than are serum peak concentrations. In high-risk patients, one should monitor serum peak and trough concentrations frequently. In human beings, trough concentrations less than 2 μg/ml for gentamicin and tobramycin and less than 5 μg/ml for amikacin are desirable.[231] Optimal trough concentrations for the aminoglycosides in equine patients have not been established, but extrapolation from human values may provide useful guidelines. In the author's laboratory, trough concentrations of less than 1 μg/ml for gentamicin and tobramycin and less than 2.5 μg/ml for amikacin are considered desired values.

One usually treats aminoglycoside nephrotoxicity by drug dosage adjustment (with the aid of therapeutic drug monitoring) or drug withdrawal, fluid diuresis, and alkalinization of urine. In patients that require aminoglycoside therapy, increased dosage interval or reduced dosage may be necessary to minimize nephrotoxicity. Horses receiving moderate to large volumes of fluid therapy rarely develop nephrotoxicity and in fact usually have less than the expected serum concentration of aminoglycoside when given at recommended dosages.

Diet also may influence the nephrotoxic potential of gentamicin because horses fed oats had a greater degree of gentamicin-induced nephrotoxicosis than did horses fed only alfalfa.[232] Low dietary calcium, sodium, and potassium have been shown to potentiate gentamicin-induced nephrotoxicosis in laboratory animals, and high dietary calcium provided a protective effect against gentamicin-induced nephrotoxicity 1503
in rats.[233] The effect of increased dietary calcium, sodium, and potassium on the nephrotoxic potential of 1504
the aminoglycosides in horses warrants further study. Additional treatments suggested for aminoglycoside-induced nephrotoxicity have included peritoneal dialysis, plasmapheresis, and hemodialysis to reduce the serum concentration of these drugs.[224]

20.6.2.2 Amphotericin B

Amphotericin B is a polyene antibiotic used to treat systemic fungal diseases, including blastomycosis, coccidioidomycosis, histoplasmosis, candidiasis, sporotrichosis, mucormycosis, chromoblastomycosis, aspergillosis, and pithiosis. Its use in the horse rarely is reported, but horses with histoplasmosis and subcutaneous pithiosis have been treated successfully with the drug.[234,235] Amphotericin B is a known nephrotoxin, and therapeutic and toxic levels of the drug overlap.[231]

Clinical signs of toxicity reported in horses include depression, anorexia, weight loss, anemia (ranging from mild to severe), and fever.[234,235] One horse receiving treatment for an extended period also developed polyuria and polydipsia.[235] All clinical signs abated following cessation of therapy.

Amphotericin B causes distal tubular epithelial cell damage and renal ischemia. Tubular cell damage results from amphotericin B combining with sterols on the cholesterol-rich lysosomal membranes of the distal tubular cells. Direct injury to the cell membrane allows for increased cell permeability, leakage of cytosol, and cell death. Excessive potassium, bicarbonate, and water are lost into the urine, and hydrogen ions gain

entrance back into the epithelial cells. Hypokalemia and metabolic acidosis can develop and lead to death if renal disease is progressive.[236]

Renal vasoconstriction also plays a role in toxicity of amphotericin B. Significant afferent arteriolar vasoconstriction occurs by mechanisms not fully elucidated, but activation of the tubuloglomerular feedback system has been suggested as a possible cause.[231]

Diagnosis of toxicity is based largely on increasing concentration of BUN and abnormal urine findings of cylindruria, hematuria, and proteinuria. In human patients, an increase in BUN concentration greater than 40 to 50 mg/dl is cause for reduced dosage or temporary discontinuance of the drug.[237]

Treatment of toxicosis involves fluid diuresis and reduced dosage or temporary discontinuance of the drug until the BUN concentration reaches a normal value. Because nephrotoxicity caused by this drug is reversible, cessation of treatment results in return of renal function to almost normal levels. Additional therapies one may use include the concomitant use of mannitol and oral sodium loading in an attempt to decrease the occurrence of azotemia.[231]

20.6.2.3 Sulfonamides

The sulfonamides are a group of antimicrobial agents widely used in equine practice to treat gram-positive and gram-negative bacterial infections. Historically, they have been incriminated as a cause of renal dysfunction but now probably rarely are involved in nephrotoxicity.

The sulfonamides are poorly soluble in water but highly soluble in alkaline solutions. They are excreted via the kidney. The nephrotoxic potential of sulfonamides results from their precipitation into crystals in renal tubules, leading to obstruction and anuria or tubular epithelial necrosis. Crystal formation increases with increasing urine acidity and ultimately leads to acute renal failure.[15,231] Animals that are hypovolemic or have reduced renal function from other causes may be at greater risk of developing nephrotoxicity than other animals.

Diagnosis is based largely on signs of acute renal failure along with a history of drug use and presence of sulfonamide crystalluria. Treatment aims at fluid diuresis and concurrent urine alkalinization.[231]

The potentiated sulfonamides (trimethoprim-sulfonamide combinations) have much greater urine solubility and have not been incriminated as a cause of nephrotoxicity in horses. No documented adverse effects of these products in horses exist, but anecdotal reports have associated their use with acute onset diarrhea.[238] Drug withdrawal is usually sufficient therapy in such cases. In Great Britain, the concomitant use of intravenously administered trimethoprim-sulfadoxine with detomidine or halothane has been associated with severe cardiac dysrhythmias and sudden death in several horses.[239,240] One should avoid the simultaneous use of these products in horses if possible.

20.6.2.4 Vitamins D_2 and D_3

Horses are capable of meeting their requirement for vitamin D if they are exposed to sunlight or have access to sun-cured forages. Although dietary requirements for the horse have not been established, a maximum safe level of 44 IU/kg body mass per day has been proposed for long-term feeding (>60 days).[241] Most cases of

vitamin D intoxication are iatrogenic, resulting from overzealous use of vitamin supplements or from improperly formulated vitamin D–supplemented feeds. Ingestion of *Cestrum diurnum* (wild jasmine) also can result in vitamin D toxicosis because this plant contains a metabolically active glycoside of 1,25-dihydroxycholecalciferol (see Wild Jasmine *[Cestrum diurnum]*).

Vitamins D_2 (ergocalciferol) and D_3 (cholecalciferol) are potentially toxic, but vitamin D_3 is much more
active and results in more severe lesions with wider tissue distribution than does an equivalent dose of 1504
vitamin D_2.[242,243] Other variables that may affect toxicosis include duration of treatment and route of 1505
administration. High concentrations of dietary calcium also might enhance the effects of excessive amounts of vitamin D. The effect of vitamin D supplementation is cumulative, and signs of toxicity may occur weeks after supplementation has begun.

The clinical signs associated with vitamin D toxicosis are associated with impairment of the renal, cardiovascular, or musculoskeletal systems. Signs may include depression, anorexia, weakness, polyuria and polydipsia, cardiac murmurs and tachycardia, limb stiffness with impaired mobility, and recumbency. Calcification of tendons, ligaments, and other soft tissue structures may be palpable on physical examination.[242] Ultrasonographic examination of these structures also may demonstrate abnormal mineralization within the tissues.

The toxicity of excessive amounts of vitamin D_3 results from extensive dystrophic mineralization rather than from any inherent toxicity of vitamin D itself. Soft tissue sites most frequently affected include the kidneys, the endocardium and walls of large blood vessels, and tendons and ligaments.[242,243]

Laboratory findings associated with toxicosis can vary with the organ system affected, but generally include pronounced and persistent hyperphosphatemia and hypercalcemia, although the latter can vary daily. Serum calcium concentration may remain within a normal range in some horses. Other laboratory evidence of chronic renal failure may become evident with progression of toxicosis. One can make a definitive diagnosis by measuring serum concentrations of vitamins D_2 and D_3 and 1,25-dihydroxycholecalciferol.[243]

Treatment of vitamin D intoxication should include removal of all exogenous sources of vitamin D. A cation chelator such as sodium phytate may be helpful in reducing intestinal absorption of calcium, but the efficacy of this product has not been determined. One should use symptomatic therapy for renal insufficiency and failure, if necessary. Recovery may take months in less severely affected horses,[243] but treatment is usually unrewarding if excessive mineralization has occurred.

20.6.2.5 Menadione Sodium Bisulfite (Vitamin K_3)

Vitamin K_3 is a reported cause of acute renal failure in horses, but the product has been withdrawn from the United States market. When the product was given at the manufacturer's recommended dosage of 2.2 to 11 mg/kg intravenously or intramuscularly, signs of toxicity became evident within 6 to 48 hours following injection in affected horses.[244] Clinical signs included depression, anorexia, colic, hematuria, and stranguria. Azotemia, electrolyte abnormalities, proteinuria, and isosthenuria also were apparent. Pathologic lesions noted at necropsy were those of acute tubular necrosis. Interstitial fibrosis and chronic renal failure were also present in one horse.[244] Treatment of affected horses is symptomatic for acute or chronic renal failure.

20.6.3 MISCELLANEOUS AGENTS

20.6.3.1 Cadmium

Intoxication with cadmium rarely is reported in horses but has been seen in animals raised near smelting operations.[196] Environmental contamination of soil and forage by cadmium and zinc was the cause of excessive intake.

Affected horses exhibited signs of unthriftiness, lameness, and swollen joints. Some of these signs were attributed to excess zinc in the diet, but the horses also had pronounced osteoporosis and nephrocalcinosis, which along with proteinuria are typical findings of cadmium toxicosis in human beings.[196]

Serum concentrations of zinc and potassium were elevated in these horses, and the serum magnesium concentration was low in one foal. Sodium, calcium, chloride, and bicarbonate concentrations were also decreased. Extensive nephrocalcinosis was characterized by multifocal loss of cortical tubules, which were replaced by dense deposits of calcium phosphate crystals.

Cadmium induces change in proximal renal tubular cells by an unknown mechanism. However, increased numbers of lysosomes and mitochondrial swelling in the proximal tubular cells are early changes. Proteinuria is usually the first abnormality noted in human beings and laboratory animals. With continued chronic exposure, fibrosis and atrophy resulting from interstitial nephritis may ensue, leading to chronic renal failure.[245]

In human beings, treatment is essentially supportive, with elimination of exposure to cadmium being imperative. Research data suggest a possible beneficial role of zinc, vitamin B complex, and nickel preparations, but their clinical efficacy is unproven.[245]

20.6.3.2 Hemoglobin and Myoglobin

The endogenous substances hemoglobin and myoglobin can be a cause of acute renal failure in horses when they are present in serum in excessive amounts. Myoglobin nephrosis may occur following severe muscle damage such as extensive crushing or bruising injuries, large burns, heatstroke, or exertional rhabdomyolysis (tying-up). Excessive hemoglobinemia usually results from extensive intravascular hemolysis caused by acute hemolytic anemia, incompatible blood transfusions, or intravenous administration of certain medications, that is, hypotonic fluids and concentrated DMSO solutions. Possible causes of acute hemolytic anemia include *Babesia caballi* or *B. equi* infection, neonatal isoerythrolysis, phenothiazine toxicosis, onion 1505
(*Allium* species) toxicosis, and ingestion of withered red maple *(Acer rubrum)* leaves. Severe intravascular 1506
hemolysis also may occur with fulminant hepatic failure and with immune-mediated hemolytic anemia caused by antierythrocyte antibodies. Equine infectious anemia may cause intravascular hemolysis, but hemoglobinuria and pigment nephrosis rarely are associated with this disease.[222]

20.6.3.2.1 Clinical Signs

Clinical signs of pigment nephropathy are those of acute renal failure along with grossly discolored urine. Urine of affected horses is usually tinged red to brown, which can vary in intensity. Additionally, horses

with myoglobinuria would be expected to exhibit some degree of muscle soreness or inflammation or have a history of muscle trauma.

20.6.3.2.2

Pathophysiology

Excessive amounts of hemoglobin or myoglobin presented to the kidney result in tubular nephrosis by yet undetermined mechanisms. Hemoglobin casts are usually present within the renal tubules of affected horses and may induce ischemic injury to the tubular cells. Hemoglobin nephropathy also has been suggested to be caused by red blood cell stromal elements rather than by hemoglobin itself.[246] More recent studies in rats suggest that iron may play a significant role in the development of pigment nephropathy caused by hemoglobin or myoglobin. Iron liberated from the hemoglobin or myoglobin molecule can promote formation of oxygen free radicals, which then initiate lipid peroxidation and other reactions, leading to renal injury.[247] In these studies, hemoglobin-induced renal injury was attenuated greatly by deferoxamine, an iron chelator that binds ferric iron. Additional factors that may contribute to the development of pigment nephropathy include hypovolemia or dehydration, circulatory failure, endotoxemia, acidosis, and hypoxia.

20.6.3.2.3

Diagnosis and Treatment

The appearance of blood or hemoglobin in urine is not specific for pigment nephropathy, so other signs and laboratory findings are important for diagnosis. Hematuria, hemoglobinuria, and myoglobinuria result in a positive orthotoluidine reaction for occult blood on multitest dipsticks. However, hematuria is evident by the presence of intact red blood cells on microscopic examination of urine sediment, and anemia may be present if hematuria is of sufficient magnitude. With hemolysis the serum is usually discolored pink, and one can verify hemoglobinemia by routine laboratory methods. Anemia also may be present if hemolysis is severe. Elevated serum CK concentration is characteristic of rhabdomyolysis, and affected horses usually exhibit some degree of muscle soreness or have a history of muscle trauma. Myoglobin is poorly bound to plasma proteins and is filtered rapidly through the glomerulus. As a result the serum remains a normal color. Definitive tests for myoglobin in urine include electrophoresis or immunoassay techniques.[222,248]

Treatment of pigment nephropathy is essentially supportive and consistent with that of acute renal failure from other causes. One should identify any predisposing cause of excessive myoglobin or hemoglobin and remove it if possible. Compatible blood transfusions may be necessary in horses with severe hemolytic anemia, and one should treat horses with exertional rhabdomyolysis or other muscle injury accordingly.

20.6.3.3

Mercury

Mercury exists in a variety of organic and inorganic forms. Both forms can be toxic to horses, but more recently reported cases involve acute toxicity resulting from inorganic mercury-containing blistering agents topically applied to skin.[152,249] Ingestion of feed or seed grain contaminated with organic mercurial seed preservatives has been a source of contamination in previous years.

Acute and chronic forms of toxicosis can occur in horses. The acute toxic dose of inorganic mercury in adults is 5 to 10 g.[15] Experimentally, chronic toxicity from inorganic mercury has been produced by ingestion of

mercuric chloride 0.8 mg/kg/day over 14 weeks.[250] Chronic organic mercury toxicosis also has been produced experimentally by feeding methylmercury at 0.4 mg/kg/day for 10 weeks.[251]

20.6.3.3.1

Clinical Signs

Signs associated with toxicity of the various mercurial compounds can differ, but they all include some degree of renal dysfunction. Acute toxicity resulting from inorganic mercury can cause signs of acute renal failure, including oliguria and depression, and signs of gastrointestinal irritation. Ulcerative stomatitis, excessive salivation, colic, and diarrhea are common findings associated with gastrointestinal tract disturbances.[152,249] Chronic intoxication with inorganic mercury can result in signs of oral ulceration, reduced appetite and weight loss, alopecia, progressive respiratory difficulty, gradually increasing urine production, and terminal azotemia.[250] Signs reported with chronic organic mercury toxicity include development of neurologic dysfunction characterized by proprioceptive deficits, exudative dermatitis, reluctance to move, reduced appetite and weight loss, dullness, and renal changes exhibited by a steadily increasing BUN concentration and glucosuria.[251]

20.6.3.3.2

Pathophysiology

Inorganic mercury compounds are absorbed from the lungs and gastrointestinal tract and are absorbed poorly through the skin. Following ingestion and absorption, accumulation in the liver and particularly the kidney occurs. Some forms of organic mercury are degraded in the body to inorganic forms, which then also accumulate in the kidney before excretion.[15]

1506

1507

Inorganic mercury is concentrated to high levels within the proximal renal tubular cells. Metallothionein, a low-molecular-weight metal-binding protein is synthesized within 48 hours following exposure to heavy metals. This protein binds mercuric ions within the endoplasmic reticulum of the tubular epithelial cells and then slowly releases mercury. This slow release of sequestered mercury can cause continuing damage to tubular cells after the source of mercury is removed.[252] Hence the development of mercury nephropathy appears to be a function of the amount of protein-bound mercury concentrated in the renal tubules. Bound mercury can persist in the kidneys for several weeks following exposure.[250] Acute toxicity results in massive tubular necrosis and acute renal failure, and chronic exposure may cause renal interstitial fibrosis leading to chronic renal failure.

Methylmercury can be biotransformed in the body to inorganic mercury, but methylmercury also accumulates in the brain to a much greater extent than do other forms of mercury.[15] The exact mechanism whereby methyl- and other alkylmercurials damage the nervous system is not understood.[251]

At the cellular level, mercury combines with sulfhydryl groups within cells. As a result, sulfhydryl enzyme systems essential to cellular metabolism and respiration are inhibited, resulting in cell death.

20.6.3.3.3

Diagnosis and Treatment

One should suspect mercury intoxication when horses show compatible clinical signs and have a history of exposure. Laboratory abnormalities are similar to those of other causes of acute or chronic renal failure and irritative gastrointestinal diseases. Definitive diagnosis usually is based on measurement of mercury

concentrations in kidney and liver.[15] One also may submit stomach and intestine samples for analysis in more acute cases.

Treatment of mercury intoxication initially involves removal of the source. In acute toxicity, evacuation of the bowel with a mild laxative may be helpful. The oral administration of 500 g of activated charcoal might help block absorption of mercury, but its efficacy has not been demonstrated. Dimercaprol (used to inactivate circulating mercury) can be given at a dosage of 3 mg/kg intramuscularly every 4 hours for the first 2 days, 4 times on the third day, and twice daily for the next 10 days until recovery is complete.[152] One also should follow other principles of therapy for acute or chronic renal failure. Treatment of chronic mercury intoxication is usually unrewarding.

21 CHAPTER 21 VETERINARY EPIDEMIOLOGY

William J. Saville

Thomas E. Wittum

This book is not meant to be another epidemiology textbook, but rather a compilation of concepts applicable to veterinary epidemiology as it pertains to equine internal medicine and equine veterinary practice. A number of such textbooks already have been written, but none have reported application to the equine species. For those who want more in-depth epidemiology, the following are textbooks to which the authors have referred in the last several years and to develop this chapter:

Martin, S., Meek, A., Willeberg, P.: *Veterinary Epidemiology*, Ames, 1987, Iowa State University Press.

Petrie, A., Watson, P.: *Statistics for Veterinary and Animal Science*, Malden, Mass., 1999, Blackwell Science.

Rothman, K., Greenland, S.: *Modern Epidemiology*, ed. 2, Philadelphia, 1998, Lippincott Williams& Wilkins.

Sackett, D., Haynes, R., Guyatt, G., et al.: *Clinical Epidemiology: a Basic Science for Clinical Medicine*, Boston, 1985, Little, Brown and Company.

Schwabe, C.W.: *Epidemiology in Veterinary Practice*, Philadelphia, 1977, Lea & Febiger.

Susser, M.: *Causal Thinking in the Health Sciences: Concepts and Strategies of Epidemiology*, New York, 1973, Oxford University Press.

Thrusfield, M.: *Veterinary Epidemiology*, ed. 2, Malden, Mass., 1995, Blackwell Science.

Torrence, M.: *Understanding Epidemiology*, St. Louis, 1997, Mosby.

An understanding of the principles of epidemiology is invaluable to internists and veterinary practitioners for understanding outbreak investigation, diagnostic testing, study design, principles of statistical analysis, and interpretation of scientific and medical literature. Epidemiology provides the background to enable clinicians to understand better what they do intuitively daily and to recognize the importance of evidence-based medicine.

Epidemiologic principles were not applied routinely to investigation of disease outbreaks until the mid-1800s when John Snow, a physician in England, determined that cases of cholera in certain areas of London occurred in a geographic pattern defined by drinking water sources. He hypothesized that waste from two companies was the main source of the epidemic. To confirm his suspicions, he removed the pump handle from one water pump with a resultant dramatic reduction in morbidity and mortality from cholera in that area of London (“The Broad Street Pump”). Another investigator, William Farr, looked at the cholera outbreak statistically and determined an effect of elevation on disease.[1] These investigations are considered the beginning of the modern science of epidemiology.

The first thing to do is to establish a definition of epidemiology. Noted epidemiologist Wayne Martin defines *epidemiology* as “the study of the frequency, distribution, and determinants of health and disease in populations.”[2] Martin notes that this is the analog of the pathogenesis of disease in individuals. Veterinarians, whether in private practice or academia, are called on daily to act as epidemiologists. When a practitioner is asked to investigate a disease outbreak, regardless of the species involved, that practitioner is going to look for common signs and common management factors by groups in an attemptto understand the outbreak and determine a cause. Epidemiology attempts to incorporate science into outbreak investigation by calculating an odds ratio, relative risk, or some other measurement to quantify the effect ofthe disease and to find factors that increase or decrease the risk 1513
of disease. The practitioner uses these risk factors as guidelines to develop a prevention plan for the owner of the 1514
facility. The purpose of this chapter is to introduce the reader to epidemiologic concepts one may use in practice to help solve clinical problems and understand better the current veterinary literature.

21.1 Epidemiologic Concepts

21.1.1 DIAGNOSTIC TESTING

The cornerstone of epidemiology is diagnostic testing. To determine the prevalence or incidence of disease, an accurate diagnosis is essential. Several basic principles of diagnostic testing are necessary for understanding how to use these tests properly, whether one is applying diagnostic tests to individual animals or is screening large numbers of animals. Diagnostic testing originally was based on postmortem findings in which changes in tissues and evidence of bacteria, viruses or parasites led clinicians to a definitive diagnosis. However, development of antemortem tests to diagnose and successfully treat individual animals has been necessary. In addition, the screening of groups of animals to detect disease and design preventive programs has become increasingly important in veterinary medicine. Diagnostic tests that directly assess the presence of infectious organisms vary greatly in sensitivity and specificity. Even more problematic is the use of surrogate tests that assess indirect evidence of infection, such as presence of antibody responses. These indirect diagnostic tests are only as good as the gold standard to which they are compared.

One must calculate and validate test sensitivity and specificity by using the test in an appropriate population in which the true disease status of the population is known. Animals that are truly negative (nondiseased) test negative, and animals that are truly diseased test positive using the gold standard. Unfortunately, no tests are perfect, and false-negative (FN) and false-positive (FP) results occur with any test. The sensitivity of a test is defined as the proportion of truly diseased animalsthat test positive (TP) (TP/TP + FN) (Table 21-1). The specificity of a test is defined as the proportion of truly healthy animals that test negative (TN) (TN/TN + FP).

TABLE 21-1 Sensitivity and Specificity of a Diagnostic Test Are Determined by Comparing the Test to a Gold Standard

	GOLD STANDARD DISEASE +	GOLD STANDARD DISEASE –	
Test +	True positive	False positive	Total test +
Test –	False negative	True negative	Total test –
	Total diseased	Total nondiseased	Total population

Diagnostic test results may be quantitative or qualitative. Qualitative test results are reported as positive, suspect, or negative. Examples of qualitative tests include Western blot for *Sarcocystis neurona* antibody or immunofluorescent antibody testing for *Neospora caninum*. Quantitative test results are available for enzyme-linked immunosorbent assay (ELISA) tests and many others. The ELISA tests are based on an optical density reading, and determination of positive tests versus negative tests is based on a cutoff value of optical density. The sensitivity and specificity of an ELISA test is determined by the cutoff used by the laboratory to which the samples are submitted.

As stated before, to establish a sensitivity or specificity for a diagnostic test, the test must be compared with a gold standard diagnosis. The population used to validate these parameters also must be a population in which the prevalence of that particular disease or infection is known. Unfortunately, validation processes are not always reported in the peer-reviewed literature. An exception to this is the validation of the Directigen Flu A assay during epidemics of influenza virus infections at a Thoroughbred racetrack.[3] This assay was developed for rapid identification of influenza virus infections and may be used by veterinary practitioners in the field. The sensitivity was reported as 33% to 45%, and the specificity was 95% to 98% depending on the standard used.[3] In other words, samples from horses with influenza virus infections yield positive Directigen Flu A test results 33% to 45% of the time. Therefore during an outbreak, one must sample several horses to determine the cause of the outbreak, perhaps for control purposes.

The prevalence of a disease in a population has an influence on the predictive value of a diagnostic test. The positive predictive value (PPV) of a diagnostic test is the probability that an animal testing positive is truly diseased (TP/TP + FP) (see Table 21-1). The negative predictive value (NPV) of a diagnostic test is the probability that an animal testing negative is truly healthy (TN/TN + FN). As prevalence of a disease increases in a population, PPV increases and NPV decreases. Conversely, as prevalence decreases, PPV decreases and NPV increases. Predictive values essentially provide the clinician with a level of confidence that the animal is truly diseased or truly healthy. This depends on whether the clinician is attempting to rule in or rule out disease in the animal(s), also called the SPin and SNout rules as explained by Sackett, Haynes, Guyatt, et al. If the cost of a false-positive test is high, then one should use the test with the highest specificity to rule in disease. This test reduces the number of false positives and therefore increases the PPV of the test. In contrast, if the cost of a false-negative result is high, one should use the test with the highest sensitivity, reducing the number of false- 1514
negative tests and increasing the NPV, leading to accurate rule-out of disease.[4] Possible reasons for false- 1515
positive results with a given test vary with the test format but may include group cross-reactions, presence of nonspecific inhibitors in serum and nonspecific agglutinins. Group cross-reactions occur commonly. For example, antibody tests for tuberculosis frequently yield false-positive results because of antigenic relatedness of *Mycobacterium* spp. Animals are likely to be exposed to related, nonpathogenic organisms that are ubiquitous in the environment. When testing for influenza viruses using hemagglutination tests, nonspecific inhibitorsmay mimic the effects of antibody. Similarly, nonspecific agglutinins may mimic the effects of antibodies.[5]

Possible explanations for false-negative test results include natural or induced tolerance to an infectious agent, improper timing of sample collection, improper test, presence of nonspecific inhibitors, antibiotic-induced immunoglobulin suppression, incomplete blocking antibody, or tests that are insensitive.[5] Induced or natural tolerance may explain why some horses do not develop antibodies to *S. neurona* in their cerebral spinal fluid.[6] Improper timing may explain false-negative serum neutralization test results from horses acutely infected with West Nile virus.[7] Subsequent samples from such horses would be positive on the same test because sufficient time would have elapsed for development of detectable antibody responses. Selection of a serum neutralization

test for African swine fever in pigs would be inappropriate because pigs do not produce detectable levels of neutralizing antibodies. Nonspecific inhibitors are a frequent problem when hemolyzed blood samples are submitted.[5] An example of false negatives resulting from using an insensitive test is use of polymerase chain reaction of cerebral spinal fluid for diagnosis of equine protozoal myeloencephalitis (EPM).[8,9]

21.1.1.1 Qualitative Tests

The effect of prevalence on predictive values of a diagnostic test is illustrated using EPM as an example. A sensitivity and specificity of 89% each is used for the Western blot analysis as reported by Granstrom and colleagues.[10,11]

In a population of neurologically normal horses, where prevalence of EPM is low, PPV of the test (probability that a Western blot–positive horse is truly diseased) is actually less than 7% (Table 21-2). Therefore testing normal horses, for example, during prepurchase examinations, is contraindicated because this test is not a good screening test. Diagnostic tests are most useful where prevalence of disease is between 40% and 60%.[4] In a population of horses with spinal ataxia and normal radiographs of the cervical spine, the prevalence of EPM is approximately 50%. In this population of horses the Western blot has a PPV and NPV of approximately 90%; that is, an approximately 90% chance exists that the horse truly has EPM if the Western blot is positive and an approximately 90% chance exists that the horse does not have EPM if the test is negative (Table 21-3). In a population of horses with asymmetric neurologic signs, the prevalence of EPM is approximately 90%. In this population the PPV of the Western immunoblot test for antibodies to *S. neurona* is approximately 99% and the NPV is approximately 45% (Table 21-4). As the prevalence increased from 1% to 50% to 90% in the populations depicted in Figures 21-1 to 21-3, PPV increased from 7% to 89% to 99% and NPV decreased from 100% to 89% to 45%. In the case in which the horse has the classic clinical signs of EPM, many clinicians presently are confirming exposure to the organism and administering treatment without performing a cerebral spinal fluid collection. Instead, they are using response to therapy as a confirmation of the disease (diagnostic test). Two recent reports have used response to therapy as a diagnostic modality for EPM; however, one should be careful in interpretation.[12,13]

TABLE 21-2 Sensitivity, Specificity, and Predictive Values of Western Blot Analysis for Antibody to *Sarcocystis neurona* in Neurologically Normal Horses When the Prevalence of Disease Is Less Than 1%[12]

	DISEASE +	DISEASE −	TOTAL	PREDICTIVE VALUE*
Western blot +	9	109	118	PPV = 9/118 = 7.6%
Western blot –	1	881	882	NPV = 881/882 = 100%
Total	10	990	1000	

* *PPV,* Positive predictive value; *NPV,* negative predictive value.

TABLE 21-3 Sensitivity, Specificity, and Predictive Values of Western Blot Analysis for Antibody to *Sarcocystis neurona* in the Neurologically Abnormal Horse When the Prevalence of Disease Is Approximately 50%

	DISEASE +	DISEASE −	TOTAL	PREDICTIVE VALUE*
Western blot +	445	55	500	PPV = $^{445}/_{500}$ = 89%
Western blot –	55	445	500	NPV = $^{445}/_{500}$ = 89%
Total	500	500	1000	

* *PPV,* Positive predictive value; *NPV,* negative predictive value.

1515

TABLE 21-4 Sensitivity, Specificity, and Predictive Values of Western Blot Analysis for Antibody to *Sarcocystis neurona* in Horses With Asymmetric Neurologic Signs and Significant Muscle Atrophy*

	DISEASE +	DISEASE −	TOTAL	PREDICTIVE VALUE†
Western blot +	801	11	812	PPV = 801/812 = 99%
Western blot –	99	89	188	NPV = 89/188 = 47.3%
Total	900	100	1000	

* In this population the prevalence of equine protozoal myeloen-cephalitis is approximately 90%.

† *PPV,* Positive predictive value; *NPV,* negative predictive value.

One may improve the accuracy of diagnostic testing using series or parallel testing. Series testing attempts to prove that an animal is truly diseased by increasing the specificity and consequently PPV. Animals that test positive on an initial screening test are retested using a different diagnostic test. The prevalence of truly diseased animals in the population undergoing the second test is higher than in the population undergoing the first test. For example, consider a population of horses with clinical signs of hepatic disease and increased serum alkaline phosphatase and bilirubin concentrations. If serumγ-glutamyl transferase and bile acid concentrations were determined only on those animals, one would find more abnormal results than if one tested all horses (regardless of clinical signs). In contrast, parallel testing attempts to prove that an animal is truly healthy or to increase the sensitivity and NPV. One example of parallel testing is the recommendation for five negative fecal cultures to demonstrate that a horse is not shedding *Salmonella* spp.

21.1.1.2

Quantitative Tests

If data obtained from test results are reported on a continuous scale, determination of cutoff points for positive and negative results and adjustment of those cutoff points have a tremendous effect on sensitivity,

specificity, false negatives, and false positives. In any population of animals some individuals are classifiedas healthy and others are classified as diseased. These distinctions may not always be clear. For example, when one examines an antibody response in populations, some antibody-negative animals may be in early stages of disease but have not yet seroconverted and are classified incorrectly as healthy. Other animals may be misclassified because of laboratory error or a failure in the validation process. When one uses a continuous scale for the test result, such as ELISA tests, one must establish a cutoff point that will aid in the most accurate classification of healthy and diseased animals.

Figure 21-1 Graphic representation of healthy and diseased populations when the results are reported on a continuous scale. Scale increases along the *x*-axis.

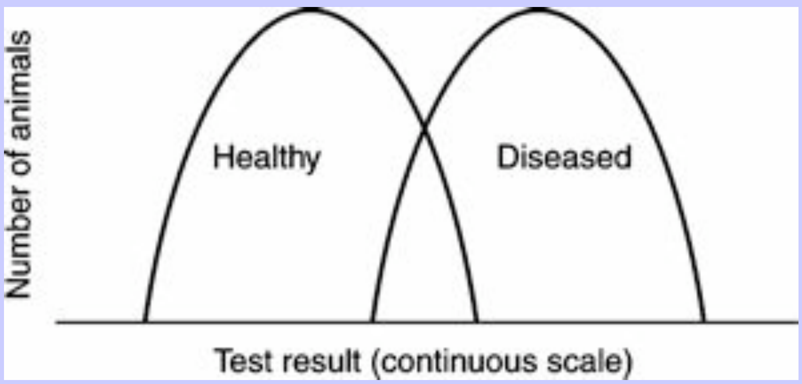

Figure 21-2 Graphic representation of test results on a continuous scale using three cutoff points: A, B, and C.

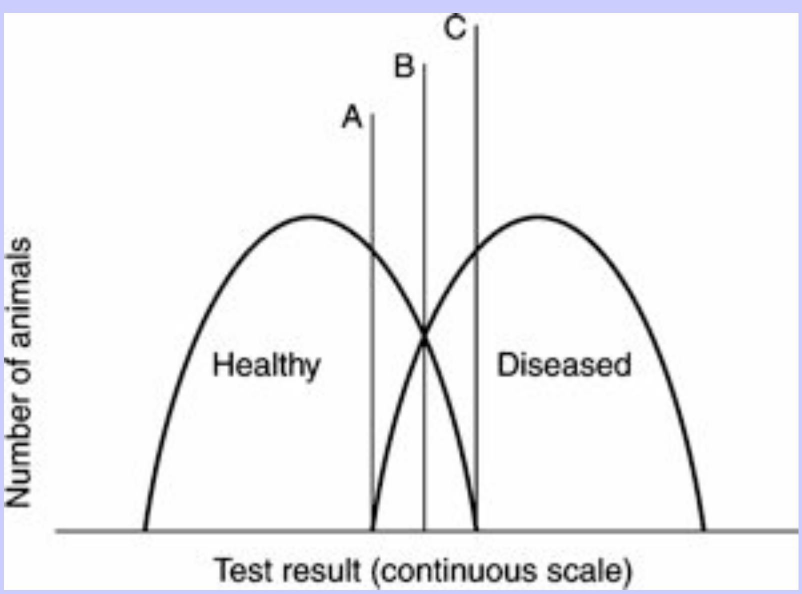
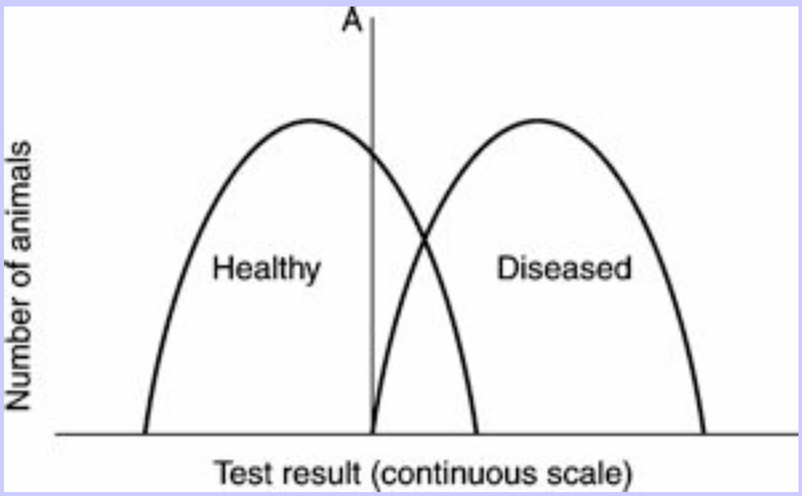


Figures 21-1 to 21-5 illustrate the changes that occur in sensitivity, specificity, false positives and false negatives when different cutoff points are used for a diagnostic test. Test results are reported on a continuous scale with increasing values depicted on the *x*-axis (see Figures 21-1 and 21-4). If the cutoff point is set at point A, the resulting test is highly sensitive (100%) and no false negatives occurred. However, specificity is low, and a large number of false-positive test results occurred (see Figure 21-2). This test would be useful as a screening test for a disease when the cost of a false negative is high.

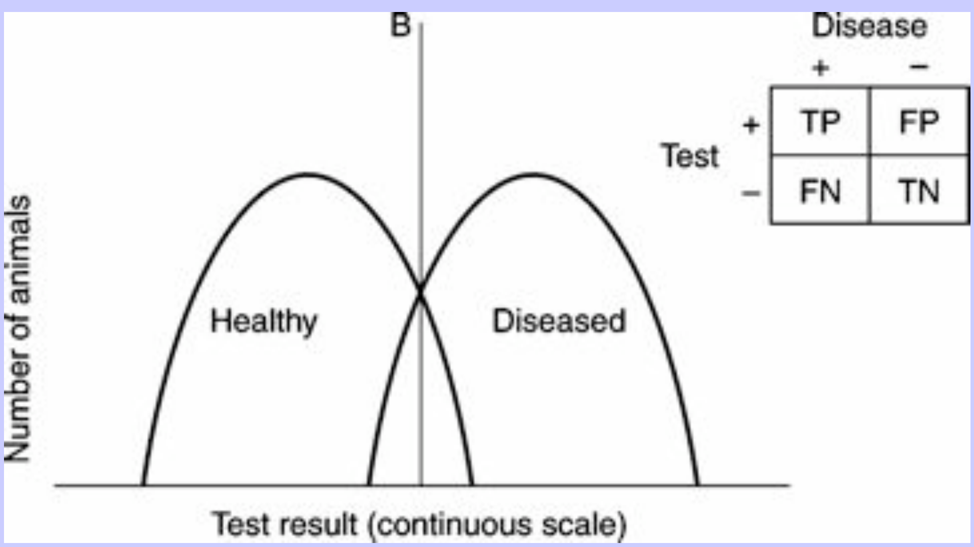
Figure 21-3 Graphic representation of test results on a continuous scale using the cutoff at point A.



1516

1517

Figure 21-4 Graphic representation of test results on a continuous scale using the cutoff point B.



If the cutoff is set at point B, the test would be equally sensitive and specific, and the number of false positives and false negatives would be equal. The usefulness of a particular test with these characteristics depends on the disease being studied. If the cutoff point is set at point C, the sensitivity is low, but specificity is high (100%) (see Figure 21-5). This test would be useful if the cost of a false positive is high. When tests are recorded on a continuous scale, specificity of a test increases as sensitivity decreases and vice versa. This confirms the importance of understanding how a test was developed, conditions under which it was studied, and the precision and validity of the test.

The sensitivity and specificity of a test generally are considered to be fixed for a given test. However, predictive values differ greatly depending on the prevalence of disease in the population tested. For example, one may elect not to test for a condition where the prevalence of the disease is low because interpreting a positive test result may be difficult. However, one may find it important to receive negative test results, and therefore in that instance the value of a negative confirms one's belief of nondiseased. As the prevalence of disease increases, so does the PPV. Conversely, as the prevalence decreases, the NPV increases. Figure 21-6 illustrates the relationship between prevalence and predictive values.

Figure 21-5 Graphic representation of test results on a continuous scale using the cutoff point C.

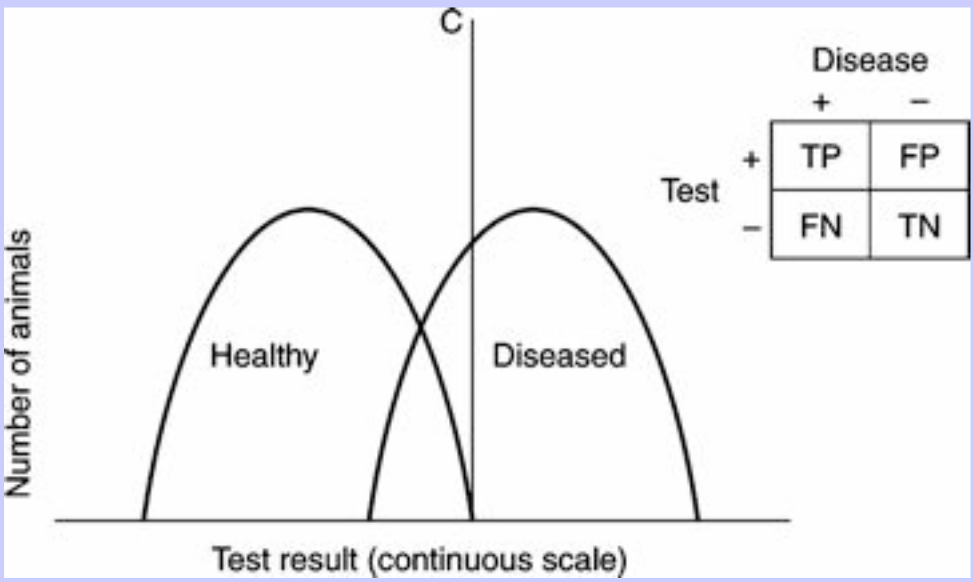


Figure 21-6 Graphic representation of the change in positive predictive value and negative predictive value as a concomitant change occurs in the prevalence of disease.

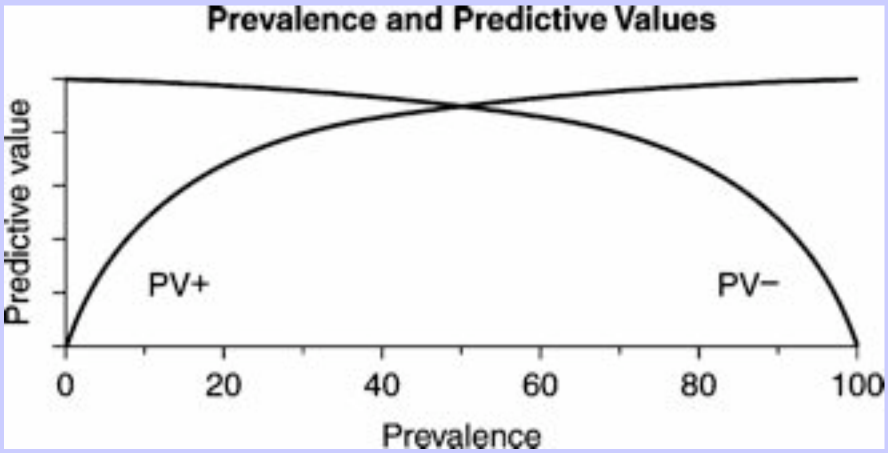


21.1.2 DATA COLLECTION

To measure the frequency and distribution of disease, one must collect data. Data are qualitative or quantitative. Qualitative data are often categoric; for example, breed of horse or gender. Categoric data may be nominal or ordinal. Nominal data assign a number to each data point, where each number represents a specific property of the data. For example, one may code gender as female = 1 and male = 2. Ordinal data use a specific term to describe members of a group that are related. For example, one might grade clinical disease as normal, mild, moderate, and severe. Quantitative data may be discrete or continuous. Discrete measurements must have a specified set of numbers such as whole numbers, often referred to as counts. Continuous data are measured data that may have any value within a defined range (interval or ratio). Examples of continuous data include prevalence, incidence, body weight, temperature, and antibody titer.

Terms used to define data one collects when studying a disease or syndrome include accuracy, refinement, precision, reliability, and validity. Accuracy is an indication of the extent to which the data conforms to the truth. The more refined the data are that describe the diseaseis referred to as refinement. *Precision* sometimes is used synonymously for refinement but more properly refers to the consistency of the measurements made in the study. Reliability usually refers to the repeatability of a measure when applied several times to the same animals. Validity suggests that the diagnostic test measures what it is purported to measure. These concepts are analogous to target shooting, in which validity refers to hitting the bull's-eye and reliability to the proximity of all shots on the intended target (the bull's-eye). 1517

1518

The objective of a study is to be able to collect unbiased data and report valid results. Bias is defined as a systematic error in the design, conduct, or analysis ofa study that leads to invalid results. Major biases onemust consider include confounding, interviewer bias, measurement bias, and selection bias. Confounding is the effect of an extraneous variable that may wholly or partially account for a spurious association between variables or can mask a real association. An example of a confounding variable is age, where exposure to an infectious organism is likely to be more common in older animals than young ones. Interviewer bias may result from

personal opinions of the interviewer altering the presentationof queries or statements to the experimental subjects. Measurement bias results from inaccurate measurements of disease, which may result in misclassification of animals into diseased or nondiseased groups. If the misclassification is differential (different for the diseased versusthe nondiseased), the bias will be severe. However, if the misclassification is nondifferential (equal between the groups), it will result in a reduction in the risk estimates. Lastly, selection bias results when study subjects are selected with different characteristics than subjects that are not selected. One can control many potential sources of bias in the experimental design. Randomization of study subjects is a primary method for reducing bias, along with matching and analysis. Unfortunately, matching on a particular characteristic results in an inability to examine the matching variable for a possible association with the outcome.

21.1.3 DESCRIPTIVE DATA

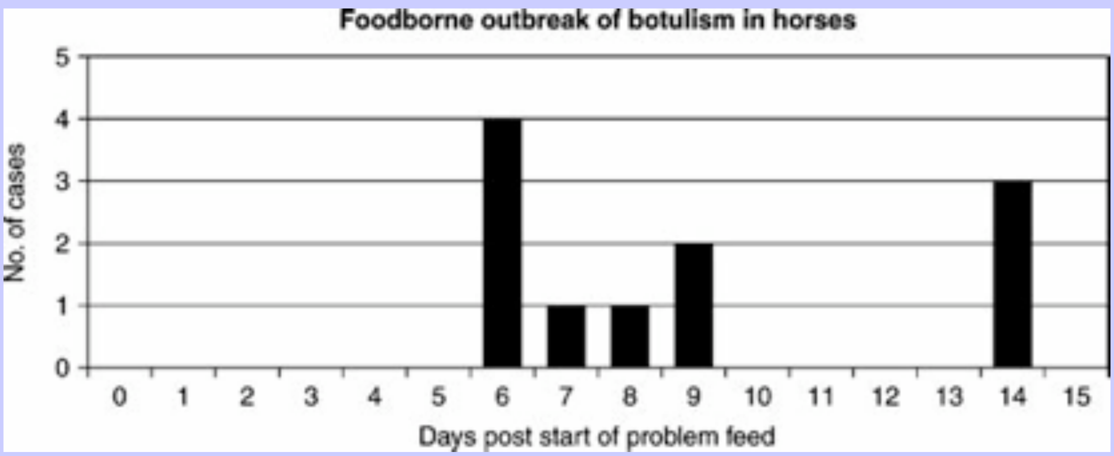
One may describe populations as contiguous or segregated. Examples of contiguous populations are wild horse herds on Bureau of Land Management land, the feral cat population in the United States, and wildlife populations. Enumeration of these populations and the occurrence of disease in these populations is difficult. In contrast, herds or flocks (segregated populations) are discrete groups that lend themselves to enumeration. Segregated populations may be closed or open, depending on the management style. Closed populations are less susceptible to introduction of infectious disease compared with open populations. Most horse populations are open because of frequent movement for showing, racing, or breeding. This movement makes for easy transfer of disease from population to population.

One measures disease in a number of different ways depending on the population and the basic factors known. For instance, prevalence is a measurement of the number of diseased animals at any given point in time without distinction between new and old cases. To calculate prevalence, the number of animals sampled on a particular day is the denominator and the number diseased or infected animals is the numerator. Prevalence is a proportion with a value between 0 and 1. One also may express prevalence as a number of the population at risk, for instance, per 10,000 animals. Prevalence estimates based on detection of antibody in populations are reasonably common. For example, a number of studies have examined the prevalence of serum antibodies to *Sarcocystis neurona* in horses.[14–18] Knowledge of prevalence rates for specific diseases are important for accurate interpretation of diagnostic tests, as discussed previously. One may calculate incidence only if the population at risk at the beginning of the study and the number of new casesthat occur over a specified period of time are known. One also may express incidence as a number of affected animals in a given population at risk, or as one study reported, in horse-years.[19] A recent study reported by the U.S. Department of Agriculture on EPM in the U.S. horse population determined the incidence of disease was 14 cases per 10,000 horses per year.[20] Morbidity data and mortality data often are expressed based on the time and place of occurrence of the disease. These expressions are referred to as temporal occurrence of disease, when timing of the disease is studied, or spatial occurrence of disease, when location of diseased animals is studied. Use of temporal and spatial cluster analysis is important in understanding pathogenesis of a disease and may provide important information to aid in prevention or development of disease.[21] Mortality data is similar to incidence data except the outcome is death rather than new cases. Case fatality rate is the number of deaths divided by the number of diseased animals. The complement of the fatality rate is survival; survival analysis is used commonly to assess the probability that an animal in a defined population will survive given a disease or other risk factors over a specified period of time.[22]

Descriptive measures such as rates, ratios, and proportions are often important tools for disease analysis. In a ratio the numerator is not a part of the denominator. A proportion is a ratio in which the numerator includes

animals that are in the denominator. Examples of proportions in epidemiology include prevalence, incidence, case fatality rate, and survival. Rates are a measure of a change in the numerator compared with the denominator, where time is incorporated into the denominator. These are used most commonly in epidemiology with incidence rates. One may express rates and proportions as crude, specific, or adjusted. For crude rates, onedoes not consider the structure of the population and possible confounding factors. One calculates specific rates for specific categories of host characteristics suchas age, breed, gender, or method of husbandry, providing more useful information than crude rates. To adjust for confounding variables and to compare rates in 1518
different populations, one may report adjusted rates. A common variable used to control or adjust for 1519
confounding is age.

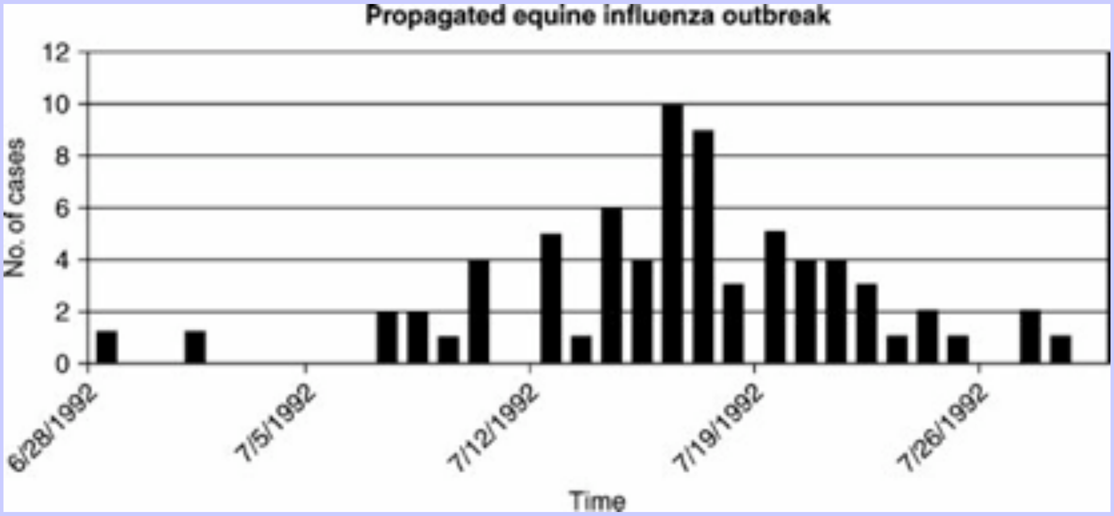
Figure 21-7 A graph depicting a common source outbreak of botulism in horses in England.



Another method of displaying descriptive data is through the use of tables, bar charts, and time trend graphs. Tables are used commonly to display numerical data. One may use bar charts for discrete data, and one may display continuous data in a similar manner using histograms.

One may use time trend graphs to plot epidemic curves. The two basic types of epidemics are common source and propagated epidemics. Point source or common source epidemics usually occur with some type of food poisoning such as occurred in horses affected with botulism after ingestion of contaminated oaten chaff.[23] The oaten chaff was distributed over many farms and fed at different intervals. Figure 21-7 illustrates the number of cases from four different premises feeding the same chaff. A propagated epidemic results from an index case with subsequent (secondary) cases developing in clusters. These secondary clusters occur after an interval determined by the incubation period of the infection. An excellent example of propagated epidemics in horses is the outbreak of influenza at a western Canadian racetrack (Figure 21-8).[24]

Figure 21-8 A propagated outbreak of equine influenza at a western Canadian racetrack.



21.1.4 DISEASE CAUSATION

Originally, early infectious disease researchers believed that each disease was associated with a single causative agent. Robert Koch proposed the one agent–one disease concept, and it remains useful in specific situations such as anthrax, rabies, and many others. However, application of Koch's postulates proved difficult in situations in which the causative agent was a necessary but not sufficient factor to cause disease. In those cases, induction of disease might depend on diverse variables such as the presence of co-factors or the susceptibility of the host.[25] Evan's postulates are more applicable to a broader range of situations[5]:

1. Proportion of animals with the disease should be higher in those exposed to the causal agent than in those not exposed. 1519
2. Exposure to the supposed cause should be present more commonly in the diseased compared with the nondiseased when all other factors remain constant. 1520
3. The number of new cases of disease should be significantly higher in those exposed compared with the nonexposed, as shown in prospective studies.
4. Temporally, the disease should follow exposure to the supposed cause with a distribution of incubation periods on a bell-shaped curve.
5. A spectrum of host responses, from mild to severe, should follow exposure to the supposed cause along a logical biologic gradient.
6. A measurable host response should appear regularly following exposure to the supposed cause and should not occur in animals not exposed.

7. Experimental reproduction of the disease should occur with greater frequency in animals appropriately exposed compared with those not exposed.

8. Elimination of the cause or modification of the cause should decrease the frequency of occurrence of the disease.

9. Prevention or modification of the host response should decrease or eliminate the disease that normally occurs on exposure.

10. All relationships and associations should be biologically and epidemiologically credible.

These postulates as put forward by Evans require that the association between a hypothesized causal factor and a disease be statistically significant; therefore the postulates require comparison between groups of animals.[5]

Two types of variables involved in the examination of disease causation are the explanatory variable (independent) and the response variable (dependent). The response variable is the variable affected by the explanatory variable. These variables may have statistical or nonstatistical associations. Nonstatistical associations are those that occur because of chance and that therefore cannot be considered causal. Not all statistical associations are causal. For example, an explanatory variable may be associated statistically with two response variables and be causal in both, but the two response variables also may be statistically associated and not be causal. Explanatory variables also may be causal directly or indirectly. Indirect causal associations occur with an intervening variable. An example is acquisition of rabies directly by human beings who enter a bat cave or indirectly through the bite of a rabid fox that inhabits bat caves. In this case the intervening variable is the fox acquiring the rabies because of cohabitation with the bats.[5]

21.1.5 CAUSAL MODELS

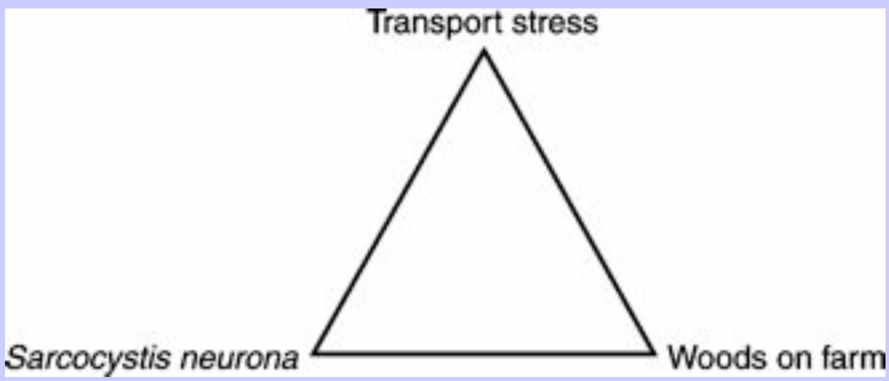
One may view indirect and direct causes in two causal models. Causal model 1 classifies causes into sufficient and necessary causes. Sufficient cause occurs if the cause produces an effect. In most cases several component causes make up a sufficient cause, consistent with a multifactorial model of disease as a function of host, agent, and environment (Figure 21-9). An example of this triad of disease is EPM of horses, in which *S. neurona* is the agent (Figure 21-10). Environmental factorsthat influence disease expression include stress such as transport of the host and a farm with woods on the property.

Figure 21-9 Graphic representation of the triad of disease: agent, host, and environment.

Many sufficient causes for a disease potentially exist. If a component cause is in every sufficient cause, that component is called a *necessary cause* (Figure 21-11). Figure 21-12 includes sufficient and necessary causesfor EPM. Equine protozoal myeloencephalitis has seven component causes, three sufficient causes, and one necessary cause, the parasites *S. neurona* and/or *Neospora hughesi* (see Figure 21-12). A disease may have many sufficient causes that include multiple component causes. Depending on the disease, it may have many sufficient causes, but not a necessary cause. An example of this is acute diarrhea of horses. The causes of diarrhea are many. However, if the diagnosis is salmonellosis, then the necessary cause is *Salmonella* spp.

In causal model 2, direct and indirect causes may occur in a chain of events leading to disease (a path model) (Figure 21-13). If multiple relationships occur with many factors acting at the same level and in more than one level, the result is a web of causation (Figure 21-14).

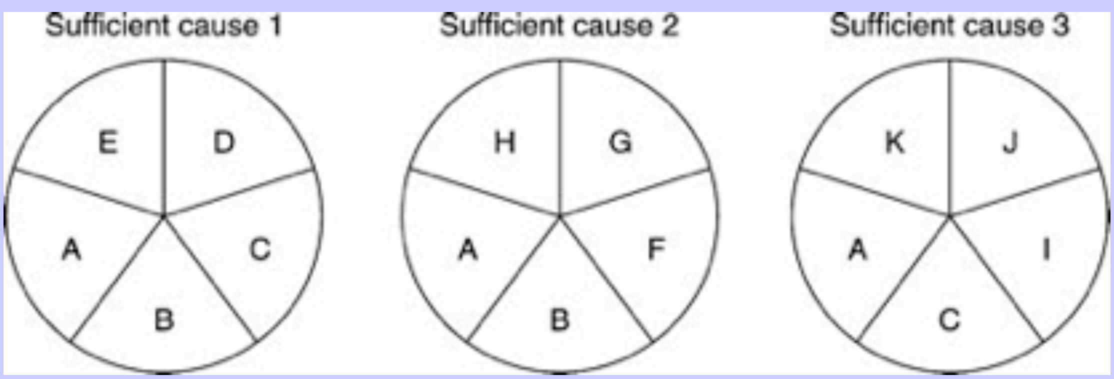
Figure 21-10 Equine protozoal myeloencephalitis as an example of the triad of disease.[26]



1520

1521

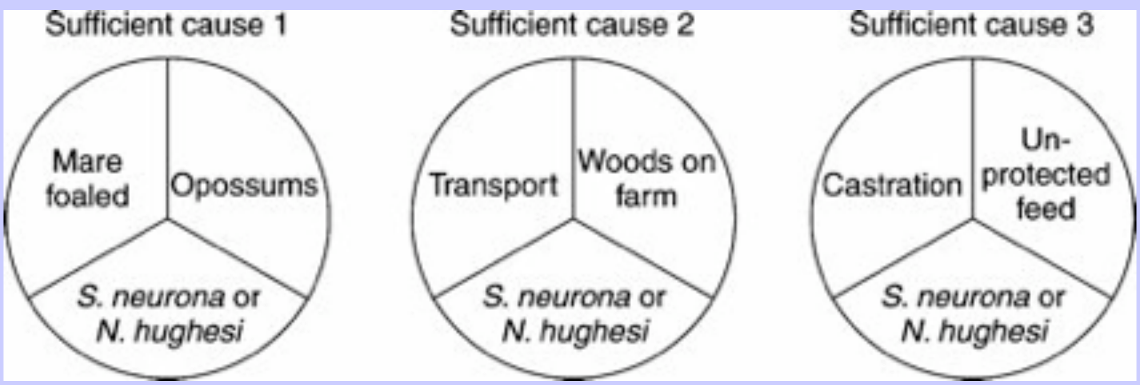
Figure 21-11 An example of sufficient causes of disease with 1 necessary cause *(A)*, 11 component causes, and 3 sufficient causes.[5,27]



21.2 Causal Hypothesis Generation

After collecting data, one generates descriptive statistics in relation to the time, place, and population under study. On completing the descriptive data, one may develop causal hypotheses. One generates hypotheses by one or more of four methods: method of difference, method of agreement, method of concomitant variation, and method of analogy. Method of difference refers to differences in disease frequency in two populations. Observation of a factor present in one population and not in the other suggests the factor may be causal. For example, in two groups of horses (exercised and unexercised) challenged with influenza virus, respiratory clinical scores were worse in the exercised group.[26] Therefore exercise may be deemed causal for the difference in clinical scores. Method of agreement refers to a factor present in several different populations in which a disease is also present, suggesting the factor may be causal. For example, several studies report that dietary factors may increase the likelihood of colic, suggesting these factors may be causal.[27–29] In the method of concomitant variation, the frequency or strength of a factor varies continuously with the frequency of the diseasein different situations. In one study, compared with horses that did not receive concentrate in their diet, as the quantity of concentrate increased, the risk for colic increased from 2.4 to 4.8 to 6.3 times.[29] An analogous situation is the increase in frequency of lung cancer in human beings with an increase in the number of cigarettes smoked daily. The method of analogy compares the pattern of disease being studied to the pattern ofa disease already understood. In a recent study of *Cryptosporidium* spp. infection in horses, the organism was suggested to become endemic on certain horse farms, similar to the observation on certain cattle farms in previous reports. Using the method of analogy to gather evidence of causation can be misleading; therefore the method is used most commonly to establish probabilities of causation.

Figure 21-12 Figures depicting three sufficient causes for equine protozoal myeloencephalitis.[26]



Sir Austin Bradford Hill proposed several criteria that one should consider before considering an associationof a factor and a disease causal.[30] These criteria include strength, consistency, specificity, temporality, biologic gradient, plausibility, coherence, experiment, and an analogy of the association. *Strength of association* refers to the increase in risk in one group compared with that of another group. For example, a tenfold increase in risk provides better evidence than a fivefold increase. One should not discount light increases in risk totally, however, because they may be important. Poor strength of the association may be caused by problems with numbers studied or study design and may need further examination. Hill's second criterion was *consistency of association*. Results 1521

of separate, similar studies should be consistent. Preferably these studies should be done at different places in 1522
different times and with different study designs (e.g., studies done retrospectively and prospectively). For example, the highest risk for EPM is in the fall of the year. This observation was corroborated by two separate studies.[20,31] Another example of consistency is in separate observations that dietary factors increase the risk for equine colic.[27–29] *Specificity of association* was the third criterion considered by Hill. This criterion may be difficult to meet in some circumstances because of multifactorial causes of some diseases. One example is the increased risk of EPM in horses if opossums are seen on the premises.[31] This finding was corroborated by a study by the National Animal Health Monitoring System of the U.S. Department of Agriculture.[20] The next criterion of importance is *temporality*, or exposure to the factor before disease. For example, horses must be exposed to *Sarcocystis neurona* or *N. hughesi* before development of neurologic signs of EPM. Demonstration of a *biologic gradient* or dose-response curve is strong evidence of causation. Compared with horses diagnosed with mild clinical signs of EPM, horses with moderate neurologic signs are 3.2 times more likely to die, and horses with severe clinical signs are 9.9 times more likely to die.[32] The biologic gradient is severity of neurologic signs. Whether biologic *plausibility* can be a steadfast criterion for association and causation is open for debate. A causal factor should be plausible; however, if the causal factor is new science never before reported or studied, it should not be refuted at least until it is repeated. Causal factors should cohere with known facts of the natural history and biology of the disease. *Experiment* is considered strong evidence for causation. If disease does not occur when a factor is removed, the evidence is strong that the factor is causal.[30] Hill's ninth criterion is that of *analogy*, in which studies that find similar conclusions offer some credence for causation. Hill's criteria for causal association are not meant as absolutes but should help guide conclusions as to cause and effect.

Figure 21-13 Path diagram for equine protozoal myeloencephalitis.[26]

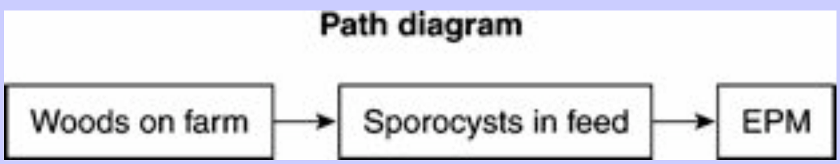


Figure 21-14 Web of causation for equine protozoal myeloencephalitis.[26]

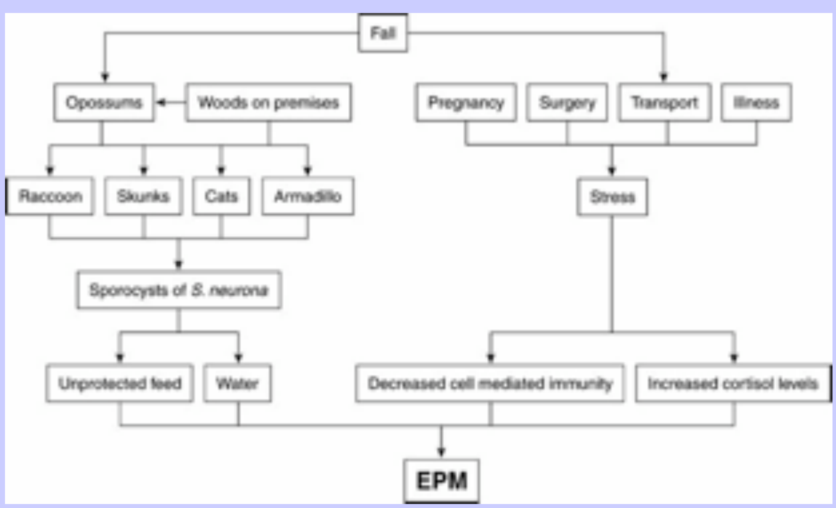

21.3 Measures of Association

21.3.1 HYPOTHESIS TESTING

One can approach association in two ways to establish causation: comparing means between two populationsor comparing proportions. Levels of significance are set based on probabilities that the differences between sample means or categoric variables would occur based on chance. Conventionally, the level of significance or α-value is set at P <0.05, meaning that the probability a finding would occur because of chance is less than 5%. The investigator may set a more conservative α-value such as 1% or 0.1%.

Statistical tests are established based on the hypothesis that no difference exists between the sample being
studied and the reference population, hence the *null hypothesis*. If the test of significance is less than the α- 1522
value established a priori, then the null hypothesis is rejected and the alternative hypothesis is accepted. 1523
Accepting the alternative hypothesis suggests that the sample population is different from the reference population. Two types of error are possible, type I and type II (Table 21-5). The type I error occurs when the null hypothesis is rejected when it is in fact true (i.e., detecting a difference when one is not present). Type I error is the same as the level of significance or alpha (α). Type II error (β) occurs when the null hypothesis is accepted when it is in fact false (i.e., failure to detect a difference when one exists). As the sample size of a study increases, α and β become smaller. In general, α and β are related inversely: as one increases, the other decreases. Type II error is related to the power of a study: 1 – β = Power. *Power* is defined as the probability of detecting a true difference (i.e., the probability of rejecting the null hypothesis when it is false). One should set α and β when designing the study, keeping in mind that each value has a direct influence on theother.

TABLE 21-5 The Four Possible Outcomes of a Study Depending on Whether Difference Is True and Whether the Study Finds a Significant Difference

		SITUATION IN THE REAL WORLD	
		No difference, H_0 true*	Difference, H_a true
Study results	No difference, H_0 true	Correct result	Type I error
	Difference, H_a true	Type I error	Correct result

* H_0, Null hypothesis; H_a, alternative hypothesis.

21.3.2 RELATIVE MEASURES OF ASSOCIATION

Relative risk is the ratio of the incidence of disease inthe exposed population to the incidence of disease in the unexposed population (Tables 21-6 and 21-7). If the relative risk is greater than 1, the association is predisposing; if the relative risk is equal to 1, no association exists; and if the relative risk is less than 1, the association is protective. One should use relative risk only in cohort studies in which the individuals are observed throughout the period of the study. Table 21-7 gives the formula for calculation of a relative risk. One can calculate the confidence interval for the relative risk estimate to help define the precision of the estimate, along with a test of significance. Confidence intervals that include 1 indicate no difference in the relative risk.

A variety of statistical software programs are available to perform these calculations; therefore explanation of the mathematic calculations of these values are not included in this chapter. Readers are referred to published references for illustrations of the use of relative risk in veterinary medical epidemiologic studies.[19,33]

TABLE 21-6 Evaluating Associations Between Exposures or Risk Factors and Disease

	DISEASE +	DISEASE −	TOTAL
Exposure +	a	b	Exposed: a + b
Exposure –	c	c	Unexposed: c + d
Total	Diseased: a + c	Nondiseased: b + d	Population: a + b + c + d

21.3.3 ODDS RATIO

The odds ratio is the ratio of the probability of anevent occurring to the probability of it not occurring (see Table 21-7). In a cohort study the odds ratio is the odds of disease in the exposed group versus the odds of disease in the unexposed group. In a case-control study the odds ratio is the odds of exposure in the diseased versus the odds of exposure in the nondiseased individuals. In cross-sectional studies, one may calculate a prevalence odds ratio using the same formula as in Table 21-7. As with the relative risk, one also may calculate a *P* value and confidence interval. Many examples of the use of odds ratios are in the veterinary literature.

21.3.4 ATTRIBUTABLE RISK

The attributable risk (risk difference or attributable rate) is the difference between the incidence of disease in the exposed population versus incidence in the unexposed population (see Table 21-7). In other words, the attributable risk is the extent to which the incidence of disease would be reduced had the individuals not been exposed to the factor. The attributable risk includes the baseline risk of the disease and therefore gives the 1523
magnitude of the effect of the causal factor in the population. Therefore the attributable risk is a better indicator 1524
of the effect of a preventive campaign when the factor is removed than is the relative risk. One must intrepret the attributable risk carefully because it measures the strength of association and demonstrates causality. Therefore demonstration of causation of a factor in the disease is important as well. A report on the adverse effects of antibiotic therapy in pneumonic foals includes an example of attributable risk calculations.[34]

TABLE 21-7 The Most Common Formulae Used to Calculate Measures of Association[*]

FORMULA NAME	FORMULA
Relative risk (RR)	RR = (a/a + b)/(c/c + d)
Odds ratio (OR)	OR = ad/bc
Attributable risk (AR)	AR = (a/a + b) – (c/c + d)
Population attributable risk (PAR)	PAR = (a + c)/n – (c/c + d)
Etiologic fraction (EF)	AF = (RR – 1)/RR
Population etiologic fraction (PAF)	PAF = [(RR – 1)/RR] × *f* (*f* = a/(a + c), the proportion of diseased individuals exposed.)

* The formulae are based on Table 21-6.

21.3.5 POPULATION ATTRIBUTABLE RISK

The population attributable risk is the difference between the total disease in the population and the disease in the unexposed individuals (see Table 21-7). This measurement indicates the amount of disease in the total population attributed to a particular risk factor. One can calculate this measurement only when one knows the disease morbidity for the total population. These population attributable risks have been calculated for cases of influenza at 3 outbreaks at a Western Canadian racetrack.[35]

21.3.6 ETIOLOGIC FRACTION (EXPOSED)

The etiologic fraction is the proportion of the incidence of disease in exposed animals attributable to exposure to a particular risk factor (see Table 21-7).

21.3.7 POPULATION ETIOLOGIC FRACTION

The population etiologic fraction is the proportion of the incidence of disease in the population attributable to exposure to the risk factor being studied. Therefore elimination of the risk factor should result in elimination of this proportion (see Table 21-7).

21.4 Study Design

Most research is designed as an experimental or an observational study. The one fundamental difference between the two is that in experimental studies the researcher can control the conditions of the experiment, whereas observational studies include no interventionby the researcher. Observational studies are basically observations and analyses of an event as it happened (prospectively) or after the fact (retrospectively).

21.4.1 EXPERIMENTAL STUDIES

One main advantage of experimental studies is the opportunity to randomize animals into treatment groups. Every animal has the same probability of being in the treatment or control group. Randomization of study subjects is one primary method to control for bias in a study. Randomization is also advantageous because one may study one variable at a time, allowing for more consistency because one can attribute the results entirelyto the exposure or treatment being studied. One of the most common types of experimental studies in veterinary medicine is the clinical trial.[26,36–38]

21.4.2 OBSERVATIONAL STUDIES

Many diseases cannot be studied in experiments because of considerations of ethics, time, or expense. An alternative is to study disease and exposure in the populations in which they are occurring by observation and analyses. Prospective or retrospective observational studies examine the effect of an exposure or the cause of a disease. These studies require a group that is exposed versus a group that is not, or a group that has the disease and a group with no disease. Advantages to observational studies include speed, ease of completion, and less expense. Because randomization is not possible, one uses other methods to attempt to control for extraneous factors.

Types of observational studies include natural, ecologic, case series or case reports, cross-sectional or surveys, prospective or cohort, and case-control or retrospective studies. *Natural experiments*, which rarely are documented, occur when an event in nature provides an opportunity to follow an exposure and its effect on animals, human beings, and the environment. An excellent example is the cholera epidemic in London in the 1850s. John Snow was able to determine that the causative agent was transmitted through the water. Ecologic studies examine exposure or an occupation and its effect on disease in communities, geographic regions, or during particular time periods. Because one does not collect the individual data, one can make no conclusions regarding the individual. Extrapolations made from the community to the individual are termed *ecologic fallacies*. This type of information is used to generate cancer registriesand state or federal databases. These studies frequently provide data in support of hypotheses for future analytic studies. *Case reports* or *case series* are descriptions of disease, whether a single clinical case or a series ofcases. These reports provide information on which to base epidemiologic studies. Numerous case reports and case series have been published in the veterinary literature.

Cross-sectional studies or *surveys* are observational studies that provide a snapshot of an exposure or disease at a particular point in time. These studies are easy to perform, often at minimal cost. One may conduct surveys using several methods: telephone interviews, face-to-face interviews, mailed or written questionnaires, self-administered questions, or by computer. The design, administration, and sampling strategies for questionnaires is critical. Sampling strategies include random, stratified, clustered, or multistage. Random sampling occurs when every animal in the population studied has the same opportunity to be included. Stratified sampling occurs when animals are sampled based on a particular characteristic, for example, age. Cluster sampling refers 1524
to sampling of groups of animals such as herds, pens, or barns. In some studies, multistage sampling occurs as 1525
the individual horse is sampled at one stage, the herd in the next stage, and then a county or a state in a third stage. Some examples of this type of survey study in veterinary medicine are those to determine exposure rates to *S. neurona*, the primary cause of EPM.[14–16] These survey studies originated from one county of a state,[14] a specific region,[15] and a specific state.[16]

Longitudinal studies include *prospective* or *cohort studies* and *case-control* or *retrospective studies*. Longitudinal studies follow exposures forward or backward in time and are designed to study risk factors and disease based on prestated hypotheses. Longitudinal studies are separated in design based on the factor being studied, exposure, or disease. Prospective or cohort studies are considered ideal. An exposure is known to have occurred in one study group, and the other group is known notto have been exposed. In cohort studies, one follows groups over time to determine if they develop disease. These studies may be time-consuming and expensive. A major advantage to cohort studies is the ability to establish incidence of disease with relative risk or attributable risk. In addition, one establishes temporality, assisting in confirmation of causation. One major disadvantage of a cohort study is the length of time necessary to confirm or deny development of disease in each group. During the time of study, individuals animals may be removed from the study or lost to follow-up. Tracking those individuals may be costly. Investigators may perform historical cohort studies if they can establish the true exposure status and development of disease.[19,29,33,39]

Lastly, *case-control* or *retrospective studies* can be completed quickly with limited expense. Initially, one must select cases based on disease, not exposure. One studies these cases retrospectively for exposures or risk factors of interest. One must select cases and controls carefully, and the criteria for selection should be the same for both. Sometimes investigators choose to use more than one set of controls for each case to increase the power of the study. For example, a recent study of EPM used one control group of horses with other neurologic diseases and another control group including horses with diseases of other organ systems.[31] Unfortunately, because these studies examine prevalent cases, one may calculate only an estimate of risk using an odds ratio. Reliance on retrospective information is a major disadvantage of these studies, particularly if data in clinical records are incomplete.

21.5 Sample Design and Size

21.5.1 SAMPLING DESIGN

A variety of sampling designs are used in epidemiologic studies. The best design is the *simple random sampling*, in which every individual in a population has an equal opportunity to be sampled. The selection of one individual has no influence on the selection of another, hence they are independent. *Stratified random sampling*, which is used commonly in the study of wildlife populations, randomly samples various strata or subpopulations, combining results to obtain overall population estimates. The aim is to have the sampling units in each strata as similar as possible and the means of the strata to be as different as possible. *Cluster sampling* commonly is used to examine herds or groups of animals. The clusters or herds to be sampled are selected randomly, and all unitsin each cluster are sampled. Unfortunately, with this technique the parameter estimates tend to be less precise than with random samples. Statistical methods are available to adjust for cluster sampling by inflating the variance. Cluster sampling can be extended to multistage sampling. In *multistage sampling* clusters are selected and the units of the selected clusters are sampled randomly. *Systematic sampling* is random selection of the first sample in the population and subsequent choosing of individuals at specific intervals thereafter. For example, the first sample may be the thirty-sixth unit in the population. One would sample every thirty-sixth unit after the initial unit until all necessary samples were collected from the population.[16]

21.5.2 SAMPLE SIZE

One should choose sample size to optimize the opportunity to detect meaningful differences between groups of study subjects without wasting resources. Unfortunately, sample size determination depends on some knowledge of likely end results of the study before conducting the study. Reliance on strict statistical calculations to determine sample size often leads to recommendations for inclusion of unrealistic numbers of animals. Sample size should be of sufficient magnitude that the study will detect statistical differences reliably if they are present. This concept is stated in terms of the *power* of the study. Most studies strive for a statistical power of 80% or higher. Appropriate sample size also is determined by the level of significance or α-level, most commonly set at 0.05. For optimal sample size calculations the investigators also must designate a minimal difference between the two populations that the study is required to detect. The standard deviation of the observations in each group must be known or estimated. This information often is estimated based on results of previous studies of the investigators or results in published literature. Alternatively, one may perform a pilot study to obtain preliminary results that will provide an estimate of population variance. After one has determined power, significance, difference to be detected, and population variance, one may use Altman's nomogram to determine the optimal sample size.[40] A variety of statistical programs are available to assist in these calculations if Altman's nomogram is not available. 1525

1526

21.6 Basic Statistical Concepts

After collecting the raw data, one calculates descriptive statistics to determine measures of position (mean, median) and measures of spread (standard deviation, standard error, range) of the population. One graphs data (frequency distributions or histograms) to observe the distribution and compare it with the normal bell-shaped curve. One determines the sample mean and uses it to provide an estimate of the population mean. The larger the sample size, the closer to the true mean of the population the sample mean becomes. The median isthe value that half of the observations are below and the other half are above (the 50th percentile). One also may divide the data into quartiles (25th, 50th, and 75th percentiles).

After determining measures of position, one calculates measures of spread, which include the range, variance, and the standard deviation of the sample. These measures are estimates of the population variance and standard deviation. Another measure of spread sometimes usedis the semiinterquartile range, the 25th to the 75th percentiles. One determines distribution of the sample mean by calculating the standard error of the mean (SEM), which is the square root of the variance of the sample means. One estimates the standard error of the sample means by using the standard deviation divided by the square root of n, the number of samples. This calculation provides an estimate of the precision of the sample mean as an estimate of the population mean. The smaller the standard error, the greater the precision. Often one calculates a confidence interval to provide a range in which the true population mean will lie, most commonly a 95% confidence interval. The formula to calculate a 95% confidence interval is as follows: mean ± 1.96 × SEM. The lower and upper values of the confidence interval are termed the *confidence limits*. One may calculate confidence intervals for numerous estimates, but formulae for calculations may change. The reader should consult epidemiology texts for these formulae.

21.6.1 STATISTICAL DISTRIBUTIONS

Before detailed statistical analysis, one must examine the data to determine whether they are distributed normally. This normal or gaussian distribution is a bell-shaped curve in which 68% of the observations should lie within 1 standard deviation of the mean and 95% should fall within 2 standard deviations. This distribution

may be appropriate for many biologic variables but may not be appropriate for ordinal or nominal data, unless the sample size is large. The distribution determines the types of statistical tests one may apply. When only two outcomes are possible where discrete data are involved, the data has a binomial distribution. For example, horse gender at birth is male or female. Another expression for the outcome of a binomial distribution could be success or failure. One applies a Poisson distribution to counts that occur randomly in space and time. Therefore the distribution describes spatial and temporal distribution of disease, an example of which could be the distribution of blood cells in a hemocytometer. Sometimes these distributions may be skewed one way or the other, or the shape of the curve may be too thin or too wide. In those circumstances, one may transform data using logarithms or some other mathematic transformation, a process done in veterinary medical studies dealing with measurements such as antibody titers. Where the sample size is large, binomial and Poisson distributions approximate normal distributions.

21.6.2 STATISTICAL TESTS

Statistical tests are chosen based on the type of samples collected. Independence of the samples is important in determining the type of test to use. If the samples are not independent (for example, repeated samples from the same animals), then one must use statistical tests to account for these repeated observations. Statistical tests may be called parametric or nonparametric. *Parametric tests* are used for analysis of normally distributed data when the variables are on the continuous scale (interval or ratio data). Some tests may require equal variance for the two populations being studied. Parametric tests are based on the use of the mean, a parameter of the normal distribution. An example of such a test for comparison of continuous data from two populations is the Student's *t*-test. One uses *nonparametric tests* with nominal, ordinal, interval, and ratio data in which the distribution of the data is not normal but the data do assume symmetry. Nonparametric tests are less robust than parametric tests and require larger sample sizes to detect differences. Examples of nonparametric tests include the Wilcoxon signed rank test, Wilcoxon-Mann-Whitney *U* test, Kruskal-Wallis one-way analysis of variance, and Spearman rank-order correlation coefficient.

When one compares proportions or nominal data, as occurs with many observational studies, one uses the chi-square test of association. The chi-square is performed routinely using a 2 × 2 contingency table, but one may use tables with many rows and columns. If sample size is small and some cells in the 2 × 2 contingency table equal less than 5, one should use a Fisher exact test. When samples are related or one is examining matched samples, one may calculate the chi-square using the McNemar change test of discordant pairs.

Another test used commonly to compare two variables is a correlation. In this measure of association, graphic 1526
presentation of data places the independent variable on the *x*-axis and the dependent variable on the *y*-axis. If 1527
the combination of pairs leads to a line from the bottom left of the graph to the top right, the association is positive. Conversely, if the line generated is from the top left to the bottom right, the association is negative. If no association exists, the data will be scattered all over the graph. One may use this procedure in normally distributed data, whether continuous or discrete. One can calculate a sample correlation coefficient *(r)* with most statistical software. If data is not normally distributed, nonparametric statistical tests such as Spearman's rank correlation are recommended.

21.6.3 MULTIVARIABLE ANALYSIS

One uses multivariate or multivariable analysis to examine the relationship between many independent variables and a dependent variable. One should decide to use a particular method before initiating the study. This decision comes after one has formulated the hypotheses, which are predicated on the type of data

generatedand the objectives to be accomplished. Statistical methods used to perform this type of analysis include survival analysis, linear regression, and logistic regression.

Multiple linear regression is recommended when more than one explanatory or independent variable is regressed on a continuous predictor or outcome or dependent variable. The primary assumption is that the dependent variable is distributed normally. Another assumption is that the independent variables are measured without error but are not necessarily required to be continuous. The primary reason to use multivariate regression isto examine the effect of one explanatory variable on the dependent variable while controlling for the effect of the other explanatory variables in the equation. The number of explanatory variables used in an analysis should not be excessively large. As a rule of thumb, the sample size should be at least 10 times the number of explanatory variables.

When the dependent or outcome variable has a binary outcome (yes or no), multiple logistic regression is recommended. Because the outcome is 0 or 1, one cannot interpret any values that are not exactly 0 or 1. Therefore one considers the probability that the dependent value takes a value of 0 or 1 and transforms this probability using logistic transformation to overcome this inability to interpret values other than 0 or 1. Hence the name logistic regression. Because of the logistic transformation, the model produces the odds of the outcome with a 1 unit increase in the explanatory variable whileall other explanatory variables are held constant. The logistic coefficients are determined by an iterative method called maximum likelihood. Examination of one explanatory variable on the outcome is explained while controlling for the effects of the other explanatory variables.

Survival analysis examines the length of time to a critical event such as death and often is used to evaluate the effect of a treatment. Special techniques are warranted because of censored data, such as animals being lost to follow-up or they never experience failure and are alive at the end of the trial. If investigators wish to examine the effect of several variables at the same time as the survival analysis, a Cox proportional hazards model, similar to logistic regression, is recommended.

In many analyses, one makes repeated measurements on the same animals over a predetermined length of time (repeated measures). In this case, the measurements are not independent and this has a tendency to decreasethe variability of the data. Most statistical programshave methods in which one can adjust the variance to take into account the lack of independence of the samples collected. This problem is common when groups of animals under the same management schemes are sampled as a unit.

21.6.4 KAPPA STATISTICS

One may compare two or more diagnostic tests or clinical examinations to measure their agreement beyond that caused by chance. One can do this only using categoric data and kappa statistics. One uses a 2 × 2 table in which the kappa (κ) is actually a measure of the discordant pairs, that is, the two cells in which the tests do not agree. The formula is as follows:

$$K = \frac{\text{Observed agreement} - \text{Chance agreement}}{\text{Maximum agreement (1)} - \text{Chance agreement}}$$

The meaning of this calculation has come into question, and ranges for the measure vary. However, an example would include the following: $\kappa < 0.20$ = poor agreement; $\kappa = 0.21$ to 0.40 is fair; $\kappa = 0.41$ to 0.60 is moderate; $\kappa = 0.61$ to 0.80 is substantial; and $\kappa > 0.81$ is good.[40] One may use statistical programs to perform these calculations.

22 CHAPTER 22 RECOGNIZING AND TREATING PAIN IN HORSES

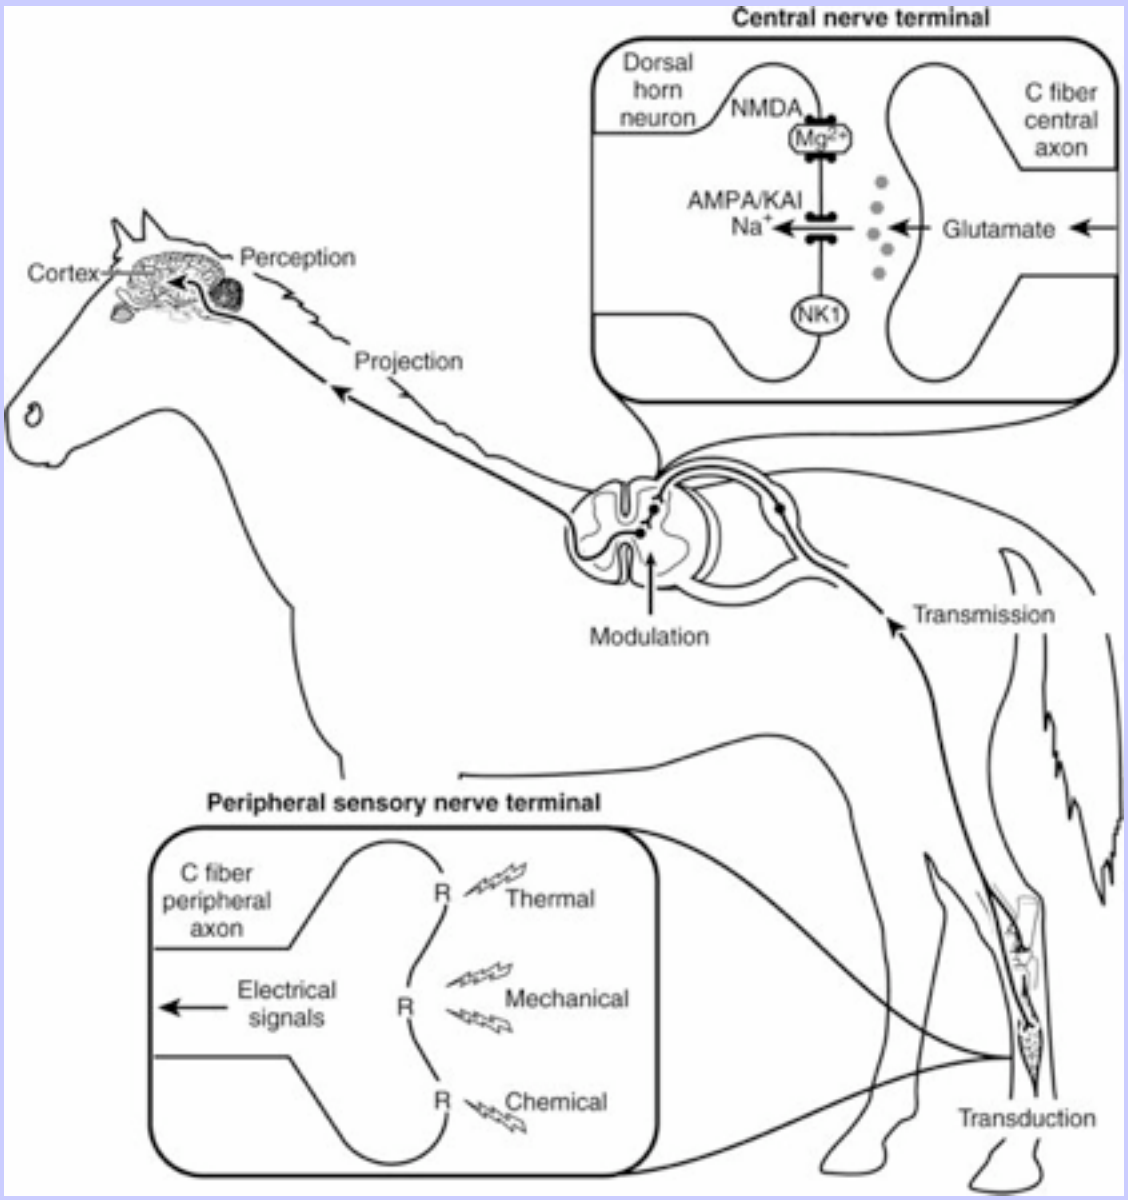
William Muir

The recognition and treatment of pain in horses, although commonplace, is evolving as evidencedby the wide variations in the attitudes, opinions, and methods used to control pain by equine practitioners.[1] Traditionally, however, pain has been used as a diagnostic tool for determining the source and potential cause (e.g., laceration, articular damage, laminitis, abscess, and colic) of pain rather than as an independent pathophysiologic process. What is intuitive to anyone that has experienced pain, particularly severe pain, is that pain can produce profound behavioral, neuroendocrine, metabolic, and immunologic effects. Chronic pain produces poor performance, inappetence, weight loss, and immunologic compromise predisposing to a generalized “sickness syndrome,” which often contributes to the natural or predetermined death of the horse.[2] Increased understanding of the neuroanatomic and molecular mechanisms responsible for pain and the discovery that untreated pain produces changes in the central nervous system (CNS) that contribute to the development of chronic pain have focused attention on the development ofmore effective and safer analgesic therapies.[3–5] One should consider pain as an independent rather than dependent variable, particularly in horses in which the cause ofpain is uncertain (idiopathic pain), pain is difficult to treat (e.g., myopathy or uveitis), or in which the causeof pain is impossible to eliminate (e.g., laminitis or osteoarthritis). The veterinary profession should consider pain as the fourth clinical sign (heart rate, respiratory rate, temperature, pain) requiring evaluation, documentation, and treatment. This attitude will help inspire the development of practical and clinically relevant diagnostic, evaluative, and therapeutic procedures for horses. This chapter presents a simplified review of the major pain pathways and the physiologic and pathophysiologic mechanisms responsible for pain and suggests clinically useful methods for evaluating and treating pain in horses.

22.1 Pain

Pain in human beings is defined as “an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage.”[6] This definition encompasses those neurophysiologic processes that warn and protect the horse from actual or potential tissue damage and help to prevent further injury and promote healing. Clinically pain involves two multifaceted components, nociception and perception.[4] Both facets are integrated to provide the immediate recognition and elimination (if possible) of the painful stimulus. Nociception is the detection of a noxious mechanical, thermal, or chemical stimulus and by itselfis not pain, because the transformation of noxious stimuli to electric impulses (transduction), their transfer to the spinal cord (transmission), and eventual projection to the brain does not ensure that the electric impulseswill be recognized (perceived), for example, as during anesthesia (Figure 22-1). Perception is the recognition that nociception has occurred or continues to occur and triggers responses that protect the horse from further insult and help to maintain homeostasis. Pain perception or the actual registration of a noxious stimulus depends on external (environmental) and internal (patient-related) issues and is responsible for the secondary behavioral 1529 1530 (vigilance, immobilization, fear), metabolic (hyperglycemia), neuroendocrine (cortisol, catecholamines), autonomic (heart rate, respiratory rate, pupillary), and immunologic responses that frequently are used to evaluate the severity of pain (pain score), determine stress, and ultimately aid in evaluating the quality of life of the horse.

Figure 22-1 Pain nociception and perception. Painful thermal, mechanical, and chemical stimuli are tranduced to electric potentials (action potentials) that are transmitted to the spinal cord, where they are modulated and then projected to the brain (perception). The major excitatory neurotransmitter in the spine is glutamate, which normally activates α-amino-3-hydroxy-5-isoxazole proprionic acid *(AMPA)* and kainate *(KAI)* receptors. *NMDA,* N-methyl-D-aspartate; *NK1,* neurokinin.



22.1.1 PHYSIOLOGIC AND PATHOLOGIC PAIN

Pain is caused by the activation of high-threshold (high stimulus intensity) nociceptors (pain receptors) located at the distal ends of unmyelinated (C) or poorly myelinated (Aδ) nerve fibers[2,4] (see Figure 22-1). The free nerve endings of these peripheral afferent nerve fibers encode noxious stimuli depending on the modality, intensity, duration, and location of the stimulus. The intensity of the stimulus required to produce painful sensations is considerably more than that required to produce nonpainful sensations (touch) and is the most important factor determining the severity of pain.[2] Pain that does not cause tissue damage is referred to as physiologic or nociceptive pain and serves to warn the horse of potential tissue damage. Pathologic pain occurs when tissue or nerve damage has occurred and frequently is categorized as inflammatory or neuropathic and occasionally as idiopathic.[5] The temporal aspects of pathologic pain are dynamic and are characterized by a 1530
reduction in the intensity of the stimulus required to initiate pain (hypersensitivity) and the production of pain 1531
by a stimulus that does not normally provoke pain (allodynia).[7] Inflammatory and neuropathic pain often are characterized by an exaggerated response (hyperalgesia) when a noxious stimulus is applied to the injured area. Peripheral sensitization is caused by the local production and release of chemicals (prostaglandins, leukotrienes, neuropeptides, nerve growth factors) that sensitize peripheral nerve fibers and activate additional pain receptors ("silent" receptors) to stimuli that normally would never produce pain.[4,8] Some of the hypersensitivity at the site of injury and all of the hypersensitivity that occurs outside the site of injury (secondary hyperalgsia) results from central sensitization.[7–11] The primary difference between peripheral and central sensitization is that the former activates and sensitizes nociceptors at the terminal ends of Aδand C fibers to low-intensity stimuli, whereas the latter changes sensory processing in the spinal cord resultingin pain from stimuli initiated in normal low-threshold sensory (touch) receptors.[5,8] Visceral pain (e.g., gut, liver, spleen, kidney, or bladder), unlike somatic pain, is transmitted by parasympathetic (principally vagal) and sympathetic splanchnic afferent nerve fibers.[12,13] The autonomic fibers involved in transmitting noxious inputs from visceral organs including the distal colon rectum and bladder are diffuse and extensively overlap. This difference from somatic transmission (transmission by parasympathetic and sympathetic nerves) means that much of the pain originating from viscera frequently involves an obvious autonomic component (tachycardia, tachypnea, mydriasis) and may be difficult to localize.[12] Generalized or diffuse inflammation, ischemia, and mesenteric stretching or intestinal dilation (e.g., of the stomach or cecum) can produce severe, unrelenting pain. Inflammatory diseases can also activate silent nociceptors in the gut or bladder, resulting in mechanosensitivity to otherwise innocuous smooth muscle contractile (normal peristaltic) activity.

22.1.2 PERIPHERAL SENSITIZATION

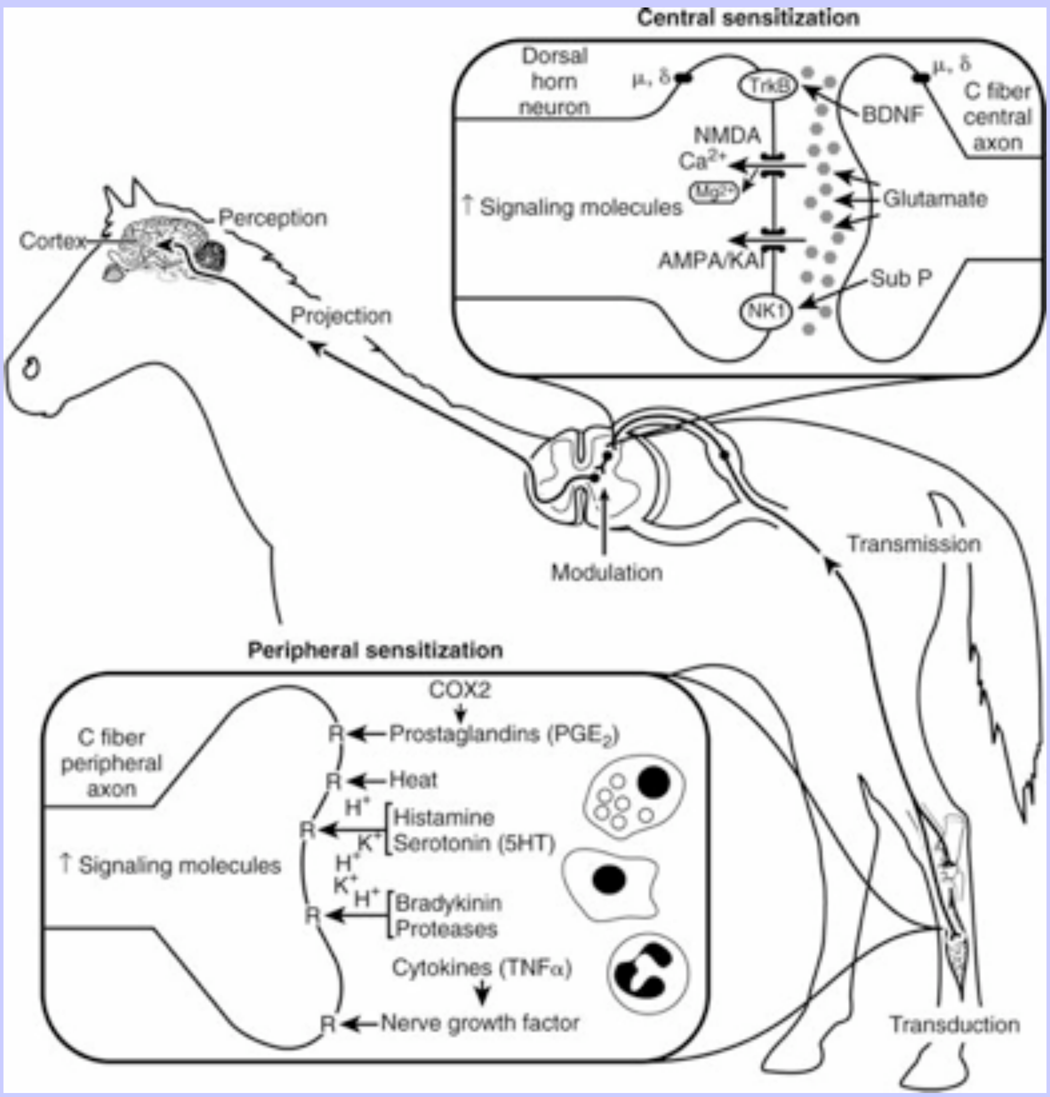
Peripheral sensitization is produced by the activationof enzymatic and reparative processes initiated by tissue damage and inflammation at the site of injury. The production or dissemination of the by-products of damaged tissues, inflammatory cells (lymphocytes, neutrophils, mast cells, macrophages), and autonomic nerves excite and increase the sensitivity (lower the activation threshold) of peripheral nociceptors[4,8] (Figure 22-2). Tissue damage results in the production of prostaglandins, bradykinin, and neurotrophic growth factors and the local release and spread of adenosine, adenosine triphosphate, and ions (H^+, K^+). Leukocytes and macrophages release cytokines (interleukin-1 [IL-1], IL-6, tumor necrosis factor α). Primary afferent sensory nerve fibers release neuropeptides (substance P, calcitonin gene-related peptide), causing mast cells to degranulate, promoting local vasodilation and plasma extravasation, further amplifying the inflammatory response. Collectively, these substances combine to produce a "sensitizing soup" that lowers nociceptor threshold and

activates silent nociceptors, thereby amplifying the pain response.[8] Peripheral sensitization is responsible for primary hyperalgesia or pain that is initiated by innocuous stimuli applied within the area of tissue injury.

22.1.3 CENTRAL SENSITIZATION

Central sensitization results from the cumulative effects (temporal summation) of repetitive and sustained summation of nociceptive inputs on central (spinal cord) neurogenic pathways.[4,7,8] Normally temporary noxious stimuli generate fast excitatory potentials within the CNS that are short lived but indicate the onset, duration, intensity, and location of the painful stimulus. This fast excitatory transmission is transmitted by $A\delta$ and C fibers and is mediated by glutamate acting on α-amino-3-hydroxy-5-isoxazole proprionic acid and kainate receptors within the dorsal horn of the spinal cord. Sustained input from damaged tissue or injured nerves releases glutamate and additional neuropeptides (substance P, neurokinin A), which activate *N*-methyl-D-aspartate and tachykinin receptors, resulting in sensitization (windup) of neurons in the dorsal horn of the spinal cord[8] (see Figure 22-2). Windup, central sensitization, and biochemical changes in the CNS represent a continuum of the pain process that generally is initiated by an acute painful process or chronic untreated pain. Central sensitization can last for hours to days and is believed to be responsible for increases in the receptive field and hypersensitivity to noxious stimuli from outside the area of primary tissue damage (secondary hyperalgesia).[8,10] Changes in the spinal cord segmental inhibitory input also can contribute to dorsal horn hyperexcitability, resulting in the perception of pain from otherwise innocuous stimuli carried by $A\beta$ (touch) nerve fibers.[8] Central sensitization is fundamentally different from peripheral sensitization in that it enables low-intensity stimuli to produce pain because of changes in sensory processingin the spinal cord. The projection of electric impulses, initiated by a painful stimulus from the spinal cord to the brain, can modify memory and may be the reason that severe or untreated acute or chronic pain can resultin permanent behavioral changes.[9] The development of central sensitization has several clinically relevant implications, including a change in the therapeutic focus from peripheral (local anesthetics, nonsteroidal antiinflammatory drugs [NSAIDs]) to central sites (opioids, α_2-agonists), the selection of potent centrally acting analgesic drugs, and the introduction of 1531
strategies that help limit or prevent the development of central sensitization (preemptive and multimodal).[5] 1532
Once hyperexcitability (central sensitization) is established, one must administer larger doses of analgesics for longer periods of time for therapy to be effective. Said another way, one should treat pain as early as possible and preemptively when possible.

Figure 22-2 Peripheral and central sensitization. Peripheral sensitization caused by tissue or nerve injury lowers the threshold of nociceptors and activates “silent” nociceptors, leading to primary hyperalgesia. Central sensitization caused by the temporal summation of nociceptive imput activates *N*-methyl-$_D$-aspartate *(NMDA)* receptors in the spinal cord, resulting in secondary hyperalgesia. *TrkB*, Tyrosine kinase B; *AMPA*, α-amino-3-hydroxy-5-isoxazole proprionic acid; *KAI*, kainate; *NK1*, neurokinin; *Sub P*, substance P; *COX-2*, cyclooxygenase 2; *5-HT*, 5-hydroxytryptamine; *TNF-α*, tumor necrosis factor α.



22.2 Stress and Distress

Pain associated with disease, accidental trauma, or surgical trauma or originating from unknown causes can result in activation of the sympathetic nervous system, secretion of glucocorticoids (primarily cortisol), hypermetabolism, sodium and water retention, and altered carbohydrate and protein metabolism. The term given to this response is *stress*, which encompasses the biologic processes whereby the horse attempts to maintain homeostasis and cope with threats to its well-being.[14] Acute and chronic pain are capable of producing a significant stress response in horses. The stress response is an adaptive pattern of behavioral, neural, endocrine, immune, hematologic, and metabolic changes directed toward the restoration of homeostasis (Figure 22-3).
During threatening circumstances, the stress response prepares the horse for an emergency reaction that fosters 1532
survival in circumstances of immediate threats (fight or flight). Most stress in horses is short lived because of the 1533
removal or short duration of exposure to the stressor. Surgery and anesthesia are a common source of stress in horses that can be modified by the appropriate choice and use of preanesthetic and anesthetic drugs.[15] Suffering occurs when horses are forced to endure the infliction or imposition of physical pain and the feeling of impending destruction or harm (fear).[16] Severe or chronic stress can become maladaptive, producing distress and the triggering of self-sustaining cascades of neural and endocrine responses that upset the physiologic homeostasis of the animal and negatively affect biologic functions critical to the well-being ofthe animal. Stress and distress directly affect the well-being of the horse, produce immune incompetence, and can lead to the gradual deterioration of the patient, resulting in death.[17] At a minimum, all animals should be granted the “five freedoms”: freedom from hunger and malnutrition, freedom from discomfort, freedom from disease, freedom from injury, and freedom from pain (Box 22-1).

Figure 22-3 Pain produces stress that activates the hypothalamus-pituitary-adrenal axis, resulting in varied behavioral, neuroendocrine, metabolic, and immune responses.

22.2.2

NEUROENDOCRINE AND AUTONOMIC STRESS

Auditory, visual, and somatosensory afferent sensory information are transmitted to the thalamus or directly to the amygdala in the brain. The noxious stimuli that produce acute and chronic pain induce stress that activates the hypothalamus-pituitary-adrenal axis.[14] This afferent information stimulates the secretion of corticotropin-releasing factor, vasoactive intestinal peptide, and adrenocorticotropic hormone (ACTH), to name a few. Corticotropin-releasing factor acts synergisticallywith vasopressin to stimulate the production of ACTH and β-endorphin, thereby enhancing cell survival and producing analgesic effects, respectively. Corticotropin-releasing factor also stimulates the adrenomedullary release of ACTH and catecholamines. Corticotropin-releasing factor is an excitatory neurotransmitter in the locus ceruleus that increases norepinephrine release and excitatory behaviors. Adrenocorticotropic hormone stimulates the adrenal cortex to secrete cortisol, corticosterone, aldosterone, and weak androgenic substances and also stimulates increased glucocorticoid production and the adrenomedullary secretion of catecholamines. Cortisol stimulates gluconeogenesis, increases proteolysis and lipolysis, facilitates catecholamine effects, and produces antiinflammatory actions. Importantly, many of these same factors (corticotropin-releasing factor, ACTH, and corticosterone) are significant modulators of learning and memory processes.[18] Increases in CNS sympathetic output increase respiratory rate, heart rate, and arterial blood pressure and produce sweating, piloerection, and pupillary dilation. Catecholamines are released from the adrenal medulla into the systemic circulation, amplifying these effects. Increased concentrations of circulating catecholamines augment glycogenolysis, increase gluconeogenesis, inhibit insulin release, and promote insulin resistance. Skeletal muscle blood flow generally increases out of proportion to increases in blood flow to other organ systems, preparing the animal for fight or flight. Epinephrine causes glycogenolysis, gluconeogenesis, and inhibition of insulin release, peripheral insulin resistance, and lipolysis. Thyroid hormones stimulate carbohydrate metabolism and heat production and increase and sensitize β-adrenergic receptors in the heart, thereby sensitizing it to the effects of circulating catecholamines.

22.2.3 METABOLISM

The neurohumoral changes produced by stress increase the secretion of catabolic hormones, promoting the production of food substrates from the breakdown of carbohydrates, fats, and protein.[17] Hyperglycemia is produced and may persist because of the production of glucagon and relative lack of insulin, although insulin levels may periodically increase. Cortisol, catecholamines, and growth hormone stimulate lipolytic activity, resulting in an increase in circulating glycerol and free fatty acids. Protein catabolism is a common occurrence and a major concern following severe trauma or extensive surgical procedures. Cortisol increases protein catabolism, resulting in the release of amino acids.

22.2.4 IMMUNE SYSTEM

The immune system functions as a diffusely distributed sense organ communicating injury-related information and the severity of stress to the brain. Pain therefore can modulate the immune response.[19] The key elementsfor determining the immune response to pain are its intensity and duration. The messengers of the immune system are cytokines (IL-1, IL-6, tumor necrosis factor α). Interleukin-1 and IL-6 induce the release of acute phase (inflammatory) reactants, cause fever, and initiate prostaglandin production (PGE_2). Severe stress fromany cause can trigger the acute phase response.[14] The main feature of the acute phase response is the release of proteins from the liver that act as inflammatory mediators and scavengers in tissue repair. These proteins includeC-reactive protein, fibrinogen, macroglobulin, and antiproteinases. Interleukin-1 and IL-6 can stimulate the secretion of ACTH from the pituitary gland and the subsequent release of cortisol. Tumor necrosis factor α produces signs of shock, including hypotension, hemoconcentration, hyperglycemia, hyperkalemia, and nonrespiratory acidosis, and activates the complement cascade. Excessive production of these proteins can contribute to systemic inflammatory response syndrome. The peripheral white blood cell count generally reflects a stress leukogram typified by an elevated number of immature polymorphonuclear leukocytes (left shift) and reduced numbers of lymphoctes. Chronic pain produces sustained increases in circulating concentrations of cortisol, epinephrine, norepinephrine, and glucagon and suppresses the humoral and cellular immune response.[17] The systemic release of endogenous opioids (endorphin and enkephalin) may contribute to immunosuppresion.

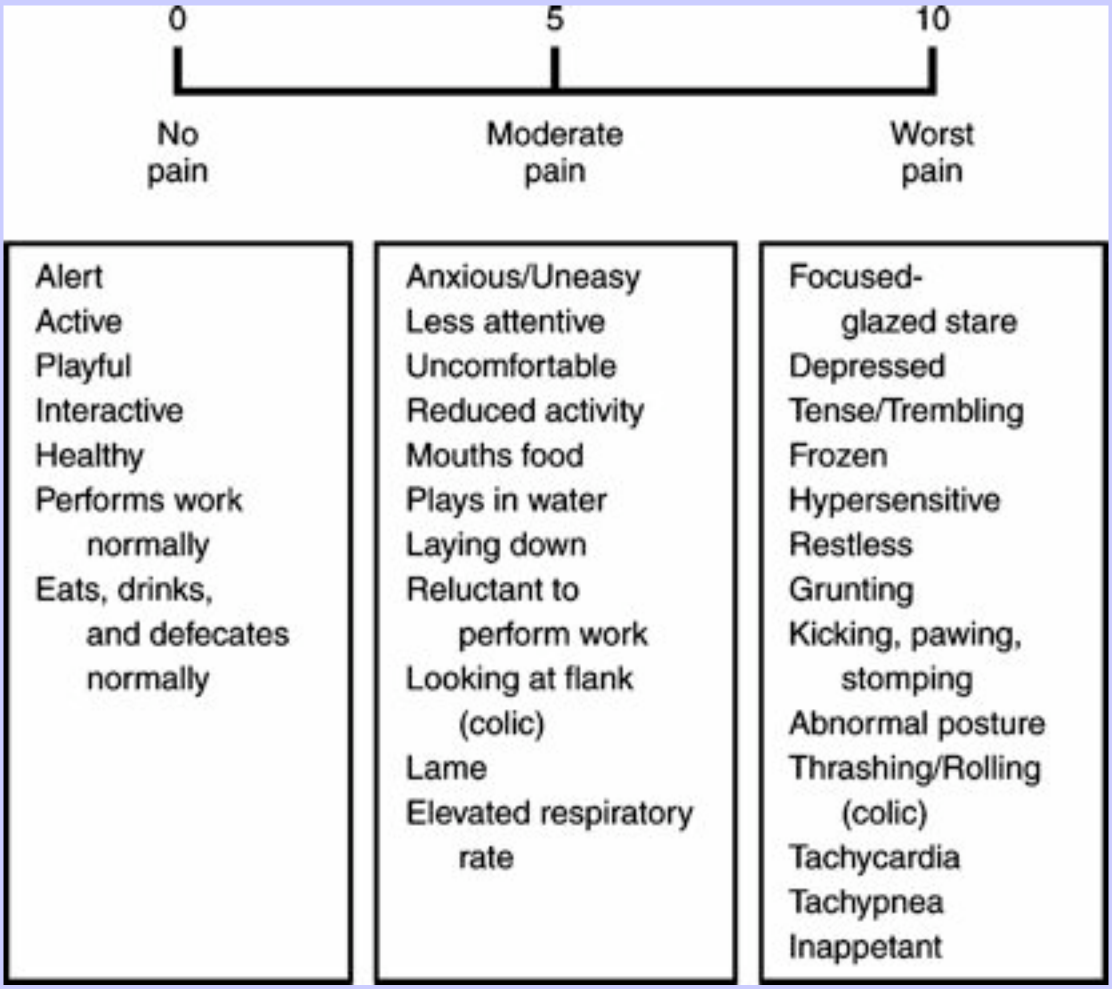
22.2.5 BEHAVIOR AND MORPHOLOGY

Pain is notorious for producing changes in behavior, attitude, performance, and memory. Pain activates the locus ceruleus, limbic regions (hypothalamus, hippocampus, amygdala), and cerebral cortex, which are involved in the adaptive responses to stress.[17] Pain-induced increases of corticotropin-releasing factor in the hypothalamus, amygdala, and locus ceruleus, for example, produce an increased startle response, anxiety, and fear. Corticotropin-releasing factor therefore serves as an excitatory neruotransmitter in the locus ceruleus, resulting in release of cortical norepinephrine, dopamine, and 5-hydroxytryptamine with resultant behavioral hyperresponsiveness, hyperarousal, vigilence, and agitation. Prolonged stress impairs the desire and ability of the horse to performand learn. Chronic stress caused by pain producestypical phenotypic changes that include a failure to thrive, poor hair coat, weight loss, and an accelerationof aging. 1534 1535

22.3 Evaluation of Pain

Although truly rational therapeutic approaches cannot be developed until the majority, if not all, of the specific mechanisms responsible for the physiologic and pathologic causes of pain are known, the use of simple yet detailed pain scoring systems can help categorize the intensity, duration, and location of pain, thereby suggesting potential treatments. Pain scoring systems, however, are of little value in suggesting therapy until the evaluator has a general understanding of the physiologic and pathophysiologic processes involved in the productionof pain.[7] This implies an understanding of the reasonsfor tissue hypersensitivity, peripheral sensitization, primary and secondary hyperalgesia, central sensitization, allodynia, spontaneous and referred pain, and the differences between somatic and visceral pain. All of these aforementioned changes modify the gain of the pain system leading to permanent alterations in the neurochemical regulation of the CNS and resultant phenotypic (physical characteristics) changes.[8] One of the most challenging problems in the clinical study of pain has beenthe development of a universally accepted and applied method of classification. The absence of a universally applied, clinically relevant pain scoring system has made it difficult to categorize patients, prescribe therapy, evaluate treatment, and compare research trials. Pain classification systems based on anatomy, etiology, body system, severity, duration, behavior, or cause are descriptive but do not identify the mechanism(s) responsible for pain and therefore do not provide the type of information required for determining effective therapy. One classification system proposes to diagnose pain based on the relationship between clinical signs, tissue type, disease, and the patient's response to predefined neurobiologic criteria.[20] This approach suggests that pain should be classified as inflammatory, neuropathic, or both and that the presence of peripheral sensitization, central sensitization, allodynia, and hyposensitivity to pain be used to subcategorize patients further and guide therapeutic decisions. Application of this approach along with anatomic, etiologic, and time- and behavior-based schemes will lead to the development of more informative diagnostic methods. When used with a visual analog scale, numerical, or categoric rating system, the aforementioned pain classification system should improve the diagnosis and the treatment of pain in horses (Figure 22-4).

Figure 22-4 The visual analog scale is a simple, practical method for evaluating the severity of pain and the efficacy of therapy.

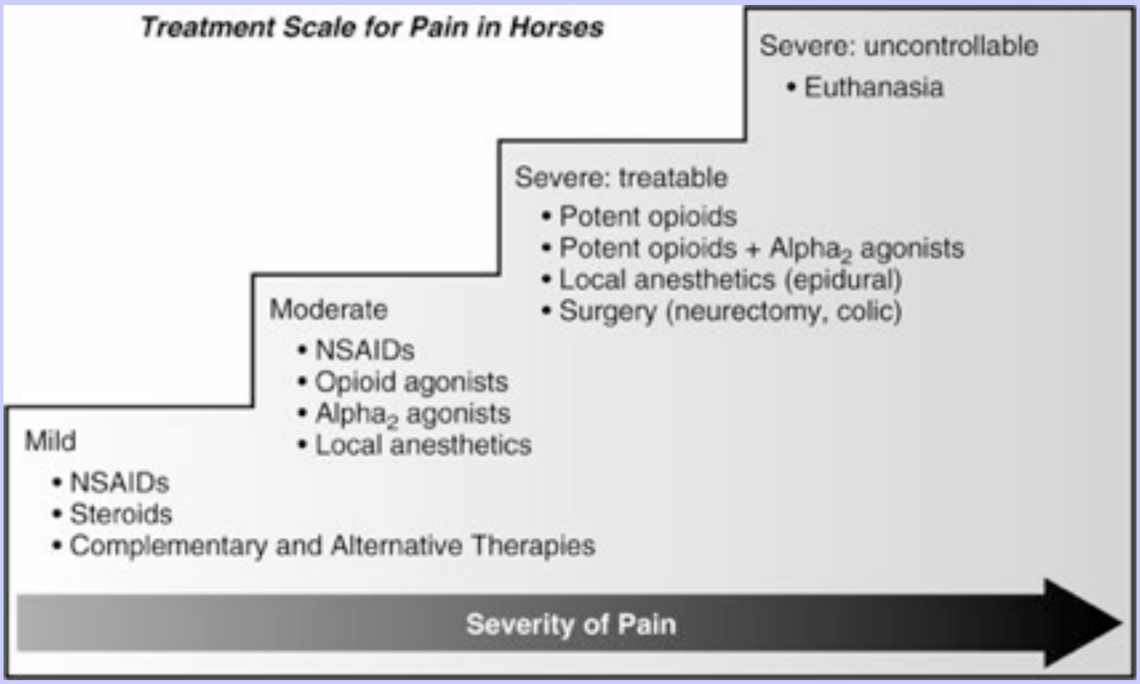


22.4 Drugs Used To Treat Pain

A vast array of clinical therapies claim to be efficaciousin the treatment of pain (inflammatory, neuropathic) in horses. Most are anecdotal or reflect individual attitudes.[1] Many therapies have been evaluated in experimental 1535
pain models (balloon colic, heat lamp, hoof nail) using otherwise normal horses, but few therapies have been 1536
subjected to blinded, randomized, controlled clinical trials in horses with spontaneous disease.[21–25] Regardless, a great deal of anecdotal data suggest that many of the same drugs used to treat pain in human beings, dogs, and cats are effective for treating pain in horses. Similarly, alternative therapies including acupuncture, chiropractic, and nutraceuticals can provide relief from acute and chronic pain in horses.[26–31] Pharmacologic approaches to the treatment of pain in horses derive their greatest benefits when drugs are selected for specific purposes (inflammation, nerve injury), scaled to the severity of pain, and used in combination (multimodal therapy) or preemptively, before the pain-inducing event(Figure 22-5). Most drugs used to treat pain fall into one of four

broad categories, which include the steroidal antiinflammatory drugs and NSAIDs, opioids, α_2-agonists, and local anesthetics. To this list can be added an expanding list of adjunct medications that produce antiinflammatory, anticonvulsant, antidepressant, or calming (acepromazine) effects[28] (Table 22-1).

Figure 22-5 A drug treatment pain scale for horses. *NSAIDs*, Nonsteroidal antiinflammatory drugs.



22.4.1 ANTIINFLAMMATORY DRUGS

Antiinflammatory drugs are comparatively weak analgesics but are effective for the most causes of mild to moderate pain particularly if the cause is inflammatory.[32–38] Glucocorticosteroids produce antiinflammatory effects by inhibiting phospholipase A_2 and the breakdown of membrane phospholipids to arachadonic acid and subsequently to prostaglandins and leukotrienes (Figure 22-6).[33] Prostaglandins and leukotrienes exaggerate the inflammatory response and are key factors in the productionof peripheral sensitization. Prostaglandins (PGE_2, thromboxane A_2) activate prostaglandin receptors throughout the body, producing pain, inflammation, and fever. Prostaglandins also are responsible for producing a protective gastric barrier to intralumenal acidity, sustaining normal gastric secretory activity, and maintaining normal gut motility. Prostaglandins regulate renal blood flow and maintain normal renal tubular function. Cyclooxygenase (COX) is an enzyme that metabolizes arachidonic acid to prostaglandins. At least two types of COX (COX-1, COX-2) exist. Cyclooxygenase 1—also termed *housekeeping COX*—is constitutive and helps maintain normal cell and tissue function. Cyclooxygenase 2 has housekeeping functions in the CNS, kidney, eye, and reproductive organs but is also inducible. Cyclooxygenase 2 is produced by inflammatory cellsand is upregulated greatly following tissue injury. Most NSAIDs produce their antiinflammatory and analgesic effects by differentially inhibiting COX-1 and COX-2.[33] Inhibition of COX-1 is believed to be responsible forthe NSAID toxicity (altered gastrointestinal motility and

ulceration). The availability of newer NSAIDs that are more selective for COX-2 versus COX-1 (COX-2; deracoxib) offers the potential to provide COX-1–sparing effects, minimizing the toxic effects on the gut.[37] Gastrointestinal, renal, or liver toxicity and the potentialfor delayed clotting are important issues that are more common with chronic drug administration.[36,39] One also must consider the potential for individual NSAIDs to alter platelet function and produce blood dyscrasias in sick horses or those with hemorrhage. Toxicity is more common in very young or old, dehydrated, or immunocompromized horses or in horses with preexisting cardiovascular, renal, or liver disease. 1536

TABLE 22-1 Drugs Used to Treat Pain in Horses

DRUG	INTRAVENOUS DOSE (mg/kg)	DOSING INTERVAL
ANTIINFLAMMATORY DRUGS		
Corticosteroids		
Hydrocortisone sodium succinate	1.0–4.0	—
Dexamethasone isonicotinate	0.015–0.050	—
Methylpednisolone	0.1–0.5	—

Butorphanol	0.01–0.05	
Xylazine	0.5–1.0	—
Morphine	0.1–0.5	

22.4.2

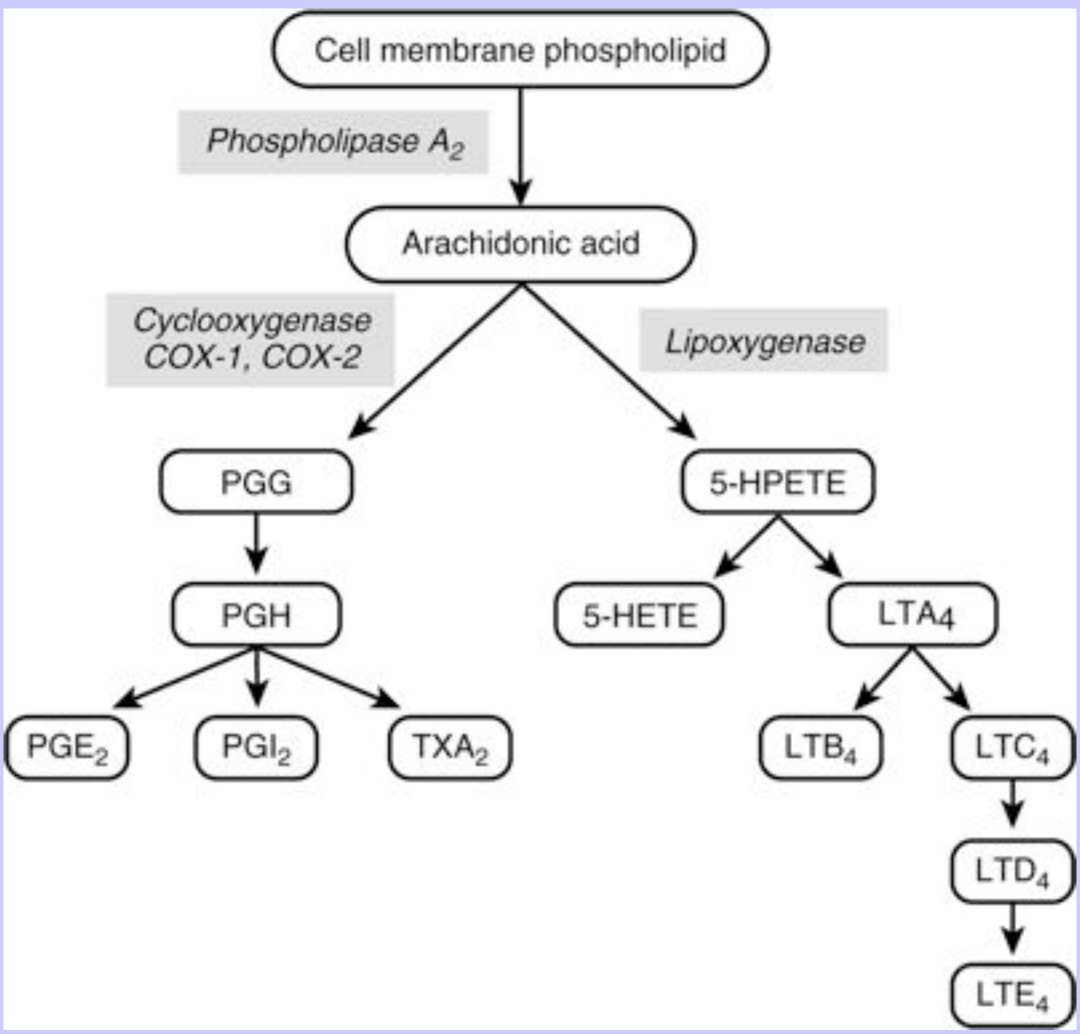
OPIOIDS

Opioids generally are considered to be the most effective of all analgesic medications but vary widely in their analgesic potency and clinical efficacy.[40–44] Opioid agonist-antagonists and partial agonists produce μ-receptor or morphinelike effects and are in general less toxic but less potent than morphine.[44] Opioid antagonists are devoid of agonist activity and are used clinically to antagonize or reverse opioid effects. Morphine is considered the prototypic opioid to which all other opioids are compared and occupies a particularly unique position among opioids in horses because of its long duration of action.[45,46] Opioids produce their effects by activating opioid receptors(μ, κ, δ, σ).[47] Most opioids produce their beneficial (analgesic, euphoric) pharmacologic effects by activating central and peripheral opioid μ-receptors, although evidence indicates that drugs with opioid κ-receptor activity may be particularly effective in treating gastrointestinal pain.[43,46] Analgesia along with minimal sedation places opioids, particularly butorphanol, in an ideal position to treat mild to moderate visceral pain.[40,44,48,49] These beneficial properties, however, are overshadowed by the requirement for special licensing and record keeping; the occasional development of ileus, constipation, and colic; and the potential for all opioids to produce excitement (increased locomotor activity), disorientation, and ataxia in horses. Opioids delay gastric emptying and prolonging intestinal transit time.[43] Increases in intestinal smooth muscle tone are caused by centrally mediated increases in vagal tone and activation of opioid receptors throughout the gastrointestinal tract. These effects are followed by a decrease in propulsive peristaltic activity and absorption of water from the intestinal tract, predisposing the patient to constipation, a condition that becomes more prominent when opioid administration lasts several days. Large or repeated dosages of opioids can inhibit the urinary voiding reflex and increase external urethral sphincter tone, resulting in urine retention. Urine retention can be an important postoperative consideration in some horses. Recommended dosages of opioids can produce sympathetic activation (sweating, mydriasis), nervousness, increased locomotor activity, agitation, and dysphoria in some horses.[47,50] The latter effects (excitement, disorientation, ataxia) are particularly troublesome because they can occur at clinically relevant dosages. Opioids, especially morhine, produce profound analgesic effects when combined with α_2-agonists (xylazine, detomidine).[51] The combination of opioids and α_2-agonists (morphine, butorphanol, and xylazine or detomidine) to produce so-called neuroleptanalgesia has been used preemptively to perform standing medical and surgical procedures that otherwise would require general anesthesia.[51–53] Fentanyl is a particularly potent but expensive opioid μ-receptor agonist with a short duration of action, making its clinical use impractical unless administered by constant rate infusion to painful horses (severe colic, laminitis).[54] Alternatively, a fentanyl transdermal drug delivery system (patch) is available, but clinical experience is limited and the patches may need to be replaced every 36 to 48 hours in horses to maintain analgesia.

As suggested previously, different opioids produce varied pharmacologic activity based on their ability to combine with and differentially activate the various opioid receptors. The prevalence and location of the various receptor subtypes determines the pharmacologic properties of the opioids. Practitioners know little concerning opioid receptor distribution, density, and selectivity in horses compared with other species. 1537
Furthermore, the potential of opioids to produce CNS agitation, increased locomotor acitivty, and excitatory 1538

effects when used alone or with inhalant anesthesia may negate their potential usefulness as analgesics.[47,50,55] Finally, few are the comparative studies or large scale randomized, controlled, and blinded multicenter clinical trials evaluating the efficacy of opioids in horses with naturally occurring disease, making their clinical use a process based on published experimental trial and error.[41,48]

Figure 22-6 Tissue or nerve injury damages cell membranes, leading to the production of arachidonic acid, prostaglandins *(PG)*, and leukotrienes *(LT)* via the activity of phospholipase A_2, cylcooxygenase, or lipoxygenase enzymes, respectively. These enzymatic pathways are important for producing inflammation and pain. They can be inhibited by corticosteroids, nonsteroidal antiinflammatory drugs, and lipoxygenase inhibitors. *5-HPETE*, 5-Hydroperoxyeicosatetraenoic acid; *TXA_2*, thromboxane A_2.



22.4.3 α_2-AGONISTS

α_2-Agonists (xylazine, detomidine, medetomidine, romifidine) produce sedation, muscle relaxation, and analgesia by activating various α_2-receptors in the CNS and peripherally.[56] Analgesia is confounded, however, by mild to significant sedation that can result in profound stupor, ataxia, and reluctance to move, although thismay be beneficial in horses suffering from colic.[34,48,57] Regardless, α_2-agonists are particularly effective therapy for the acute treatment of moderate to severe pain (colic) and can be administered by infusion to treat acute injuries or intraoperatively to reduce the requirement for inhalant anesthesia.[41,56] α_2-Agonists are particularly effective when administered with an opioid (butorphanol, morphine) or acepromazine.[51,53,58] The effects of α_2-agonists can be antagonized by the α_2-antagonists yohimbine, tolazoline, and atipamezole. Sedation is attributed to activation of the CNS α_2-A– and D–receptors in areas of the brain that are responsible for awareness, arousal, and vigilance. Activation of α_2-receptors in the brain and spinal cord decreases the release of excitatory neurotransmitters and interferes with sensory processing and transmission.[56] Individual drug effects vary based on chemical structure, α_2 versus α_1 selectivity, metabolism, and elimination. Xylazine is considered the prototypic α_2-agonist and demonstrates a comparatively low α_2-receptor selectivity and short half-life. Xylazine also produces local anesthetic effects, presumably because of its structural similarity to lidocaine.

Clinically the administration of α_2-agonists generally produces profound sedation, bradycardia, respiratory depression, and occasionally unexpected or aggressive behavior. Sinus bradycardia and bradyarrhythmias are common following the administration of α_2-agoniststo horses and are typified by the development of sinus arrhythmias and first- or second-degree atrioventricular block. Decreases in heart rate and atrioventricular block 1538
are caused by the combined effects of decreases in CNS sympathetic output and increases in vagal tone.[59] 1539
Atropine or glycopyrrolate can help to prevent bradycardia and atrioventricular block but generally are not required. Arterial blood pressure initially increases transientlyand then decreases from baseline values. Arterial hypertension is initiated by stimulation of peripheral vascularα_1- and α_2-receptors and resultant increases in baroreceptor activity. The subsequent decrease in arterial blood pressure is caused by a decreases in CNS sympathetic output and heart rate.[56,60] Cardiac output decreases almost immediately in parallel with decreases in heart rate.[59] Respiratory rate and tidal volume decreasewith CNS depression. These effects contribute to the development of respiratory acidosis and hypoxemia insome horses, although this rarely is a clinical problem. Relaxation of the muscles of the nostrils, pharynx, and larynx can result in respiratory stridor, snoring, irregular breathing patterns, inspiratory dyspnea, and upper airway obstruction in some horses, particularly those with upper airway diseases.

α_2-Agonists produce immediate and pronounced decreases in gastrointestinal tone and motility that can be pronounced and last for 8 to 10 hours.[61–63] Gastrointestinal stasis is caused by stimulation of α_2-receptors in the gut and increases in serum gastrin concentration. The decrease in gut motility is dose dependent but is believed to be responsible for postoperative ileus, gas accumulation, and the occasional development of colic in some horses and requires the administration of anα_2-antagonist (yohimbine).[64] α_2-Agonists promote diuresis in horses by increasing blood pressure and producing direct actions on the renal tubules to decrease renal tubular salt and water absorption. Labor can be delayed or prolonged because of sedative and muscle relaxant effects.

22.4.4 LOCAL ANESTHETICS

Local anesthetics (lidocaine, mepivacaine) frequently are used to produce a loss of sensation by administering them at specific sites (topical, local) or on nerves (regional), and they also have been administered epidurally and systemically to decrease the need for additional analgesics or to reduce the requirement for inhalant anesthesia[43] (Table 22-2). The systemic infusion of lidocaine decreases the requirement for inhalant (isoflurane, sevoflurane) or injectable (ketamine, propofol) anesthetics and potentiates the analgesic actions of opioids or α_2-agonists.[65,66] Analgesia results from blockade of sodium ion channels, thereby preventing the initiation and conduction of electric activity (action potentials) in small-diameter (C, Aδ) sensory nerve fibers. Larger (clinical) dosages of local anesthetics also block electric activity in large fibers (Aβ), thereby producing loss of motor function and temporary motor paralysis. Most local anesthetic drugs produce mild CNS depression (anesthetic sparing), antiarrhythmic, antishock, and gastrointestinal promotility effects.[43,67,68] Mild sedation occurs because of membrane-stabilizing effects, a generalized decrease in neuronal activity, and a centrally mediated decrease in sympathetic tone. Local anesthetics have the potential to produce a loss of motor function (paralysis) that can become problematic in some surgical patients (rectal-vaginal fistula repair), leading to untoward behavioral responses. Local anesthetics produce minimal cardiovascular or respiratory effects in otherwise normal, healthy horses but can decrease cardiac output, arterial blood pressure, and heart rate when administered intravenously because of decreases in CNS sympathetic output, myocardial contractile force, and venous return.[65,66] These effects are more prominent in stressed or sick animals that depend on sympathetic nervous system activity for maintaining homeostasis. Although local anesthetics are considered to have antiarrhythmic effects, they can produce sinus bradycardia and bradyarrhythmias and hypotension when administered rapidly intravenously. Significant differences exist among the various local anesthetics regarding these effects and their metabolism, elimination, and potential to produce CNS toxicity (disorientation, ataxia, seizures).[68] Horses are comparatively sensitive to the neurotoxic side effects of local anesthetics and bolus 1539

1540 dosages exceeding 2 mg/kg usually produce CNS stimulation typified by nervousness, excitement, agitation, disorientation, nystagmus, and seizures. These effects can result in death from respiratory paralysis. Local anesthetic drugs have the potential to produce respiratory paralysis when administered by epidural or spinal (subarachnoidal) routes. The migration of the local anesthetic cranially to the sixth cervical nerve roots can paralyze the diaphragm, resulting in hypoventilation and apnea.

TABLE 22-2 Caudal Epidural Analgesia in the Horse

DRUG	DOSE (mg/kg)	POINT OF ADMINISTRATION	DURATION OF ANALGESIA
LOCAL ANESTHETICS			
Mepivacaine HCl	0.20	S3-S4, S4-S5	1–1$^{1}/_{2}$ hours
Lidocaine HCl	0.16–0.22	Coccygeal 1–2	30–60 minutes
Lidocaine HCl	0.28–0.37	S3-S4, S4-S5	1$^{1}/_{2}$-3 hours
α_2-**AGONISTS**			
Xylazine	0.03–0.35	Coccygeal 1–2	3–5 hours
Detomidine HCl	0.06	S4-S5	2–3 hours
Romifidine	80 g/kg		2–3 hours
OPIOID			
Morphine	0.05–0.10	Coccygeal 2	8–16 hours
COMBINATIONS			
Lidocaine	0.22	Coccygeal 2	5$^{1}/_{2}$ hours
Xylazine	0.17		
Morphine	0.20	S1-L6	>6 hours
Detomidine	0.03		
Ketamine	0.5	S1-L6	12–18 hours
Morphine	0.1		
Ketamine	0.5	S1-L6	>2 hr
Xylazine	0.2		

22.4.5
NONTRADITIONAL ANALGESICS

New drugs are being developed continuously to treat acute and chronic pain. Anticonvlusants (gabapentin) and behavior-modifying drugs (chloripramine) have been administered to horses to produce adjunct analgesic effects, but their efficacy and safety are unknown. Alternative therapies including acupuncture, chiropractic, and nutraceuticals are used to treat pain in horsesas adjuncts to various drug regimens. Several of these therapies are considered effective pain therapy by clinical experts, but most have not been evaluated carefully. 26–31

23 APPENDIX A APPLIED NUTRITION*

Donald R. Kapper

The mainstay of all diets for horses is the forage they consume. Understanding how the equine digestive tract functions optimally and how forage quality and quantity help maintain the health of the horse, reduce the incidence of colic, and keep the horses growing, reproducing, and performing to their genetic ability is what every veterinarian should know. With this knowledge veterinarians can help their clients select the best forage in their area and the appropriate grain mixture to complement it to meet all the nutrient needs of their horses. Once horsemen understand that horses do not have a requirement for cereal grains—for example, oats, barley, corn—but they do have an absolute requirement for forage, they understand better how to manage and feed their horses successfully. The only reason to feed a grain mixture or ration balancer to horses is to make up the difference between what nutrients are in their forage and what horses need to meet their daily nutrient requirements.

23.1 Equine Forage Quality

23.1.1 FEEDS

All horsemen add cereal grains or grain mixtures to increase the calories in the diet of their horses to meet their desired body condition. The feed manufacturer has the responsibility to explain for which physiologic status their feed mixture is prepared, what type of forage their grain mixture is formulated to complement, and what is the minimum amount of this grain mixture to feed per day to meet the nutritional requirements of the horse. These requirements vary with the age, size, growth rate, reproductive status, and performance level of the horse.[1,2] The owner or manager then is responsible for reading the information on the feed tag or bag and following the directions. If one feeds fewer pounds per day than the manufacture recommends as minimum in its feeding directions, one is feeding the horse a deficient diet.[3]

* With contributions from Gayle Ecker, Sarah L. Ralston, and James B. Rowe.

23.1.2 FORAGES: DETERMINING QUALITY

By definition, forages are the aerial parts of the plant commonly fed to livestock. Their history, like pasture, predates that of human beings. Forages supply various levels of nutrients depending on their type (species) and maturity at harvest. Today horses consume forages fresh, as pasture; dried, as baled or cubed hay; or preserved in silos or plastic bags, as haylage. Horses have limited ability to use poor-quality forages, so owners and trainers must understand how to determine quality and different types of forages. Because the maturity of the plant affects the digestibility of the fiber and the availability of the protein, calories, major minerals, trace minerals, and vitamins, feeding immature forages to horses that need the highest amount of nutrients per day is vital. Such horses are sucklings, weanlings and yearlings, nursing mares, and horses in moderate to intense training. The first visual appraisal of all types of forage includes (1) the length of the seed head in grasses (boot stage) and (2) the percent of blossoms in bloom in legumes (bud stage). Ideally, grasses should have seed heads less than one inch long, and legumes should have less than 10% of the buds in blossom. Because all plants prepare to blossom, the acid detergent fiber (ADF), which measures crude fiber (cellulose plus insoluble lignin) and soluble lignin, and neutral detergent fiber (NDF), which measures the ADF plus hemicellulose, increase so 1543
the stem has enough strength to hold up the seed heads or blossoms. Unfortunately, as the fiber portion 1544
increases, all other nutrients decrease and become less digestible and available to the horse.

The Hay Market Task Force of the American Forage and Grassland Council has published a quality grading standard to help determine the quality of different forages based on the maturity of the plants when harvested.

Table 1 explains ADF and NDF levels during different levels of maturity in forages and grades them accordingly with a scoring system of Prime and 1 through 5, with a corresponding relative feed value number. The description, in parentheses, beside each forage grade is the author's terminology.

Forage with a relative feed value (RFV) score of 102 or less will have a negative effect on the ability of the horse to meet its nutrient needs from this quality of forage. The lower feed value is due to the thickened layer of hemicellulose surrounding the cell walls that prevents the fermentation process from breaking them down to make the nutrients available to the horse. As the plant matures, the nondigestible fiber increases, affecting palatability negatively and slowing the rate of passage through the gut. These lower-quality forages cause the horse not to be able to maintain the desired body condition on forage alone, and one must add cereal grain or grain mixtures to the diet. A RFV score between 103 and 150 will have a positive effect on the nutrients in the plant being available to the horse. A RFV score greater than 151 will increase the absorption of nutrients in the small intestine because of the lower lignin content. A portion of the proteins contained in this high-quality forage can be absorbed as amino acids in the small intestine, depending on its RFV. Thus when feeding a forage with a RFV score of 103 or higher, one needs to feed less cereal grain or grain mixtures per day to maintain desired body condition. When fed forage with a RFV score between 103 and 150, mature horses can consume from 2.0% to 3.0% of their body weight in forage dry matter per day.

TABLE 1 Relative Feed Value of Grass, Mixed, and Legume Forages

	ANALYSIS (DRY MATTER BASIS)†			
QUALITY STANDARD*	**% ADF‡**	**% NDF**	**DMI,§ % OF BODY WEIGHT**	**RFV**
Prime (Prime)	<30	<40	>3.0	>151
1 (Premium)	31–35	41–46	3.0–2.6	150–125
2 (Good)	36–40	47–53	2.5–2.3	124–103
3 (Fair)	41–42	54–60	2.2–2.0	102–87
4 (Poor)	43–45	61–65	1.9–1.8	86–75
5 (Reject)	>46	>66	<1.8	<74

* Quality grading standard assigned by Hay Market Task Force of the American Forage and Grassland Council.

† Analysis associated with each standard.

‡ *ADF,* Acid detergent fiber; *NDF,* neutral detergent fiber; *RFV,* relative feed value.

§ Dry matter intake (DMI) as percentage of body weight. This measure is for mature horses only. Young, growing horses consume lesser amounts of this forage.

TABLE 2 Protein and Calorie Levels in Forages Based on Type and Maturity[*]

	GRASS			GRASS/LEGUME MIXED			LEGUME		
QUALITY STANDARD	% PROTEIN	% LYSINE[†]	Mcal DE/lb[‡]	% PROTEIN	% LYSINE	Mcal DE/lb	% PROTEIN	% LYSINE	Mcal DE/lb
Prime (Prime)	>11	>0.38	>1.05	>16	>0.68	>1.10	>21	>1.07	>1.17
1 (Premium)	8–10	0.31	0.95	13–15	0.60	1.03	18–20	0.97	1.10
2 (Good)	7–8	0.26	0.86	11–13	0.51	0.93	16–18	0.87	1.00
3 (Fair)	5–7	0.21	0.80	9–11	0.43	0.86	14–16	0.77	0.94
4 (Poor)	4–5	0.16	0.77	7–9	0.34	0.82	12–14	0.66	0.89
5 (Reject)	<4	<0.14	<0.73	<7	<0.30	<0.78	<12	0.56	<0.83

* These percentages are based on forages analyzed by Holmes Laboratory from 1980 to 2002 and are on a dry matter basis.

† Percentage of lysine in crude proteins: grass, 3.4%; mixed (50/50), 4.25%; legume, 5.1%.

‡ *DE,* Digestible energy.

Table 2 explains the relationship between maturity of the plant, or grading system, and the amount of protein, lysine, and calories available. Crude protein is not included in the RFV equation because it is not correlated highly with forage digestibility or intake. However, the more mature the plant, the lower the percent of protein, lysine, and calories per pound.

Table 2 demonstrates why purchasing hay based only on percent protein is not recommended. A 12% crude protein analysis could come from Prime grass, 2 (good) mixed, or 4 (poor) legume forages. The calories and availability of all nutrients are less per pound in the more mature forages. Just because hay contains a legume such as alfalfa or clover does not mean it is always better quality. Maturity of the plant when harvested (RFV) determines the palatability, digestibility, and availability of the nutrients and the true value of each type of forage, whether it is grass, mixed, or legume. 1544

The timing of harvest is the most important consideration when trying to produce top-quality feed. If forage is 1545 cut after maturation, one can do nothing to change the quality of that forage. All forage crops decline in feeding value as they mature. In the cool growing seasons, once the buds appear, forages lose 0.2% per day in protein and about 0.4% per day in digestibility.[4] During the hotter growing seasons, the protein and digestibility (RFV) decrease even faster. Therefore the time allotted for forages to go from Prime to 5 in the cool seasons of spring and autumn takes 4 to 5 weeks. In the hot summer months in the northern states or the entire growing season in the southern states, complete maturation takes less than 3 weeks. This faster maturing is related directly to ambient temperature.

TABLE 3 Mineral Ranges Based on Type of Forage When Relative Feed Value Is Between 103 and 150

NUTRIENTS	GRASS FORAGE ANALYSIS	MIXED FORAGE ANALYSIS	LEGUME (ALFALFA) FORAGE ANALYSIS
Calcium	0.25%-0.80%	0.80%-1.20%	1.20%-1.80%
Copper	2–10 ppm	4–10 ppm	4–10 ppm
Iron	60–200 ppm	60–200 ppm	60–200 ppm
Magnesium	0.15%-0.25%	0.20%-0.30%	0.20%-0.35%
Manganese	40–70 ppm	40–60 ppm	40–50 ppm
Molybdenum	1–2 ppm	2–4 ppm	3–6 ppm
Phosphorus	0.20%-0.30%	0.25%-0.35%	0.25%-0.35%
Potassium	0.80%-1.50%	1.50%-3.00%	2.00%-3.50%
Sulfur	0.15%-0.30%	0.20%-0.35%	0.25%-0.35%
Zinc	12–26 ppm	14–26 ppm	14–28 ppm

Table 3 shows the expected major mineral and trace mineral ranges by forage type when the RFV is between 103 and 150. These mineral ranges are from actual analysis completed by Holmes Laboratory, Millersburg, Ohio, from 1980 through 2001, and are based on type of forage and maturity when harvested.[5] If the RFV is greater than 150 or less than 103, the nutrient analysis is expected to change accordingly. The following also affect the mineral levels in the plant: type (species) of forage, maturity at harvest, type of soil where they are grown, amount of fertilizer applied, amount of rainfall, and ambient temperature during the growing season.

In general, grass forages are lower in crude protein, the amino acid lysine, calcium, and potassium. One must take these values into consideration when evaluating and recommending forages and feeding programs for horses. These nutrients are more critical in diets of horses under stress conditions, such as growing, reproducing, and training.

23.1.3 GRASSES

Grass species generally are divided into two groups: cool season and warm season. They are shallow rooted and therefore not drought tolerant. Grass species germinate and grow best in soils with a pH of 6.5, when the subsoil pH is less than 6.0. All grasses are classified as monocotyledon, and lysine makes up 3.4% of the crude protein.[6]

The cool season grasses include Kentucky Bluegrass, Orchard grass, Timothy, Tall Fescue, Smooth Bromegrass, Reed Canary grass, Ryegrass and cereal grasses. These grasses are grown predominantly in the northern half of the United States. These species are of greatest nutritional value as pasture in the spring and fall when the temperature is lower and the rainfall is higher.[7]

The warm season grasses include Bermuda grass, Bahia grass, Prairie grass, Bluestem, Sorghum, and Wheatgrass. These grasses are grown in the southern half of the United States and are more drought tolerant.[8] They have the potential to produce good hay and pasture growth during the warm and dry midsummer months. Warm season grasses produce well on soils with low moisture holding capacity, low pH, and low phosphorus levels.

23.1.3.1 Cool Season Grasses

23.1.3.1.1 Kentucky Bluegrass

Kentucky bluegrass is a long-lived perennial grass especially well suited to pastures. Kentucky bluegrass forms a dense, tough sod under favorable conditions, providing good footing for grazing animals. Kentucky bluegrass is one of the most forgiving grasses, able to tolerate and persist under a wide range of soil conditions and mismanagement; however, it responds well to good management. Kentucky bluegrass grows best under cool and moist conditions and usually becomes semidormant during the summer. Planting good-quality seed results in a more productive pasture than the naturally volunteering bluegrass.

23.1.3.1.2 Orchard Grass

Orchard grass is a versatile perennial bunch-type grass (no rhizomes) that establishes rapidly and is suitable for hay and pasture. Orchard grass is probably the most productive cool season grass, especially under good fertility management. Orchard grass has rapid regrowth, produces well under intensive cutting or grazing, and attains more summer growth than most of the other cool season grasses. Orchard grass tolerates drought better than several other grasses and grows best in deep, well-drained, loamy soils. 1545
Orchard grass is especially well suited for mixtures with tall legumes such as alfalfa and red clover. The 1546
rapid decline in palatability and quality with maturity is a limitation with this grass. Timely harvest is essential for obtaining good-quality forage. Improved varieties of orchard grass, with high yield potential and improved resistance to leaf diseases, are available. For seeding orchard grass/legume mixtures, one should select varieties that mature at about the same time. The later maturing varieties are best suited for growing with alfalfa, because they match the maturity development of alfalfa and are easier to manage for timely harvest to obtain good-quality forage.

23.1.3.1.3 Timothy

Timothy is a hardy perennial bunchgrass that grows best in cool climates. It generally grows better in the northern states because its regrowth is limited by its intolerance of hot and dry conditions. The shallow root system of timothy makes it unsuitable for droughty soils. Timothy produces most of its annual yield in the first crop. Timothy is used primarily for hay and is especially popular for horses, requires well-drained soils, and is less competitive with legumes than most other cool season grasses. Because frequent cutting easily weakens timothy, a sufficient recovery period is necessary for accumulation of energy reserves for regrowth.

23.1.3.1.4

Tall Fescue

Tall fescue is a deep-rooted, long-lived, sod-forming grass that spreads by short rhizomes. Tall fescue is suitable for hay and pasture because it is widely adapted and persists on acidic, wet soils of shale origin. The grass is drought resistant and survives under low fertility conditions and abusive management. Tall fescue is the best grass for areas with heavy livestock and excessive traffic. Most of the tall fescue in older, permanent pastures contains a fungus (endophyte) growing in the plant. The endophyte is associated with poor palatability and broodmare performance.[9] This endophytic fungus, *Acremonium coenophialum*, in the pastures and the hay affects the reproductive performance of the broodmare and the growth performance of young horses. One should include deep-rooted legumes with tall fescue if the grass is to be used for pasture. Legumes improve animal performance, increase forage production, and dilute the toxic effects of the endophyte when it is present. Newer endophyte-free varieties are recommended for pastures and hay. When buying seed, one should make sure the tag states that the seed is endophyte free. Because endophyte-free varieties are less stress tolerant than the endophyte-infected varieties, they require more careful management.

23.1.3.1.5

Smooth Bromegrass

Smooth bromegrass is a leafy, sod-forming perennial grass best suited for hay and early spring pasture. Smooth bromegrass spreads by underground rhizomes and through seed dispersal and is best adapted to well-drained silt-loam or clay-loam soils. Smooth bromegrass is a good companion with cool season legumes, matures later than orchard grass in the spring, and makes less summer growth or tons per acre. Smooth bromegrass is winter hardy and because of its deep root system survives periods of drought. Smooth bromegrass produces excellent-quality forage, especially if harvested in the early seed head (boot) stage.

23.1.3.1.6

Perennial Ryegrass

Perennial ryegrass is a bunchgrass suitable for hay or pasture. Perennial ryegrass produces excellent-quality and palatable forage, is a vigorous establisher, has a long growing season, and is high yielding under good fertility when moisture is not lacking. Because perennial ryegrass is less winter hardy than other grasses, it is best seeded in combination with other grasses and legumes. Perennial ryegrass does not do well in the central and southern states because it is not heat or drought tolerant; however, perennial ryegrass is used commonly in those regions to provide winter grazing. Perennial ryegrass can be grown on occasionally wet soils. Perennial ryegrass is less competitive with legumes than orchard grass and is usually later to mature than orchard grass. Perennial ryegrass can withstand frequent cutting or grazing but is more difficult to cut with a sickle bar mower and is slower to dry than other grasses, causing it to mold more easily.

23.1.3.1.7

Cereal Grasses

Cereal grasses are those from common cereal grain crops: oats, barley, wheat, and rye. They are cut while the crops are still green, usually in the dough stage, and the grain remains part of the hay.[10] When cut at the appropriate stage of maturity, cereal grasses can be a satisfactory forage for horses. Field observations indicate that horses may prefer small grain hays in the order of oats, barley, wheat, and rye.[11] As these

cereal grain crops mature, their quality and digestibility decrease rapidly and they become tough and fibrous as the ADF and NDF increase.[12]

23.1.3.2 Warm Season Grasses

23.1.3.2.1 Bermuda Grass

Bermuda grass is popular in the southern United States. Coastal Bermuda grass more often is grown for hay because it grows taller than common Bermuda, which is generally too short for good hay yields. The nutrient content is similar to timothy, if cut at the same stage of maturity. To assure as high a RFV as possible, Bermuda grass should be well fertilized and cut at a 15-inch height for the first cutting hay and every 21 to 28 days thereafter.

23.1.3.2.2 Bahia Grass

Bahia grass is grown over much of the southern coastal plain, primarily for grass pasture and secondarily for hay.[8] Therefore hay often is made from surplus pasture growth, which results in overly mature hay with a RFV of less than 86. However, Bahia grass cut in the prebud stage has a RFV of greater than 103.

23.1.3.2.3 Prairie Grass

Prairie grass (Matua) is a tall-growing perennial bunchgrass introduced from New Zealand. Prairie grass is
used mainly in the midwestern and western United States. Prairie grass is adapted to well-drained soils 1546
with medium to high fertility and a pH of 6.0 or higher. Prairie grass is a type of bromegrass but differs 1547
from smooth bromegrass in that it does not spread by rhizomes and produces seed heads throughout the growing season. The RFV of prairie grass can equal cool season grasses, if cut in the boot stage of maturity.

23.1.3.2.4 Bluestem

Bluestem grows throughout the Central Plains of the United States. The most common types used for hay are big and little bluestem. Both make highly palatable horse hays of acceptable quality, but they mature rapidly. Therefore the RFV drops quickly if they are not cut in the preboot stage.

23.1.3.2.5 Sorghum

Sorghum families of grass include Sudan grass, Johnsongrass, and Sorghum/Sudan hybrids. Johnsongrass is a tall, rapidly growing grass often regarded as a weed because of its rapid maturity rate, leading to coarse, unpalatable, and low RFV hay.[8] Sudan grass hay if cut too early can contain toxic levels of prussic acid and should be tested before feeding. A report by J. C. Reager (Texas Veterinary Medicine Diagnostic Laboratory, unpublished data, 1987) indicates that Sudan grass hay may cause the same types of problems described for horses consuming Sudan grass pasture.[1] Careful management and harvesting are necessary to avoid these problems, and one should take extra precaution if one intends to feed any of the sorghum family to horses.

23.1.3.2.6 Wheatgrass

Wheatgrass normally is grown for pasture in the Northern Plains states. Wheatgrass is hardy and if cut in the boot stage can produce good-quality forage with a RFV greater than 103. However, as this grass matures, its quality and digestibility decrease rapidly.

23.1.4 LEGUMES

Legume species include alfalfa, clovers, lespedeza, and bird's-foot trefoil. All legumes require a deep, well-drained, fertile soil with a near neutral pH of 7.0 and a subsoil pH of 6.0 for germination, greatest production, and persistence. All legumes are classified as dicotyledon, and the lysine makes up 5.1% of the crude protein.[6]

23.1.4.1 Alfalfa

Alfalfa has become the predominant legume grown in the United States. Alfalfa is leafy and fine stemmed, produces high yields, is resistant to many pests and diseases, and is high in digestibility and palatability when harvested with a RFV of greater than 103. Alfalfa has good seedling vigor and excellent drought tolerance and produces good summer growth. However, alfalfa is prone to damage by the alfalfa weevil and potato leafhopper. To capitalize on the potential of alfalfa, one should select high-yielding alfalfa varieties with resistance to problem diseases in the growing area. Blister beetles sometimes enter alfalfa fields and can end up in the harvested product. Cantharidin toxicosis from the ingestion of the blister beetles was first reported in horses in 1978. The larva of the blister beetle only consumes grasshopper eggs, so the areas with the best control of the grasshopper have less chance of their forages containing the beetle. The adult blister beetle is attracted to the flower of the alfalfa plant, so it becomes critical to cut and harvest alfalfa in the prebud stage, before the blossom develops, or to remove the crimper on the hay bind so the beetle can escape.[13]

23.1.4.2 Red Clover

Red clover is a short-lived perennial legume grown for hay, pasture, and green manure crop. Red clover is better adapted than alfalfa to soil that is poorly drained and slightly acidic; however, greatest production occurs on well-drained soils with high water holding capacity and pH above 6.5. Red clover is one of the easiest legumes to establish but is not as productive as alfalfa in the summer. Most of the improved varieties are medium types and have good levels of disease resistance to northern and southern anthracnose and powdery mildew. These and other diseases can reduce stands quickly. If red clover is cut after the bloom stage of maturity, the hay has course, thick stems that are difficult to dry and may become moldy, dark, and dusty when baled. Red clover also can be infected by *Rhizoctonia leguminicola*, a fungus that produces an alkaloid called slaframine, resulting in the condition know as “slobbers.”[13] This fungus is found in the flower, so harvesting or topping the pastures in the bud stage can keep this from occurring.

23.1.4.3 White Clover

White clover is a low-growing, short-lived perennial legume well suited for pastures. White clover improves forage quality of grass pastures and reduces the need for nitrogen fertilizer. White clover has a shallow root system compared with other legumes and does not tolerate prolonged dry spells. Although well-drained soils improve production, white clover tolerates periods of poor drainage.

23.1.4.4 Alsike Clover

Alsike clover is a short-lived perennial legume that is tolerant of wet, acidic soils. Alsike clover grows in low-pH soils, which are too acidic for red clover and alfalfa, and survives in alkaline (high pH) soils. Alsike can withstand spring flooding for several weeks. A cool and moist environment is ideal for alsike clover growth; it has poor heat and drought tolerance. Mild to severe photosensitization reactions and hepatitis have been reported in horses consuming alsike clover.[14] The thick stem and leaf make alsike clover difficult to dry for hay, increasing its susceptibility to mold. Common molds such as *Penicillium* species can convert coumarin, a nontoxic substance, to dicumarol, which interferes with the activation of vitamin K, making it a potent anticoagulant. 1547

1548

23.1.4.5 Lespedeza

Lespedeza is a warm season legume and can be used for hay, pasture, and soil erosion control. Lespedeza is low yielding but can be grown on acidic and low-phosphorus soils; however, it responds well to lime and phosphorus fertilization. Lespedeza grows best on well-drained soils, is a dependable reseeder, and can persist in pastures for years if allowed to reseed each year.

23.1.4.6 Bird's-Foot Trefoil

Bird's-foot trefoil is grown in parts of the temperate zone but has lost favor with many producers because it is difficult to establish and weak stemmed and is slow to recover from gazing.[16]

23.1.5 SOIL FERTILITY

Management of soils for pastures and hay fields is a continuous process, often only considered by horsemen during establishment. Managing fertility for continued productivity and health of the plant is also important.[16] If the soil lacks major or trace minerals, the health and productivity of the plant is affected negatively. When horses consume plants, as pasture or hay, grown on poorly maintained soils, their health, skeletal development, reproductive status, and performance level also can be affected negatively.

If forages are grown and fertilizer is not added to replace the nutrients the plants have used, the nutritional value of the soil decreases. Over time, from “mining” of the soil, the quantity and quality of the forage grown on it also decreases. The decrease in forage quality and yields depend on the following:

- The initial nutrients in the soil, as indicated by soil test results
- The nutrients removed each year by the harvested crop (pasture or hay)
- The reserve nutrients of the soil
- The length of time from the last application of fertilizer

Forage crops traditionally have received less fertilizer than grain crops, yet high-yielding forage crops remove much more phosphorus and potash than grain crops. Adequate fertility is essential to maintain the forage stand and to prevent forage yields from tapering off as the stand ages.[4] Each ton of forage is estimated to remove 13

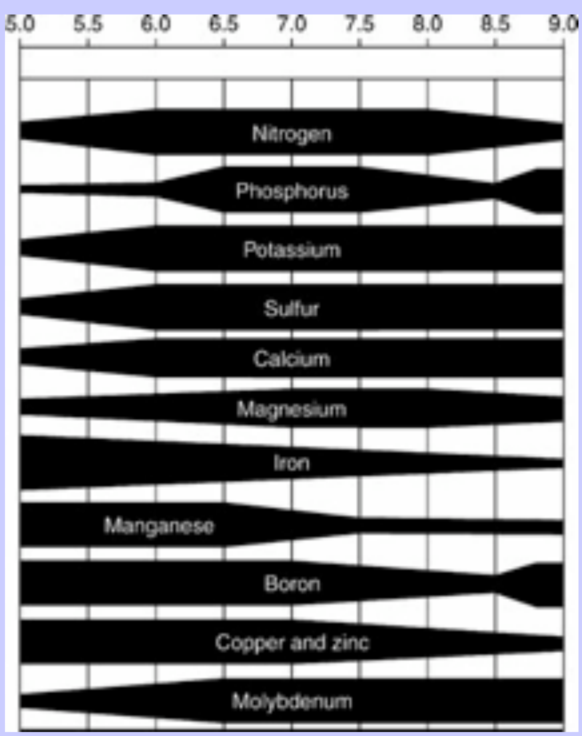
pounds of phosphate and 50 pounds of potash from the soil per year. Forage productivity varies from 1 ton to 8 tons per acre, depending on plant type, soil type, climate conditions, rainfall, and fertilizer applied. These nutrients must be replaced through commercial fertilizers or spreading manure to recycle the urine and manure of the horse[16]; otherwise, the health of the plant and then the health of the horse also will be affected negatively.

Soil pH has considerable influence on forage quality and plant growth. Soils may become more acidic naturally because of the leaching of basic cations, primarily calcium, magnesium, potassium, and sodium. Furthermore, when the plant takes up these basic cations from the soil, they are replaced with hydrogen, contributing further to acidification of the soil. Soil pH is of the utmost importance in plant nutrition, because it has an influence on the availability of many crop nutrients. The most common way to increase the soil pH is to apply lime. Application of limestone at least 6 months before seeding and splitting the yearly applications for spring and fall gives time for the lime to affect the soil pH.[4] One should consult an agronomist, fertilizer company, or local agriculture extension agent for assistance. Forage plants have optimal growth and nutrient absorption when the soil pH is between 6.0 and 7.0 (Figure 1).[16]

Nitrogen availability in the soil is associated with microbial activity. Microbes are involved in organic matter decomposition, which helps convert organic nitrogen into forms that are available to the plant. As soil pH decreases, the bacteria become less adapted, decreasing the mineralization of organic nitrogen compounds.

Phosphorus becomes less available as soil pH decreases. Insoluble iron and aluminum phosphates form, thus phosphorus becomes essentially unavailable to plants grown on soils below 5.5 pH.

Figure 1 The relative availability of nutrients essential for plant growth at different soil pH levels.



1548

Calcium and pH are directly related because the soil calcium concentration primarily determines pH. When the soil base saturation of calcium is high, 90% or more, the pH usually is high (6.5 or greater). When the base saturation of calcium is low, 50% or less, the pH usually is low (5.0 or less).

Potassium is particularly important for legumes, because it influences not only yield but also persistence. When legumes lack potassium, they are more likely to suffer winterkill. Two applications per year, rather than one, may be desirable on sandy soils that have a low exchange capacity. High applications of potassium lower the magnesium content of forages, which often has no affect on legume yield but may influence the mineral feeding program required.[4]

As with calcium, soil pH also influences magnesium, a basic ion. When the soil pH is low, magnesium becomes less available and has the potential to leach.

Sulfur and its availability are influenced greatly by the activities of microorganisms. A soil pH that favors forage growth generally favors microbial activity and sulfur availability. Sulfur has great potential to attach to many of the other minerals (calcium, magnesium, and potassium), which then leach out as sulfates.

Iron, manganese, zinc, and copper become increasingly available as soil pH drops. Soil pH levels of 7.0 or greater can result in low concentrations of these trace minerals in forages.

Aluminum availability increases when the pH drops below 5.0, such that it may become toxic to horses.[16]

23.1.6 FEEDING FORAGES

23.1.6.1 Fresh Pasture

Horses are herbivores by design and foragers by nature. They graze up to 18 hours per day on pasture, hay, or haylage.[17] Climates that allow forages to grow and horses to be pastured on them provide the ideal setting to raise horses. A well-managed pasture provides excellent-quality forage at a reasonable price, and if the types of forages can be blended together, one can maximize the number of grazing months available for horses and minimize the amount of hay and grain used for feed. An example is to blend cool season grasses to provide excellent spring and fall grazing and warm season grasses to provide summer grazing and to mix in a legume, which withstands grazing, to provide a higher quality of protein and calcium. The legumes also help reduce fertilizer cost because legumes have the capacity to use atmospheric nitrogen, reducing the need to apply it as commercial fertilizer. Legumes also supply a considerable amount of nitrogen to the grasses associated with them in the mixture, depending on the percentage of legume in the mixture.[4]

One should not feed fresh lawn clippings to horses. The possibility of (1) molds forming in the uneaten wet clippings and (2) high nitrates in lawn grasses that have been fertilized frequently can be detrimental to their health. One should *never* feed clippings from ornamental shrubs to horses. Most of the shrub clippings are or become toxic to horses as they wilt.

23.1.6.2 Dried Hay

If forages in a pasture field are not available for horses to graze, farm managers must provide dried hay, ad lib, in their exercise lot or box stall. Horses are continuous grazers because of their small stomach and the

fast rate of passage of forage through their intestinal tract. To maximize feed efficiency, increase nutrient absorption, decrease the incidence of colic, and improve the mental state of the horses, managers should provide hay for them to eat 24 hours per day. This is the same as allowing horses to graze on pasture 24 hours per day.

Harvesting forage and putting it into bales is advantageous to preserve it and enable it to be transported in a more dense form. The disadvantages are the labor to move the bales, storage requirements, and absorbing the losses incurred with baling and storage. The nutrients lost in storage are (1) protein, which occurs in the first 3 weeks after storing, and (2) the oxidizable vitamins A and E. Major and trace minerals, fiber level, and digestible calories per pound do not change in stored hay. Hay having more than 20% moisture is at risk from spoilage because of microorganisms metabolizing sugars in the hay and giving off heat. The final internal temperature reached in the curing hay is related to (1) percentage of moisture in the hay, (2) density of the bales and how tightly they are packed in the mow, and (3) the temperature and humidity of the outside air. The Browning reaction, caused by too high a temperature during the curing process, can be identified first by the odor of caramel candy, from the caramelization that occurs. The heat damaged protein can be analyzed for and subtracted from the crude protein in the hay when one balances the diet.[5] Flash fires also can result from the internal curing temperature becoming too high within 3 weeks after storing. Ninety percent of the oxidizable vitamins are lost during the drying and curing process, and their half-life after that is 60 days. For example, fresh grass pasture contains 330 IU or mg/lb of vitamin E on a dry matter basis.[18] After cutting, drying, and curing in storage for 3 weeks, the grass contains 33 IU/lb. For every 60 days in storage after that, the amount of vitamin E decreases by half. Therefore after 6 months the hay would contain approximately 4 IU/lb of vitamin E. This is one reason during the winter that one sees vitamin A and vitamin E deficiencies in horses fed hay that has been stored more than 6 months along with straight cereal grains.

1549

Table 4 provides the horse owner with a visual estimate for evaluating hay quality. Although not as reliable 1550
as forage testing, these guidelines allow sensory evaluation. Hay that is cut early, leafy, soft, green, and free of foreign material and has a pleasant aroma is high-quality and has a high RFV.[19]

TABLE 4 Scorecard for Visual Hay Quality Evaluation

VISUAL EVALUATION[*]		POSSIBLE SCORE	YOUR SCORE
I. Stage of Harvest			
Example: Timothy head length			
1. Prebud	1. Before blossom or heading	26–30	
2. Less than 1 inch	2. Early blossom or early heading	21–25	
3. 1 to 4 inches	3. Mid to late bloom head	16–20	
4. More than 4 inches	4. Seed stage (stemmy)	11–15	
II. Leafiness	1. Very leafy	26–30	
	2. Leafy	21–23	
	3. Slightly stemmy	16–20	
	4. Stemmy	0–6	
III. Color			
Note: The *outside* of a bale will bleach out from light, but this does not affect quality.	1. Natural green color of crop	13–15	
	2. Light green	10–12	
	3. Yellow to slightly brownish	7–9	
	4. Brown or black	0–6	
IV. Odor	1. Clean: crop odor	13–15	
	2. Dusty	10–12	
	3. Moldy: mousy or musty	7–9	
	4. Burned (caramel smell)	0–6	
V. Softness	1. Very soft and pliable	9–10	
	2. Soft	7–8	
	3. Slightly harsh	5–6	
	4. Harsh, brittle	0–4	
		Subtotal:	
VI. Penalties	1. Trash, weeds, dirt, etc.	Subtract 0–35	
QUALITY STANDARD[†]	**RFV**[†]	**VISUAL GRADING SCORES**[‡]	

Prime (Prime)	>151	95–100	Total:
1 (Premium)	150–125	85–94	
2 (Good)	124–103	75–84	
3 (Fair)	102–87	65–74	
4 (Poor)	86–75	55–64	
5 (Reject)	<74	Below 54

† Quality standard and relative feed value (RFV) are assigned by Hay Market Task Force of the American Forage and Grassland Council.

‡ Visual grading scores.

Dried hay can be fed as long stemmed, as a square or round bale, or chopped and then cubed or pelleted. The form is irrelevant, once the horse becomes used to it. But the manager must feed these different forms by the pound. If cubes or pellets are fed, they too must be fed in similar quantity to the long-stemmed hay. However, the horses are able to consume the processed forages faster, so feeding them the cube or pellet 4 to 6 times per day is recommended. This reduces the incidence of boredom and prevents bad habits from developing, such as eating their bedding and feces, cribbing, wood chewing, weaving, and stall walking.

23.1.6.3 Preserved Haylage

In areas of the country where drying is difficult, harvesting forage at 50% dry matter and putting it into a plastic bag to ferment and stabilize has become popular. Fermentation has some advantages over storing the forage as hay that include (1) lower harvest losses and (2) less dependence on good drying conditions, thereby allowing the crop to be cut at the desired maturity. The disadvantages are that (1) if a rodent or machine punctures the bag, allowing oxygen inside the bag, the forage will mold or spoil and should not be fed and (2) the higher moisture level increases the cost of dry matter pounds shipped. When forage is first put into a plastic bag, conditions are aerobic (air is present). Aerobic bacteria produce heat as they breakdown 1550
carbohydrates and sugars into carbon dioxide and water and use up the trapped oxygen. When the air has 1551
been consumed, the haylage becomes anaerobic (free of oxygen) and this promotes the growth of anaerobic bacteria. These organisms convert the carbohydrates and sugars to organic acids that preserve the haylage. Within 3 weeks, the haylage reaches a stable pH of 4.5 to 5.0 and all bacterial and enzymatic activity stops. Once this stable pH has been reached, further breakdown of nutrients and spoilage stops, preserving the haylage for extended periods, provided that no oxygen enters.[4]

Preserved haylage has proved to be palatable to horses when harvested at optimal maturity and can provide excellent-quality forage. Unfortunately, if harvested late, the quality of the haylage is the same as dried hay cut at the same maturity level.

23.1.7 SUMMARY

All horse owners and managers must become more quality conscious of the forages they are feeding. Knowledge of forage quality and how it influences the growth, reproduction, and performance of their horses also can result in a more efficient and economical feeding program. Reliable analytic data is the foundation of a

balanced diet. Nutrients in forages such as protein and major and trace minerals can be measured accurately and their results entered into an equine computer ration–balancing program for ease of calculation.

However, the requirements of horses for ADF and NDF have not been established. Fiber levels in the total diet may have to be adjusted based on the veterinarian's and farm manager's experience and specific conditions found on the farm. When evaluating problem cases, nutritionists and veterinarians should not place much confidence in book values. They represent a good average but may not necessarily represent the specific forage being fed on that problem farm. When a diet appears adequate on paper but does not perform as expected, one should evaluate the data used to formulate the total diet. One still should consider equine nutrition an art and a science.

23.2 Cereal and Protein Grains: Explanation and Analysis

Concentrate is a broad term for all grains or mixture of grains used to manufacture feeds for the sole purpose of feeding it to horses. Concentrate is one grain mixed with another to improve the nutritive balance of the total and is intended to be diluted further to produce a grain mixture or a complete feed. Concentrates also are classified into two types: calorie-dense cereal grains from the grass family and high-protein grains from the legume and the grass families. All cereal grains, including oat, barley, corn, milo, wheat, rice, are grasses, and their lysine levels make up 2.9% to 3.8% of the crude protein. Cereal grains are considered low in quality amino acids, based on their lysine levels, and are higher in starch (carbohydrates) than all grass forages. Cereal grains also can be added to the diet of horses to provide extra calories to help maintain or gain body weight. The highest-quality protein grain is soybean, a legume with the lysine level making up 6.3% of its crude protein. The quality of amino acids is excellent, based on the lysine level.[2] Medium to high oil grains from the grass family include cottonseed, canola, linseed, and distiller's and brewer's grains and have a lower lysine level of 1.7% to 4.3% of the crude protein, and the quality of their amino acids is low based on the lysine levels. However, oil grains are higher in crude protein concentration than their grass or legume forage counterparts (Table 5). Lysine is the first limiting amino acid in horse diets today. To optimize growth and reproductive performance when feeding growing horses and pregnant or lactating mares, all amino acid concentrations, including lysine, must be present and in adequate amounts in their total diet. If a protein source other than soybean meal is used in the grain mixture, additional amino acids may be required. One adds protein grains or individual amino acids when they are needed to complement the forage part of the diet and to meet the nutrient needs of the horse. Usually one mixes a combination of cereal grains and protein grains with major minerals, trace minerals, and vitamins to balance the diet of horses. This grain mixture improves the nutritive balance or performance of the total and is intended to complement the forage part of the diet.[20] The percentage of each cereal and protein grain in a grain mixture depends on (1) the type and quality of forage it is formulated to complement, (2) how many pounds are to be fed per day per horse, and (3) the physiologic status of the horse, that is, idle, growing, reproducing, or performing.

23.2.1 CEREAL GRAINS

Many cereal grains are fed to horses throughout the world. The most abundant cereal grains in North America are oat, barley, corn, milo, and wheat. These grains vary in calories per pound and in percentage of crude protein, fat, and fiber. The largest variable is the quantity and type of starch structure found in each cereal grain. Each cereal grain varies based on percent fat, lysine, and the percentage of starch. Because all oils and proteins (amino acids) are found in the germ portion of the seed, the higher the protein and oils, the lower the starch content and weight per bushel. Therefore the higher the bushel weight of cereal grains, the lower the percentage of protein and oil in the analysis, and visa versa. All cereal grains are fed to provide a more concentrated source of calories in the diet of the horse. Compared to forage with a RFV below 86, cereal grains can provide 50% to 1551

100% more digestible energy per pound and in a much smaller volume. Cereal grains vary in size, weight per unit of volume, and nutrient content. For this reason, grains and grain mixtures should be fed by weight and not volume (i.e., by coffee cans or scoops).[15] Cereal grains, in order of ease of digestion, are oat, rice, wheat, barley, red milo, and corn. This order is based on the percentage of tertiary bonds in the starch structure, which slow the rate at which starch can be broken down by the enzyme amylase. 1552

TABLE 5 Comparison of the Range of Nutrient Contents of Cereal Grains, Grass Hays, High-Protein Grains, and Legume Hays

NUTRIENTS	CEREAL GRAINS[*]	GRASS HAY[†]	PROTEIN GRAINS[‡]	LEGUME HAYS[§]
Crude protein (%)	6.00–12.00	4.00–12.00	27.00–48.00	18.00–24.00
Cystine (%)0.07–0.14	0.04–0.14	0.32–0.68	0.24–0.34	
Lysine (%)0.20–0.42	0.14–0.42	0.90–3.30	0.92–1.22	
Methionine (%)	0.08–0.16	0.05–0.16	0.35–0.75	0.28–0.37
Threonine (%)	0.22–0.43	0.14–0.43	0.97–2.10	0.79–1.05
Fat (%) 1.80–4.60	1.00–3.00	1.00–18.00	2.50–3.50	
Digestible energy (Mcal/lb)	1.20–1.60	0.80–1.00	1.30–1.90	1.00–1.20
Acid detergent fiber	3.60–14.20	35.00–48.00	5.50–17.50	28.00–35.00
Calcium (%)0.01–0.10	0.25–0.80	0.17–0.35	1.20–1.80	
Copper (ppm)	4–8	4–10	20–25	6–10
Iron (ppm)31–73	80–200	35–319	100–200	
Magnesium (%)	0.11–0.14	0.15–0.25	0.30–0.60	0.20–0.35
Manganese (ppm)	5–36	40–70	21–49	40–50
Phosphorus (%)	0.25–0.35	0.20–0.30	0.50–1.10	0.25–0.35
Potassium (%)	0.32–0.44	0.80–1.50	1.20–2.10	2.00–3.50

* Oat, barley, corn, milo, wheat, and rice.

† Timothy, orchard grass, Kentucky bluegrass, fescue, bromegrass, Bermuda, Bahia, prairie, and bluestem.

‡ Soybean, linseed, cottonseed, peanut meal, distiller's grains, and brewer's grains.

§ Alfalfa, clover, peanut, lespedeza, and bird's-foot trefoil.

Monitoring body condition and weight changes of individual horses is generally the preferred method to assess calorie balance, because differences in horse breeds, metabolic rates, body type, and temperaments tend to produce more variation among equines than all other livestock species. Carbohydrates, fats, proteins, and some fibers are all useful sources of energy. Horses can use fats/oils effectively and easily absorb fat at concentrations of up to 7% in the total diet or 15% in the grain mixture, which is approximately 0.8 kg of fat/oil per 500 kg of body mass per day. Even though horses have no gall bladder, they have a continuous flow of bile from the liver into the small intestine to emulsify the fats/oils in their diets. Everything that the horse consumes contains some fat/oils. For example, fresh forage and pasture contain greater than 5.0%, whereas dried, baled forages contain between 1.0% and 3.0%, based on the maturity when harvested. Adding fat to equine diets is an effective method of increasing caloric density for horses that have difficulty meeting calorie needs because of maladies of old age, such as poor teeth or malabsorption; for horses with high calorie demands because of intense work schedules[21]; for horses affected with equine polysaccharide storage myopathy; or for horses with glucose intolerance and hyperinsulinemia. Research suggesting that added dietary fat may reduce the heat production of performance horses working under hot and humid conditions[22] and enhance the oxidative capacity of muscle[23] continues to stimulate interest in this dietary supplement for horses.[21]

23.2.1.1 Oat

Oat has long been the favorite and preferred grain of horse owners. Oat, depending on its weight per bushel, contain between 9.0% and 12.0% crude protein, 0.26% and 0.46% lysine,[20] and 10.0% and 15.0% crude fiber. The heavier the oat, the lower the percentage of protein, lysine and fiber, because it has a higher percentage of starch. The starch content in heavier oat averages 38% and is amorphous structured, which means the carbon chains are in a straight line and digestive enzymes can break them down easily so the horse can absorb them in the small intestine. Therefore oat is the safest of all the unprocessed cereal grains to feed
to horses because more pounds are required per feeding to cause a digestive upset. The maximum safe 1552
amount to feed per feeding of oats is 5 lb/1000 lb body weight. Oat is purchased in the United States based 1553
on weight per bushel. Normally the price is based on 32 lb; however, a bushel can weigh as much as 46 lb. To grow a plump, white oat, the growing season must be cool and have low humidity. Thus oat grown in the northern part of the United States, Canada, or the Norwegian countries is the most sought after and the most expensive. Cold crimping or heat processed crimping of the oat does not make the starch easier to digest but makes it more available for the enzymes to break down because it cracks the outer hull. Crimping increases the cost 10% to 14% over whole oat. A good rule of thumb is that if one sees 10% or more of the oat passing through in the manure, one should purchase the crimped oat and feed 10% less per day.

Steam rolled oats and naked oats have a similar analysis because they have no oat hull. The steam rolled oats have had their hull removed before rolling, and the naked oat is grown without a protective covering (hull). They are basically the groat of the oat, which is where the digestible nutrients are found. They analyze at between 14% and 16% crude protein, 0.39% and 0.46% lysine,[20] and 2.0% and 3.5% crude fiber. The starch content averages 60% and is the easiest type of starch for the equine digestive system to break down (amorphous structure). The calories per pound are almost as high as corn but are much easier to digest. Thus oat is a common ingredient in foal feeds, for horses which have sensitive digestive systems, and the halter horse industry, where feeding 10% to 20% higher calories/day is necessary to maintain the desired 10% to 20% extra body condition.

23.2.1.2 Corn

Corn has taken over as the number one grain fed to horses in the United States because of its lower cost and higher calories per pound. Corn, depending on its weight per bushel, contains between 6.5% to 9.0% crude protein, 0.20% and 0.27% lysine,[20] and 2.0% and 3.0% crude fiber. The starch in corn averages 65% and is crystalline, which means the carbon chains are tightly bound tertiary bonds that hydrate more slowly than the amylopectin starches and are less vulnerable to enzymatic activity while passing through the equine digestive system.[24] Therefore one should feed corn most carefully because it is the easiest to overfeed and can cause digestive upsets in the horse. The maximum safe amount to feed per feeding of whole or cracked corn is 4 lb per 1000 lb body weight. Corn is purchased in the United States by how much it weighs per bushel. Normally the price is for 56 lb, but corn can vary from 50 to 60 lb per bushel. The same is true for corn as for all grains: the heavier the grain, the higher calories per pound, but the lower the percent of crude protein and fiber, and visa versa.

Cracking or cold rolling the corn does not change the starch structure; however, breaking the hull makes the starches more available for the enzymes to break down. Heat processing, which is the approved term of the Association of American Feed Control Officials (AAFCO) to use on a feed tag for "cooking," changes the starch structure and makes it easier to break down in the small intestine. The different internal temperature of the grain, when cooked, results in different responses to improved digestibility. The approximate values are these:

- Pelleting, at 180° F, improves feed efficiency of corn by 5% to 6%.
- Steam, at 212° F, improves feed efficiently by 10% to 12%.
- Extruding, at 260° F and under pressure, has the highest effect on digestibility and improves feed efficiently by 30%.

Extrusion or popped corn results in the starch being broken down to maltose, allowing it to be absorbed easily in the small intestine. For this reason, extruded horse feed may be recommended for horses with hindgut functioning problems, horses prone to colic, horses having had intestinal surgery, those rescued from starvation, and high-performance horses when more than half of their diet is grain and they are still loosing body condition. The manufacturing cost of pelleting and steam crimping increases the price 6% to 8%, and 12% to 16%, respectively, whereas the cost of extruding increases the price by 30% to 40%.

Recent advances in corn genetics have produced corn containing up to 7.0% oil and crude protein 1.0% higher than the current average (higher lysine). As the sum of oil and protein percentage increases, the starch content decreases by approximately the same percentage.[25] Genetic research also has improved the phosphorus availability by greater than 50%, thus reducing the need to increase the total phosphorus in the diet, and changed the starch structure to remove the amylose and replace it with amylopectins.[24] More will be heard about "environmental friendly" corn in the future, as well as the feed industries' addition of the phytase enzyme (to improve digestibility of phosphorus) into grain mixtures.

Molds in the soil lay dormant until the right environmental conditions are present, and then they propagate. All grains grown under drought or stressed conditions and harvested under moist conditions are prone to contain molds. Corn is the most susceptible because it is harvested in the autumn. Outbreaks of aflatoxicosis and leukoencephalomalacia in horses, caused by toxins produced by *Aspergillus flavus* and *Fusarium*

moniliforme, respectively, have raised concerns.[26] In response, most feed companies voluntarily began screening corn shipments for the presence of aflatoxins, reducing the threat of commercial feed contamination.[15]

23.2.1.3 Barley

In certain parts of the world barley is the only cereal grain fed to horses. In the United States, barley is grown 1553
primarily on the East and West Coasts and therefore commonly is used in horse grain mixtures in those 1554
regions. However, with the increasing cost of oat, more barley is being fed to horses throughout the United States. Barley, depending on its weight per bushel, contains between 9.0% and 12% crude protein, 0.33% and 0.44% lysine,[20] and 4.0% and 6.0% crude fiber. The starch content of barley averages 50%, and ease of digestibility falls between corn and oat; therefore barley is a good choice for horses. The grain is larger in diameter than oat but has a tenacious seed coat; therefore barley should be cold or heat processed crimped to improve digestibility.[15]

23.2.1.4 Milo

In the southern United States milo is a common, high-calorie feed for horses. Milo, depending on its weight per bushel, contains between 9.0% and 11.0% crude protein, 0.27% and 0.33% lysine, and 2.0% and 3.0% crude fiber. The starch content of milo averages 57%, which is lower than corn and wheat but higher than all other cereal grains. The same cautions apply as for corn regarding overfeeding, and milo should be heat processed steam flaked or rolled to change the starch structure and improve digestibility.

23.2.1.5 Wheat

In Europe, where more wheat is grown than other cereal grains, heat processed rolled wheat is a mainstay in the formulae of horse grain mixtures. Wheat contains between 9.0% and 11.0% crude protein, 0.26% and 0.32% lysine,[20] and 2.0% and 3.0% crude fiber. The starch content of wheat averages 60%, which makes the calories per pound almost equal to corn. If wheat is not heat processed crimped or rolled, it should make up no more than 30% of the grain mixture because of the doughy consistency of its raw starch, which can affect palatability negatively.

TABLE 6 Protein Grains: Partial Analysis

PROTEIN GRAINS	% DRY MATTER	% CRUDE PROTEIN	% LYSINE	% ETHER EXTRACT	% ADF*	% NDF	% LIGNIN
Brewer's dried grain	90.7	27.0	0.90	4.7	20.0	43.0	4.5
Canola	90.3	18.4	1.04	36.4	10.4	16.0	4.1
Canola meal	89.9	34.1	1.92	4.9	18.5	26.9	6.7
Cottonseed meal solubles	90.5	41.0	1.68	1.7	18.0	27.9	6.9
Cottonseed, whole	90.1	21.0	0.92	17.4	36.1	45.3	11.6
Flaxseed	90.0	18.0	0.64	38.0	11.8	19.3	4.5
Linseed meal (mechanically extracted)	91.0	32.0	1.10	3.5	18.5	30.2	5.5
Linseed meal (solvent extracted)	91.0	33.0	1.30	0.5	19.9	32.5	5.9
Maize distiller's dried grain with solubles	90.2	27.0	1.08	9.0	17.8	35.0	3.9
Peanut meal solubles	92.3	48.0	1.60	1.3	12.5	19.8	4.2
Soybean meal, 48%	89.5	48.0	3.30	1.0	5.5	8.8	0.4
Soybeans, cooked	91.0	38.0	2.50	18.0	13.4	20.1	2.8

* *ADF,* Acid detergent fiber; *NDF,* neutral detergent fiber.

23.2.2 PROTEIN GRAINS

All protein grains are produced as high-oil seeds, heat processed, and fed as a high-protein and high-calorie feed, or the oil is extracted, using an expeller or solvent process, and fed as a by-product feed containing higher protein levels; or they are a by-product of the distilling or brewing industries. The true value of each of these depends on the cost per unit of protein, amino acid composition and bioavailability, fat level, and cost per ton delivered to the manufacturing facility (Table 6).

23.2.2.1 Soybean

Soybean meal is the most common protein grain fed in the horse industry today because of the amino acid balance and the low cost per unit of protein. *Whole soybeans* must be heat processed by roasting or cooking to inactivate the trypsin inhibitor, but not overheated, which negatively affects the availability of the amino acids in the horse. In the soybean oil industry, the whole soybean is heat processed, the oil extracted, and the hulls removed. This dehulled soybean meal contains up to 48% crude protein, 3.3% lysine, and 3.0% crude fiber depending on the amount of oil extracted. Soy hulls are added back into the meal to create a 46%, 44%, or 42% protein meal, depending on what the purchaser wants, and the crude fiber varies from 6.0% to 7.0%. Of course, the lower the percentage of protein (amino acids), the lower the cost per bag or per ton, but the cost per unit of protein increases. Heat processed whole soybeans, a legume, are used more in the equine 1554

industry today because of the value of the added oil with the high-quality amino acids. Heat processed whole or flaked soybean contains 38% protein (2.5% lysine), 18% oil, and 5.0% crude fiber.

23.2.2.2 Linseed Meal

Linseed meal for years was fed to increase crude protein and improve hair coat. However, when the flaxseed oil extraction process went from the press, or expeller process, to solvent extraction, the remaining oil in linseed meal decreased from 8.0% to 0.5%. Thus horses fed processed linseed meal today lose the extra bloom from their hair coats. *Flaxseed* is called linseed meal after the extraction of the oil, but the name was not changed after the reduction in the percentage of oil on the analysis tag. Because linseed is in the grass family, the percent of lysine is low; however, the high level of the ω-3 fatty acid is what imparts the extra health and shine in the hair coat of the horse. Linseed meal contains 33% crude protein (1.3% lysine), 0.5% fat, and 9.5% crude fiber, whereas flaxseed contains 18% crude protein (0.64% lysine), 38% fat, and 6.7% crude fiber.

23.2.2.3 Canola

Canola seed is starting to be used more in the Midwestern states as horse feed. Canola is a high-oil seed that can be used for its protein and high calories or as a high-protein grain after the oil has been extracted. Canola seed or meal may contain antinutritional components, such as erucic acid at varying levels. Canola seed contains 18% crude protein (1% lysine), 36% fat, and 14% crude fiber, whereas canola meal contains 34% crude protein (1.9% lysine), 4.9% fat, and 8.3% crude fiber.

23.2.2.4 Peanut Meal

Peanut meal has found favor in the horse industry in the southern states because that is where it is grown and harvested and the oil is extracted, so peanut meal is economical to use in that region. Although peanuts are legumes, they are a poor lysine source compared with soybean meal. Peanut meal contains 48% crude protein (1.6% lysine), 1.3% fat, and 10% crude fiber.

23.2.2.5 Cottonseed

Cottonseed meal has been included in horse diets for several years in the southern states. Cottonseed has been used extensively in dairy cow rations because of its high fat and high digestible lint content. The hulls are poorly digested but act as a good scratch factor in ruminant animals. The gossypol content of cottonseed meal limits its use. Cottonseed is a member of the grass family and so has a low lysine content; therefore one should supplement lysine when using cottonseed in a grain mixture for horses. Whole cottonseed contains 21% crude protein (0.9% lysine), 17% fat, and 29% crude fiber, whereas cottonseed meal contains 41% crude protein (1.6% lysine), 1.7% fat, and 15% crude fiber.

23.2.2.6 Maize Distiller's Dried Grains

Maize distiller's dried grains are made available to the feed industry as a by-product from the distilling industry. Basically, the hull, germ, and parts of the yeast are what remain after the starches have been used by the microbes in the distilling process and the liquid is removed. Once the grains have been dried to 10% moisture, they can be added as a protein grain and for the yeast content. One must take care during the drying

process because too much heat burns the grains, turns them black, and makes them unpalatable, and the protein is not available. Maize distiller's dried grains should be golden. Although made up of several different grains, the grains have a low lysine content but can increase fat and digestible fiber and give a pleasant aroma to horse feed. Maize distiller's dried grains contain 27% crude protein (1.0% lysine), 9.0% fat, and 14.5% crude fiber.

23.2.2.7 Brewer's Dried Grains

Brewer's dried grains are made available from the brewing industry. The grains are palatable once dried to 10% moisture and can be added to horse feed as a protein source. Because the lysine content is low, the grains should be supplemented with amino acids if used in horse feeds. Brewer's dried grains contain 27% crude protein (0.9% lysine), 4.7% fat, and 16% crude fiber.

23.2.2.8 By-Product Feeds

By-product feeds come from the food industry. They are normally low in starch, high in crude fiber, and vary in the ability of the horse to ferment and digest them. The only way to tell their nutritional value is to look at the level of fat and ADF, NDF, and lignin levels. These fiber levels allow one to see whether they are fermentable or whether they are added as a low-calorie ingredient that cannot be broken down and used by the horse.

Comparing the analysis of the by-product feeds in Table 7 to the cereal and protein grains, one sees that the by-product feeds have a higher ADF, NDF, and lignin percentages. These higher percentages, especially the percentage of lignin, reflect a fiber source the horse is less able to break down by fermentation in the hindgut.

23.3 Major Minerals, Trace Minerals, and Vitamins

The purpose of adding major minerals, trace minerals, and vitamins to a grain mixture is to provide those nutrients 1555
that are low or deficient in forages in an amount to meet the nutrient needs of the horse. The vitamin 1556
recommendations from the National Research Council (NRC) for horses only include vitamins A, D, and E; thiamine; and riboflavin.[15]

TABLE 7 By-Product Feeds: Partial Analysis

BY-PRODUCT FEEDS	% DRY MATTER	% CRUDE PROTEIN	% LYSINE	ETHER EXTRACT	% ADF*	% NDF	% LIGNIN
Beet pulp, dried	88.3	8.8	0.38	1.0	20.4	40.4	1.4
Citrus pulp	85.8	5.9	0.15	4.2	19.0	20.8	0.8
Cottonseed hulls	89.0	5.5	0.26	2.2	57.8	75.7	20.0
Oat hulls	93.0	2.0	0.08	3.5	39.0	72.5	7.4
Rice bran, 13% ether extract	90.6	14.0	0.65	13.8	11.9	23.6	4.2
Rice bran, 20% ether extract	90.6	13.1	0.61	20.0	11.0	22.0	3.9
Soy hulls	90.9	12.6	0.79	2.5	40.5	54.8	2.3
Wheat bran	89.1	15.4	0.62	3.8	13.8	37.9	2.7
Wheat middlings	89.5	16.6	0.60	4.0	10.8	32.8	3.8

* *ADF,* Acid detergent fiber; *NDF,* neutral detergent fiber.

Tables 8 and 9 list the most common sources of major and trace minerals used to formulate horse diets and their nutrient concentrations. Table 10 lists the vitamins commonly used in horse feed formulations.

23.3.1 FEED LABELING GUIDE

The AAFCO sets the standard for each state to accept and follow on what should be listed on the tag or bag of each horse feed.[28] The standard determines the following:

1. How much of the analysis to guarantee
2. How to list the ingredients used in the formula
3. The detail of the feeding directions to help the end user identify which feeds are best suited for their horses

TABLE 8 Major Minerals Analysis

	ELEMENT (PERCENT)						
MAJOR MINERAL	Ca	TOTAL P	Na	K	Mg	S	Cl
Calcium carbonate	38.0	—	0.06	0.06	0.5	—	0.03
Defluorinated phospahte	33.0	18.0	4.50	0.09	—	—	0.92
Dicalcium phosphate	22.0	18.5	0.08	0.07	0.6	—	1.00
Magnesium sulfate	—	—	—	—	10.0	13.0	—
Magnesium sulfate	—	—	—	—	20.0	26.6	—
Monodicalcium phosphate	16.0	21.0	0.05	0.06	0.5	—	0.70
Potassium chloride	—	—	—	51.0	—	—	49.0
Potassium sulfate	—	—	—	44.8	—	18.8	—
Sodium chloride	—	—	39.00	—	—	—	61.0
Sodium phosphate (monobasic)	—	21.8	32.30	—	—	—	—

The current AAFCO recommendations for horse feed are as follows:

Guaranteed Analysis

Crude protein	Minimum	Percent
Crude fat	Minimum	Percent
Crude fiber	Maximum	Percent
Calcium (Ca)	Mininum and maximum	Percent
Phosphorus (P)	Minimum	Percent
Copper (Cu)	Minimum	ppm
Zinc (Zn)	Minimum	ppm
Selenium (Se)	Minimum	ppm
Vitamin A	Minimum	IU/lb

Other nutrients can be listed on the tag or bag at the discretion of the manufacturer.

The most expensive ingredients used in horse feeds today are protein, phosphorus, fat, and vitamin E. The horse 1556
owner will benefit from comparing tags and purchasing the feed that compliments the forage and meets the 1557
nutrient needs of the horse at the amount per day the horse is fed to maintain desired body condition.

TABLE 9 Trace Minerals Analysis

	ELEMENT (ppm)						
TRACE MINERALS	Co	I	Mn	Fe	Cu	Zn	Se
Calcium iodide		650,000					
Cobalt carbonate	490,000						
Cobalt proteinate	90,000–100,000						
Cobalt sulfate	380,000						
Copper carbonate					570,000		
Copper oxide					800,000		
Copper proteinate					100,000–130,000		
Copper sulfate					250,000		
Ethylene-diaminedihy-droiodide		770,000					
Ferric ammonium citrate				170,000			
Ferric carbonate				480,000			
Ferric chloride				210,000			
Ferric oxide				700,000			
Ferrous fumarate				330,000			
Ferrous sulfate				200,000–300,000			
Iron dextran				20,000–50,000			
Manganese proteinate			150,000				
Manganese sulfate			230,000				
Manganous oxide			770,000				
Potassium iodide		760,000					
Sodium selenite							200 and 400
Zinc methionine						40,000 and 100,000	
Zinc oxide						800,000	
Zinc proteinate						150,000–220,000	
Zinc sulfate						330,000	

23.3.1.1 Ingredient Terminology

Individual ingredients and collective terms are the two approved ways to list ingredients on a feed tag.

23.3.1.1.1 Individual Ingredients

Individual ingredients are written out and listed in decreasing amounts used in the formula. This list permits the practitioner to assess the suitability of ingredients, which is important when one must consider the quality and consistency of major components or when specific ingredients may be contraindicated. For instance, one should consider the amino acid composition from protein grains, type of starch structure from cereal grains, and how fermentable (digestible) the fiber source is from the ingredients that make up the feed in question.

23.3.1.1.2 Collective Terms

Collective terms recognize a general classification of ingredient origin, which perform a similar function but do not imply equivalent nutritional values. When a collective term is used, individual ingredients within that group cannot be listed on the label.[27] Manufacturers are permitted to use the ingredient listing of their choosing as long as they meet the specified analysis. Box 1 shows the practitioner which ingredients can be used under each broad classification, called collective terms.

23.3.1.2 Feeding Directions

All horse feeds shall have the following:

1. Purpose statement

2. Directions for use and any warning or caution statements

    a. The statement of purpose shall contain the specific species and animal class(es) for which the feed is intended.

    b. The manufacturer shall have the flexibility in describing in more specific and common language the defined animal class, species and purpose, while being consistent with the category of animal class. This may include, but is not limited to, the weight ranges(s), sex, or ages of the animal(s) for which the feed is manufactured.

    c. The purpose statement may be excluded from the label if the product name includes a description of the species and animal class(es) for which the feed is intended. 1557

TABLE 10 Vitamins Commonly Used in Horse Feed Formulations

VITAMIN	SOURCE
Biotin	*d*-Biotin
Choline	Choline chloride
Cyanocobalamin (B_{12})	Cyanocobalamin
Folacin (folic acid)	Folacin
Niacin	Nicotinic acid
	Nicotinamide
Pantothenic acid	Calcium pantothenate
Pyridoxine (B_2)	Pyridoxine hydrochloride
Riboflavin (B_2)	Riboflavin
Thiamine (B_2)	Thiamine hydrochloride
	Thiamine mononitrate
Vitamin A	Vitamin A acetate
	Vitamin A palmitate
	Vitamin A propionate
	β-Carotene (precursor)
Vitamin C	Ascorbic acid
Vitamin D	Activated animal sterol (D_2)
	Cholecalciferol
	Ergocalciferol (D_2)
Vitamin E	α-Tocopherol acetate
Vitamin K	Menadione sodium bisulfite

23.3.2 FEED INDUSTRY TERMINOLOGY

To assist the equine practitioner in terminology generally used by the feed industry, Box 2 lists the terms and their explanations.[27]

23.4 Equine Digestive System

The equine digestive system is designed to function most efficiently and effectively on a forage-based diet. One should feed grain mixtures and ration balancers to provide the difference between what the horse needs and what nutrients are in their forage. Knowledge of the digestive system and how it functions enables equine practitioners to better understand the role of available feed stuffs, forages, and grain mixtures in the health and performance of

the horse. The horse is a nonruminant herbivore or hindgut fermenter with the ability to digest and use diets predominantly of forage. In contrast to the ruminant, the primary absorption sight for starches, amino acids, major and trace minerals, and vitamins precedes the fermentation vat. Therefore the quality of ingredients is far more important to the equine than to the ruminant, especially those that are stressed, that is, growing, reproducing, or performing.[18] The horse is classified as a “selective, continuous grazer” and is capable of consuming large quantities of forage while grazing up to 18 hours each day.[17]

The small size of the equine stomach in relation to the rest of the digestive tract limits meal size. The best recommendation is not to feed more than 2.25 kg of grain per feeding per 500 kg of body mass. The stomach empties rapidly after initial exposure to acidic gastric secretions; then the digesta becomes more alkaline when mixed with bile as it enters into the small intestine. Horses are best suited to handling small, frequent meals and should have continual access to forage. If allowed to graze pasture, hay, or haylage continuously, a 500-kg horse can produce 95 to 114 L of saliva per day.[17] The saliva assists the rate of passage through the gut, provides an important source of enzymes, and together with the bile provides a buffering solution to help maintain normal pH for optimal hindgut fermentation of forage.[28]

The chance of impaction colic is enhanced greatly if forage or water is limited. Lack of adequate forage limits saliva production and predisposes all horses to impaction, as does inadequate water supply. The small intestine is the primary absorption site of the amino acids, starches, fats/oils, minerals, and vitamins found in grain mixtures and ration balancers. The maturity (RFV) of the forage determines how much, if any, of these nutrients will be broken down and absorbed in the small intestine. Because the transit time through the small intestine is only 2 to 3 hours, the quality and bioavailability of these nutrients are critical for optimal absorption. Nutrients that are not digested or absorbed pass into the hindgut for fermentation and absorption or excretion.

The digestive tract of the horse has the ability to break down and use plant fiber because of the microbes contained in their fermentation vat, that is, the cecum, large intestine, and colon. However, these microbes are pH sensitive, and the vat must maintain a pH of 6.7 to 6.8. If too many rapidly fermentable carbohydrates, such as starch, reach the cecum or large intestine, the D-lactic acid–producing bacteria proliferate. The microbes necessary for optimal fermentation start to die when the pH is 6.5 or less. The visible results are loose stools and, if not corrected, diarrhea from D-lactic acidosis. If the acid-loving bacteria grow out of control, the pH continues to drop, and when the cecal pH reaches 6.0, 80% of horses founder.[28] The large volume and blind sac design of the cecum, along with slower transit time, give the protozoa and bacteria ample opportunity to facilitate fiber digestion. The end products of microbial action or fermentation are volatile fatty acids, ammonia, and B-complex vitamins, with the by-products being gas and heat. The large intestine is a continuation of fermentation and absorption of those nutrients made available by the microbial population. The colon is the site of water recycling and controls the water resorption and stool formation. The total transit time is approximately 50 hours, depending on the percentage of ADF and NDF in the forage.[18]

1558

1565

The digestive system of the foal evolves from being monogastric and completely dependent on milk, to the ability to utilize starches, and then later to a fermentation vat that can use some nonstructural carbohydrates and cellulose or plant fiber. Enzymatic activities have been measured in the small intestine of fetuses and foals.[29] The lactase begins to rise within a few hours of birth. Lactase, maltase, and sucrase activities are present; however, the lactase is the predominant disaccharidase in the foal until 3 to 4 months of age (Figure 2). At this time, maltase activity continues to increase, surpassing lactase, and becomes the primary disaccharidase in the small intestine.[15] The growth of the gastrointestinal tract parallels the changes in enzyme activity.[30] Significant increases in the length and diameter of the small intestine occur within the first month, increasing the available villous surface area and making it possible for the foal to process increasing volumes of milk to meet its needs. During the next 5 months,

continued growth of the small intestine occurs, but the greatest increases occur in the lengths of the cecum and large colon at a time when foals traditionally begin mimicking adult grazing behavior and increasing their intake of forage and grain.[31] From >6 months on, most of the growth occurs in the cecum and large intestine, allowing for the increased consumption and use of fibrous feeds.[15]

23.4.1

BOX 1 INGREDIENT ORIGIN OF COLLECTIVE TERMS

Animal protein products may include one or more of the following:

Animal blood dried

Animal by-product meal

Buttermilk, condensed

Buttermilk, dried

Casein

Casein, dried hydrolyzed

Cheese rind

Crab meal

Fish by-products

Fish meal

Fish solubles, dried

Hydrolyzed hair

Hydrolyzed leather meal

Hydrolyzed poultry feathers

Lactalbumin, dried

Meat and bone meal

Meat meal

Meat meal tankage

Meat solubles, dried

Milk protein, dried

Milk, dried whole

Poultry by-product meal

Poultry by-products

Shrimp meal

Skimmed milk, condensed

Skimmed milk, dried

Whey product, dried

Whey solubles, dried

Whey, condensed

Whey, condensed hydrolyzed

Whey, dried

Forage products may include one or more of the following:

Alfalfa meal, dehydrated

Alfalfa hay, ground

Alfalfa meal, sun-cured

Coastal Bermuda grass hay

Corn plant, dehydrated

Flax plant product

Ground grass

Soybean hay, ground

Grain products in any of the normal forms such as whole, ground, cracked, screen cracked, flaked, kibled, toasted, or heat processed may include these:

Barley

Corn

Grain sorghum

Oats

Rice, ground brown

Triticale

Wheat

Plant protein products may include one or more of the following:

Algae meal

Beans, dried

Canola meal

Coconut meal

Cottonseed

Cottonseed flakes

Cottonseed meal

Linseed meal

Peanut meal

Peas

Soy flour

Soy protein concentrate

Soybean feed

Soybean meal

Soybeans, heat processed

Soybeans, ground

Whole yeast, active dry

Yeast brewers

Yeast, culture

Yeast, dried

Processed grain by-products may include one or more of the following:

Aspirated grain fractions

Brewer's dried grains

Buckwheat middlings

Condensed distiller's solubles

Corn flour

Corn gluten feed

Corn gluten meal

Corn grits

Distiller's dried grains

Distiller's dried grains/solubles

Grain sorghum grits

Hominy feed

Malt sprouts

Oat groats

Peanut skins

Rice bran

Wheat bran

Wheat flour

Wheat germ meal

Wheat middlings

Wheat mill run

Roughage products may include one or more of the following:

Almond hulls, ground

Apple pomace, dried

Bagasse

Barley hullsBarley mill by-product

Beet pulp, dried

Citrus meal, dried

Citrus pulp, dried

Corn cob fractions

Cottonseed hulls

Flax straw by-products

Husks

Oat hulls

Oat mill by-product

Peanut hulls

Rice hulls

Rice mill by-product

Soybean hulls

Straw, ground

Sunflower hulls

Tomato pomace, dried

Molasses products may include one or more of the following:

Beet molasses

Beet molasses, dried product

Beet pulp, dried molasses

Cane molasses

Citrus molasses

The Food and Drug Administration does not recognize *molasses* as a collective term.

23.4.2

BOX 2 OFFICIAL FEED TERMS

Additive An ingredient or combination of ingredients added to the basic feed mix or parts thereof to fulfill a specific need. Usually used in microquantities and requires careful handling and mixing.

(Note: A *food additive* is defined by federal law as any substance that becomes a component or affects the characteristics of a feed or food if such substance generally is not recognized among experts qualified by scientific training and experience to evaluate its safety as having been shown adequately through scientific procedures to be safe under the conditions of its intended use. Excepted are substances having prior sanction and pesticide chemicals under certain conditions. See Public Law 65-929 for details.)

Aerial parts (part) The above-ground parts of plants.

Antibiotics A class of drug. They usually are synthesized by living microorganisms and in proper concentration inhibit the growth of other microorganisms.

Artificially dried (process) Moisture having been removed by other than natural means.

Aspirated, aspirating Having removed chaff, dust, or other light materials by use of air.

Bagasse (part) Pulp from sugar cane. (See *pulp*.)

Balanced A term that may be applied to a diet, ration, or feed having all known required nutrients in proper amount and proportion based on recommendations of recognized authorities in the field of animal nutrition, such as the National Research Council, for a given set of physiologic animal requirements. The species for which the feed is intended and the functions such as maintenance or maintenance plus production (growth, fetus, milk, eggs, wool, feathers, or work) shall be specified.

Barn-cured (process) Forage material dried with forced ventilation in an enclosure.

Beans Seed of leguminous plants especially of the genera *Phaseolus, Dali Chos*, and *Vigna*.

Biscuits (physical form) Shaped and baked dough.

Blending (process) To mingle or combine two or more ingredients of feed. Blending does not imply a uniformity of dispersion.

Blocked, blocking (process) Having agglomerated individual ingredients or mixtures in to a large mass.

Blocks (physical form) Agglomerated feed compressed into a solid mass cohesive enough to hold its form and weighing more than 2 lb and generally weighing 30 to 50 lb.

Blood albumin (part) One of the blood proteins.

Bone (part) Skeletal parts of vertebrates.

Bran (part) Pericarp of grain.

Brand name Any word, name, symbol, or device or any combination thereof identifying the commercial feed of a distributor and distinguishing it from that of others.

Bricks (physical form) Agglomerated feed, other than pellets, compressed into a solid mass cohesive enough to hold its form and weighing less than 2 lb. (See *blocks*.)

Browse (part) Small stems, leaves, and flowers and fruits of shrubs, trees, or woody vines.

Buttermilk (part) All residue from churning cream.

By-product (part) Secondary products produced in addition to the principal product.

Cake (physical form) The mass resulting from the pressing of seeds, meat, or fish to remove oils, fats, or other liquids.

Chaff (part) Glumes, husks, or other seed coverings together with other plant parts separated from seed in threshing or processing.

Charcoal Dark-colored porous forms of carbon made from the organic parts of vegetable or animal substances by their incomplete combustion.

Chipped, chipping (process) Cut or broken into fragments; also meaning prepared into small thin slices.

Chopped, chopping (process) Reduced in particle size by cutting with knives or other edged instruments.

Cleaned, cleaning (process) Removal of material by methods such as scalping, aspirating, and magnetic separation or by any other method.

Cleanings (part) Chaff, weed seeds, dust, and other foreign matter removed from cereal gains.

Cobs with grain (part) The ears of maize without the husks, but consisting of the entire cobs and adhering grain.

Cobs with husks (part) Kernel-free fibrous inner portion of the ear of maize with enveloping leaves.

Complete feed A nutritionally adequate feed for animals other than human beings; by specific formula, complete feed is compounded to be fed as the sole ration and is capable of maintaining life and promoting production without any additional substance being consumed except water.

Concentrate A feed used with another to improve the nutritive balance of the total and intended to be diluted further and mixed to produce a supplement or a complete feed.

Condensed, condensing (process) Reduced to denser form by removal of moisture.

Conditioned, conditioning (process) Having achieved predetermined moisture characteristics and/or temperature of ingredients or a mixture of ingredients before further processing.

Cooked, cooking (process) Heated in the presence of moisture to alter chemical and physical characteristics or to sterilize.

Cracked, cracking (process) Particle size reduced by a combined breaking and crushing action.

Crimped, crimping (process) Rolled by use of corrugated rollers. Crimping may curtail tempering or conditioning and cooling.

Crumbled, crumbling (process) Pellets reduced to granular form.

Crumbles (physical form) Pelleted feed reduced to granular form.

Cubes (physical form) See *pellets*.

Cull Material rejected as inferior to the process of grading or separating.

Culture Nutrient medium inoculated with specific microorganisms that may be in a live or dormant condition.

Cultured, culturing (process) Biologic material multiplied or produced in a nutrient media.

Customer-formula feed Consists of a mixture of commercial feeds and/or feed ingredients each batch of which is manufactured according to the specific instructions of the final purchaser.

D-activated, D-activating Plant or animal sterol fractions that have been vitamin D activated by ultraviolet light or by other means.

Defluorinated, defluorinating (process) Having had fluorine removed.

Degermed (process) Having had the embryo of seeds wholly or partially separated from the starch endosperm.

Dehulled, dehulling (process) Having removed the outer covering from grains or other seeds.

Dehydrated, dehydrating (process) Having been freed of moisture by thermal means.

Diet Feed ingredients or mixture of ingredients including water that is consumed by animals.

Diluent (physical form) An edible substance used to mix with and reduce the concentrate of nutrients and/or additives to make them more acceptable to animals, safer to use, and more capable of being mixed uniformly in a feed. (Diluent also may be a carrier.)

Dried, drying (process) Materials from which water or other liquids have been removed.

Drug (as defined by FDA as applied to feed) A substance (a) intended for use in the diagnosis, cure, mitigation, treatment, or prevention of disease in human beings or other animals or (b) a substance other than food intended to affect the structure or any function of the body of a human being or other animals.

Dust (part) Fine, dry pulverized particles of matter usually resulting from the cleaning or grinding of grain.

Ears (part) Fruiting heads of Zea maize, including only the cob and grain.

Egg albumin (part) Whites of eggs of poultry.

Enzymatic activity The catalytic activity required to convert a given amount of assay substrate to a given amount of product per unit time under the standard conditions set forth in the assay procedure.

Enzyme A protein made up of amino acids or their derivatives that catalyzes a defined chemical reaction. Required cofactors should be considered an integral part of the enzyme.

Enzyme product A processed, standardized enzyme-containing material that has been produced with the intention of being sold for use in animal feed and feed ingredients.

Emulsifier A material capable of causing fat or oils to remain in liquid suspension.

Endosperm (part) Starchy portion of seed.

Ensiled (process) Aerial parts of plants that have been preserved by ensiling. Normally the original material is finely cut and blown into an airtight chamber such as a silo, where it is pressed to exclude air and where it undergoes an acid fermentation that retards spoilage.

Expanded, expanding (process) Subjected to moisture, pressure, and temperature to gelatinize the starch portion. When extruded, its volume increases because of abrupt reduction in pressure.

Extracted, mechanical (process) Having removed fat or oil from materials by heat and mechanical pressure. Similar terms are *expeller extracted, hydraulic extracted*, and *old process*.

Extracted, solvent (process) Having removed fat or oil from materials by organic solvents. Similar term is *new process*.

Extruded (process) A process by which feed has been pressed, pushed, or protruded through orifices under pressure.

Fat (part) A substance composed chiefly of triglycerides of fatty acids and that is solid or plastic at room temperature.

Fatty acids (part) Aliphatic monobasic acids containing only the elements carbon, hydrogen, and oxygen.

Feed(s) Edible material(s) that are consumed by animals and contribute energy and nutrients to the diet of the animal. (Usually refers to animals rather than human beings.)

Feed grade Suitable for animal consumption.

Feed mixture See *formula feed*.

Fermentation aid A substance added to assist in providing proper conditions that result in action by yeasts, molds, or bacteria in a controlled aerobic or anaerobic process used for the manufacture of certain products.

Fermented, fermenting (process) Acted on by yeasts, molds, or bacteria in a controlled aerobic or anaerobic process in the manufacture of products such as alcohols, acids, vitamins of the B-complex group, or antibiotics.

Fiber (part) Any of a large class of plant carbohydrates that resist digestion hydrolysis.

Fines (physical form) Any materials that will pass through a screen the openings of which are immediately smaller than the specified minimum crumble size or pellet diameter.

Flaked, flaking (process) See *rolled, rolling*.

Flakes (physical form) An ingredient rolled or cut into flat pieces with or without prior steam conditioning.

Flour (part) Soft, finely ground and bolted meal obtained from the milling of cereal gains, other seeds, or products. Flour consists essentially of the starch and gluten of the endosperm.

Formula feed Two or more ingredients proportioned, mixed, and processed according to specifications.

Free choice A feeding system by which animals are given unlimited access to the separate components or groups of components constituting the diet.

Fresh (process) Ingredients(s) having not been subject to freezing, to treatment by cooking, drying, rendering, hydrolysis, or similar process, to the addition of salt, curing agents, natural or synthetic chemical preservatives or other processing aids, or to preservation by means other than refrigeration.

Gelatinized, gelatinizing (process) Having had the starch granules completely ruptured by a combination of moisture, heat, and pressure and in some instances by mechanical shear.

Germ (part) The embryo found in seeds and frequently separated from the bran and starch endosperm during the milling.

Gluten (part) The tough, viscid nitrogenous substance remaining when the flour or wheat or other grain is washed to remove the starch.

Gossypol (part) A phenolic pigment in cottonseed that is toxic to some animals.

Grain (part) Seed from cereal plants.

GRAS Abbreviation for the phase *g*enerally *r*ecognized *a*s *s*afe. A substance that generally is recognized as safe by experts qualified to evaluate the safety of the substance for its intended use.

Grease Animal fats with a titer below 40° C.

Grits (part) Coarsely ground grain from which the bran and germ have been removed, usually screened to uniform particle size.

Groats (part) Grain from which the hulls have been removed.

Ground, grinding (process) Reduced in particle size by impact, shearing, or attrition.

Hay (part) The aerial portion of grass or herbage especially cut and cured for animal feeding.

Heads (part) The seed or grain-containing portions of a plant.

Heat-processed, heat-processing (process) Subjected to a method of preparation involving the use of elevated temperatures with or without pressure.

Hulls (part) Outer covering of grain or other seed.

Hydrolyzed, hydrolyzing (process) Complex molecules having been split to simpler units by chemical reaction with water, usually by catalysis.

Ingredient, feed ingredient A component part or constituent of any combination or mixture making up a commercial feed.

Iodize, iodized (process) To treat with iodine or an iodide.

Irradiated, irradiating (process) Treated, prepared, or altered by exposure to a specific radiation.

Kernel (part) A whole grain. For other species, dehulled seed.

Kibbled, kibbling (process) Cracked or crushed baked dough, or extruded feed that has been cooked before or during the extrusion process.

Lard (part) Rendered fat of swine.

Leached (process) The condition of a product following subjection of the material to the action of percolating water or other liquid.

Leaves (part) Lateral outgrowths of stems that constitute part of the foliage of a plant, typically a flattened green blade, and primarily function in photosynthesis.

Lecithin (part) A specific phospholipid. The principal constituent of crude phosphatides derived from oil-bearing seeds.

Liver (part) The hepatic gland.

Malt (part) Sprouted and steamed whole grain from which the radicle has been removed.

Mash (physical form) A mixture of ingredients in meal form. Similar term is *mash feed*.

Meal (physical form) An ingredient that has been ground or otherwise reduced in particle size.

Medicated feed Any feed that contains drug ingredients intended or presented for the cure, mitigation, treatment, or prevention of diseases of animals other than human beings or that contains drug ingredients intended to affect the structure or any function of the body of animals other than human beings. Antibiotics included in a feed growth promotion and/or efficiency levels are drug additives, and feeds containing such antibiotics are included in the foregoing definition of medicated feed.

Microingredients Vitamins, minerals, antibiotics, drugs, and other materials normally required in small amounts and measured in milligrams, micrograms, or parts per million.

Middlings (part) A by-product of flour milling comprising several grades of granular particles containing different proportions of endosperm bran and germ, each of which contains different levels of crude fiber.

Mill by-product (part) A secondary product obtained in addition to the principal product in milling practice.

Mill dust (part) Fine feed particles of undetermined origin resulting from handling and processing feed and feed ingredients.

Mill run (part) The state in which a material comes from the mill, ungraded and usually uninspected.

Mineralize, mineralized (process) To supply, impregnate, or add inorganic mineral compounds to a feed ingredient or mixture.

Mixing (process) To combine by agitation two or more materials to a specific degree of dispersion.

Molasses (part) The thick, viscous by-product resulting from refined sugar production or the concentrated, partially dehydrated juices from fruits.

Natural A feed or ingredient derived solely from plant, animal, or mined sources in its unprocessed state or having been subject to physical processing, heat processing, rendering, purification, extraction, hydrolysis, enzymolysis, or fermentation, but not having been produced by or subject to a chemically synthetic process and not containing any additives or processing aids that are chemically synthetic except in amounts as might occur unavoidably in good manufacturing practices.

Nutrient A feed constituent in a form and at a level that helps support the life of an animal. The chief classes of feed nutrients are proteins, fats, carbohydrates, minerals, and vitamins.

Offal (part) Material left as a by-product from the preparation of some specific product, less valuable portions, and the by-products of milling.

Oil (part) A substance composed chiefly of triglycerides of fatty acids and that is liquid at room temperature.

Parboiling A hydrothermal process in which the crystalline form of starch is changed into the amorphous form because of the irreversible swelling and fusion of starch. This is accomplished by soaking, steaming, drying, and milling to produce physical and chemical modifications.

Pearled, pearling (process) Dehulled grains reduced by machine brushing into smaller, smooth particles.

Pelleted, pelleting (process) Having agglomerated feed by compaction and forcing through die openings.

Pellets (physical form) Agglomerated feed formed by compacting and forcing through die openings by a mechanical process. Similar terms are *pelleted feed* and *hard pellet*.

Polished, polishing (process) Having a smooth surface produced by mechanical process usually by friction.

Pomace (part) Pulp from fruit. See *pulp*.

Premix A uniform mixture of one or more microingredients with diluent or carrier. Premixes are used to facilitate uniform dispersion of the microingredients in a large mix.

Premixing (process) The preliminary mixing of ingredients with diluents or carriers.

Preservative A substance added to protect, prevent, or retard decay, discoloration, or spoilage under conditions of use or storage.

Pressed, pressing (process) Compacted or molded by pressure; also meaning having fat, oil, or juices extracted under pressure.

Product (part) A substance produced from one or more other substances as a result of chemical or physical change.

Protein (part) Any of a large class of naturally occurring complex combinations of amino acids.

Pulp (part) The solid residue remaining after extraction of juices from fruits, roots, or stems. Similar terms are *bagasse* and *pomace*.

Pulverized, pulverizing (process) See *ground, grinding*.

Range cubes (physical form) Large pellets designed to be fed on the ground. Similar term is *range wafer*.

Ration The amount of the total feed provided to one animal over 24 hours.

Raw Food in its natural or crude state not having been subjected to heat in the course of preparation as food.

Rolled, rolling (process) Having changed the shape and size of particles by compressing between rollers. Rolling may entail tempering or conditioning.

Roots (part) Subterranean parts of plants.

Rumen inert Refers to a nutrient that does not result in a change in rumen fermentation parameters yet is available to the animal in the intestine.

Rumen protected Refers to nutrient fed in such a form that it provides an increase in the flow of that nutrient, unchanged, to the abomasum yet is available to the animal in the intestine.

Scalped, scalping (process) Having removed larger material by screening.

Scratch (physical form) Whole, cracked, or coarsely cut grain. Similar terms are *scratch gain* and *scratch feed*.

Screened, screening (process) Having separated various sized particles by passing over and/or through screens.

Seed (part) The fertilized and ripened ovule of a plant.

Self-fed A feeding system by which animals have continuous free access to some or all components of a ration, individually or as mixtures.

Separating (process) Classification of particles by size, shape, and/or density.

Shoots (part) The immature aerial parts of plants, stems with leaves, and other appendages in contrast to the roots.

Shorts (part) Fine particles of bran, germ, flour, or offal from the tail of the mill from commercial flour milling.

Sifted (process) Materials that have been passed through wire sieves to separate particles in different sizes. The separation of finer materials than would be done by screening.

Sizing (process) See *screened, screening*.

Skimmed (process) Material from which floating solid material has been removed. Skimmed also is applied to milk from which fat has been removed by centrifugation.

Skin (part) Outer coverings of fruits or seeds, as the rinds, husks, or peels. May also apply to dermal tissue of animals.

Solubles Liquid containing dissolved substances obtained from processing animal or plant materials. Solubles may contain some fine suspended solids.

Solvent extracted (process) A product from which oil has been removed by solvents.

Spray dehydrated (process) Material that has been dried by spraying on the surface of a heated drum and is recovered by scraping from the drum.

Spray dried Material that has been dried by spraying or atomizing into a draft of heated dry air.

Stabilized (process) To retard degradation of ingredients. (The process used to be specified.)

Stalk(s) (part) The main stem of a herbaceous plant often with its dependent parts as leaves, twigs, and fruit.

Starch (part) A white, granular polymer of plant origin; the principal part of seed endosperm.

Steamed, steaming (process) Having treated ingredients with steam to alter physical and/or chemical properties. Similar terms are *steam cooked, steam rendered*, and *tanked*.

Stem (part) The coarse, aerial parts of plants that serve as supporting structures for leaves, buds, fruit, etc.

Sterols (part) Solid cyclic alcohols that are the major constituents of the unsaponifiable portion of animal and vegetable fats and oils.

Stillage (part) The mash from fermentation of grains after removal of alcohol by distillation.

Stover (part) The stalks and leaves of corn after the ears, or sorghum after the heads, have been harvested.

Straw (part) The plant residue remaining after separation of the seeds in threshing, including the chaff.

Sun-cured (process) Material dried by exposure in open air to the direct rays of the sun.

Supplement A feed used with another to improve the nutritive balance or performance of the total and intended to be

1. Fed undiluted as a supplement to other feeds,
2. Offered free choice with other parts of the ration separately available, or
3. Further diluted and mixed to produce a complete feed.

Tallow (part) Animal fats with titer above 40° C.

Titer A property of fat determined by the solidification point of the fatty acids liberated by hydrolysis.

Toasted (process) Browned, dried, or parched by exposure to a fire or to gas or electric heat.

Trace minerals Mineral nutrients required by animals in minute amounts only (measured in milligrams per pound or smaller units).

Tubers (part) Short, thickened fleshy stems or terminal portions of stems or rhizomes that usually are formed underground; bear minute scaled leaves, each with a bud capable under suitable conditions of developing into a new plant; and constitute the resting stage of various plants.

Vitamins Organic compounds that function as parts of enzyme systems essential for the transmission of energy and the regulation of metabolisms of the body.

Wafers (physical form) A form of agglomerated feed based on fibrous ingredients in which the finished form usually has a diameter or cross-section measurement greater than its length.

Whey (part) The watery part of milk separated from the curd.

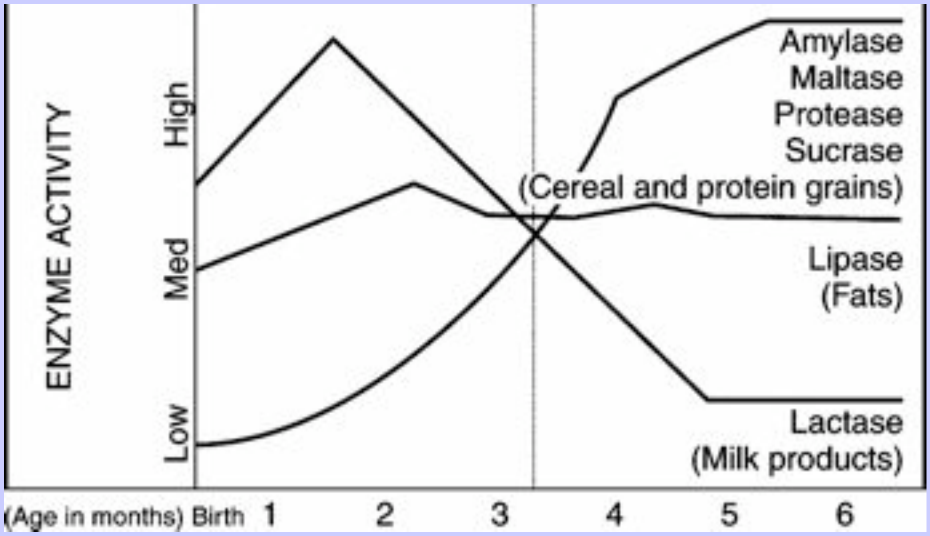
Whey solids (part) The solids of whey (proteins, fats, lactose, ash, and lactic acid).

Whole (physical form) Complete, entire.

Whole pressed, whole pressing (process) Having the entire seed to remove oil.

Wilted (physical form) A product without turgor as a result of water loss.

Figure 2 Digestive enzyme activity of the young, growing horse.



After the hindgut has been inoculated with microbes, the young foal can start using plant fiber, which occurs at 10 to 12 weeks of age. Their fermentation vat is not efficient or effective at this age, so one should feed the softest, most immature forage available to the suckling and early weanling. A RFV of 115 or higher in the forage is recommended. A distended abdomen, or hay belly, becomes visible if the forage is too mature. As the body increases in size, so does the fermentation vat. The larger the capacity to ferment, the more efficient the vat becomes. Therefore as young horses grow, their need for forage increases in their diet, their need for milk is eliminated, and grain mixtures are decreased. The NRC recommends that from 12 months of age, greater than 50% of their total diet, by weight, should be forage or forage equivalent (on a dry matter basis)[1] (Table 11). The amount of grain mixture required per day to maintain desired body condition is related directly to the quantity and quality of forage being consumed.

TABLE 11 National Research Council Recommendation of Diet Proportions for Young, Growing Horses

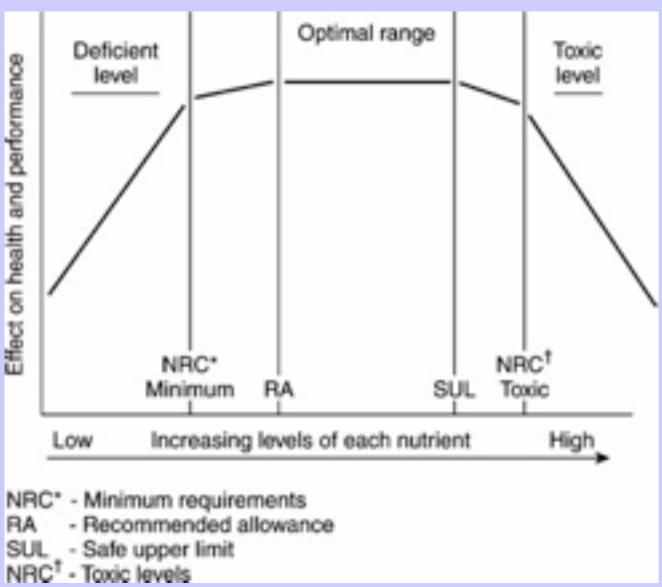
AGE	FORAGE	GRAIN MIXTURE
Birth to 2 months	0	100% (milk only)
3 months	20%	80%
6 months	30%	70%
12 months	50%	50%
18 months	60%	40%
24 months	70%	30%

From Nutritional Research Council: *Nutrient requirements of horses,* Washington, DC, 1989, National Academy Press.

The research has not been completed on the absorption of the essential amino acids from different ingredients, grains and forages, or the optimal level of ADF and NDF to maintain hindgut function and intestinal health. Therefore horsemen feed forage and grain mixtures to achieve the desired body condition in their horses. What is needed today is an easy way to measure how much and of which feed is necessary to meet nutrient needs of horses, whether they are growing, reproducing, or performing. Feed manufactures in the United States now are required to have a purpose statement and feeding directions explaining the minimum amount to feed to each horse per day, depending on their age, size, growth rate, reproductive status, and performance level.[27] Feeding less than the manufacturer recommended amount per day provides the horse with a deficient diet. (See the section Feed Labeling Guide.)

Figure 3 shows how the amount of each nutrient fed has an effect on the health and performance of the horse. The NRC has listed individual nutrients and their minimum amounts in the total ration to be fed per day to prevent deficiencies. The NRC also has listed the known toxic levels of those nutrients. The owner/manager, veterinarian, and nutritionist are responsible for balancing the diet and staying between the deficient and the toxic levels to maintain optimal health for growth, reproduction, and performance. Because of the varying quality of different forages, nutritionists balance diets on recommended allowances. If one uses the NRC minimum to balance a forage and grain combination, and one's forage quality decreases, one will be feeding a deficient diet and not
know it until the health, performance, or appearance of the horse declines. So grain mixtures and ration balancers 1565
formulated for horses need a recommended allowance built into their formula and feeding directions. An optimal 1566
range for each nutrient in the equine diet exists. Before reaching toxic levels, nutrients will antagonize or interfere with one another, reducing their availability. This antagonism also will affect the health and performance of the horse negatively. So the manager needs to know what the minimum pounds are per day of the recommended allowance and the safe upper limit (SUL) of their selected grain mixture or ration balancer to stay within the optimal range.

Figure 3 Nutrient effects on health and performance. *NRC*, National Research Council requirements; *RA*, recommended allowance; *SUL*, safe upper limit.



23.5 Feeds and Feeding Amounts: Digestive Upset and Abnormal Behavior

James B. Rowe

23.5.1 ACIDIC GUT SYNDROME

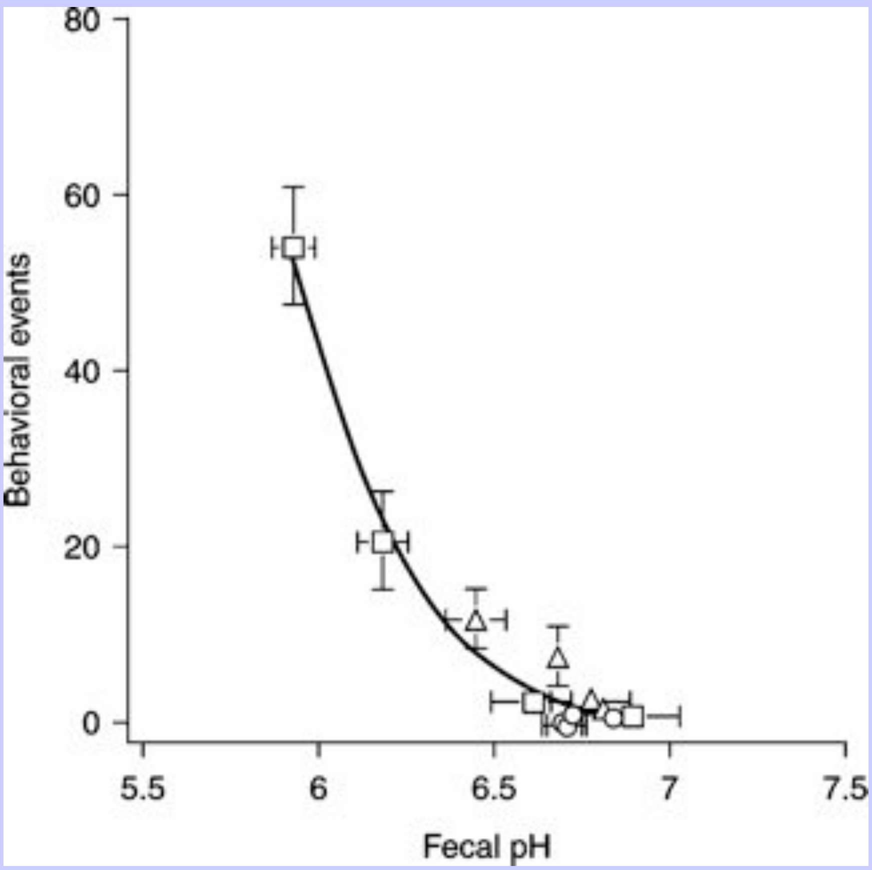
Acid accumulation in the gut occurs when a number of dietary factors and animal digestive responses interact to deliver readily fermentable carbohydrates to parts of the digestive tract colonized by bacteria capable of rapid fermentation and multiplication. Lactic acidosis is a well-documented condition characterized by the absorption of lactic acid from the hindgut, the slow metabolism of D-lactic acid, and the effect of these processes on the acid-base balance in the tissues of the horse. Acidic gut syndrome is characterized by the accumulation of acid in the gut at concentrations that previously have not been considered harmful to horses. The detrimental effects initiated by lactic acid and low pH may be mediated through direct action on the gut wall, through the production and absorption of bacterial endotoxin, through the combination of acid and endotoxins, or through other factors. The adverse effects associated with acidic gut syndrome are not defined conclusively but may include behavioral changes, increased risk of gut infections, skin and respiratory conditions, and a range of other problems that traditionally have been attributed to food allergies or reactions to stress. Acidic gut syndrome may impact or influence the immune system and in this way forms a basis for understanding a range of secondary diseases of previously unknown origin. Acute lactic acidosis still is acknowledged as a serious problem in extreme circumstances, but possibly acidic gut syndrome may be more common and may affect production, health, and welfare in significant ways.

A number of dietary and animal digestive factors interact to influence the possibility of acid accumulation in those parts of the digestive tract adapted for microbial fermentation where the normal pH is between 6.6 and 6.8. The problem of lactic acidosis is recognized widely in ruminants, and although lactic acidosis is attributed largely to the fermentation of starch and sugars in the rumen, it is also a significant problem in the hindgut of equines.[32,33] Hindgut acidosis is also well recognized in horses, for this condition is related closely to founder or laminitis.[34,35] In lactic acidosis, or D-lactic acidosis, considerable amounts of lactic acid are absorbed through the wall of the fermentation vat and some undoubtedly moves into and is absorbed from the intestinal tract.[36] D-lactic acid is metabolized more slowly than L-lactic acid and therefore accumulates in the tissues, where it causes severe D-lactic acidosis. This author suggests that endotoxin released with the death of gram-negative bacteria in the gut may play a role in the pathogeneses of lactic acidosis. Acidic gut syndrome, however, may not depend on metabolic acidosis as a primary or secondary factor in its pathogenesis, but rather on acidity within the gut. The adverse toxic effects may be mediated through the direct effect of acid on the gut wall or through microbial endotoxins, or through a combination of these factors, or through some other factor initiated within the gut or gut wall and acting systemically.

A recent study on adverse behavioral changes in the horse in response to increasing levels of grain in the diet showed that the frequency of unusual behavioral activities was related closely to fecal pH. Traditionally, normal fecal pH has been considered to be within the range of pH 6 to 7; however, the more acidic the feces, the higher the frequency of adverse behavior, that is, eating bedding or feces, wood chewing, and cribbing (Figure 4).[37] Conditions of low pH in the cecum and colon do not normally occur without accumulation of lactic acid. Therefore although lactic acid itself appears unlikely to be an important trigger in the chain of events leading to laminitis, it may be an important indicator of an acidic pattern of fermentation in the gut. 1566
Bacteria in the gut produce two isomers of lactic acid in almost equal proportions. These are D- and L-lactate. 1567
However, only one of these isomers, L-lactate, is produced by body tissue and can be detected at elevated levels

in blood during strenuous exercise or in response to pain or stress. No D-lactate is present in the blood unless a significant accumulation of lactic acid occurs in the gut. For this reason, measurable amounts, in millimoles per liter, of blood D-lactate always provide an accurate indication of abnormal fermentation/digestion and acidic conditions in the hindgut.

Figure 4 Adverse behavioral events versus fecal pH. Relationship between fecal pH and behavioral events (eating bedding, grasping or cribbing, wood chewing, and stall licking). Each point represents the weekly sum of observations for 2 hours every day of the week. Horses were fed increasing levels of grain over 4 weeks, and differences in fecal acid were related directly to the amount of grain consumed per day.



Good circumstantial evidence also exists for other disease conditions being linked to acidic gut syndrome. These conditions are associated mainly with high levels of grain (starch) feeding and circumstances in which a well-recognized risk of lactic acidosis exists but a low incidence of the frank disease condition occurs. A more sensitive assessment of acid accumulation, at least in the gut, could be the pH of feces that would allow investigation of the possible link between gut acidity and secondary disease problems.[37,102]

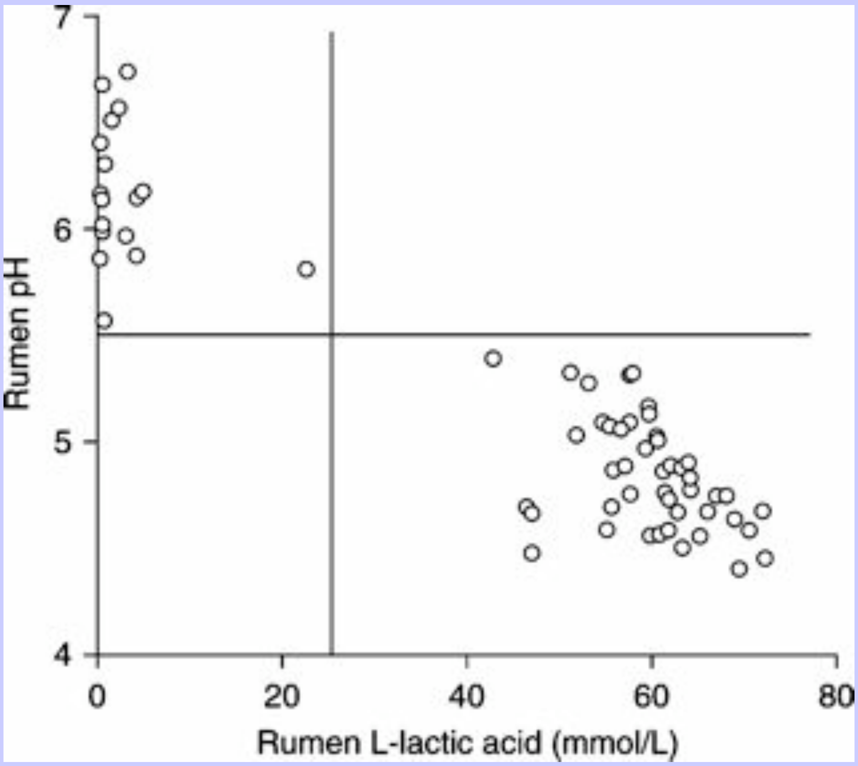
The results of a recent study suggest that TNF-α was released from epithelial cells of the gut into the gut lumen in substantial quantities after lactic acid accumulation and low pH in the rumen and cecum. This increase in TNF-α indicates that a significant immune response occurred with the development of lactic acidosis. This represents a substantial increase in understanding the etiology of lactic acidosis. It seems likely that the increase in acid load in the hind gut and decrease in pH acting on the gut wall may initiate a break down of integrity of the gut wall.[102] This agrees with similar evidence of the breakdown of the structural integrity of the cecum in horses during acidosis (Kruegar et al., 1986).

23.5.2 FERMENTATION ACTIVITY

Under normal conditions of fermentation in the hindgut, lactic acid is not present in measurable amounts even though it can be an important intermediate in the production of propionic acid. The conversion of lactic acid to propionate is thermodynamically favorable for microbes, and this process is normally rapid and complete. The accumulation of lactic acid only occurs when the bacteria responsible for the conversion of lactic acid to volatile fatty acids are in a reduced pH environment. The lactic acid–using bacteria are far more sensitive to low pH than the lactic acid producers, and once the balance is upset, the situation is exacerbated by further accumulation of lactic acid that results in even lower pH.[38] Thus any net production of lactic acid in the cecum leads to an accumulation of acid that lowers pH.

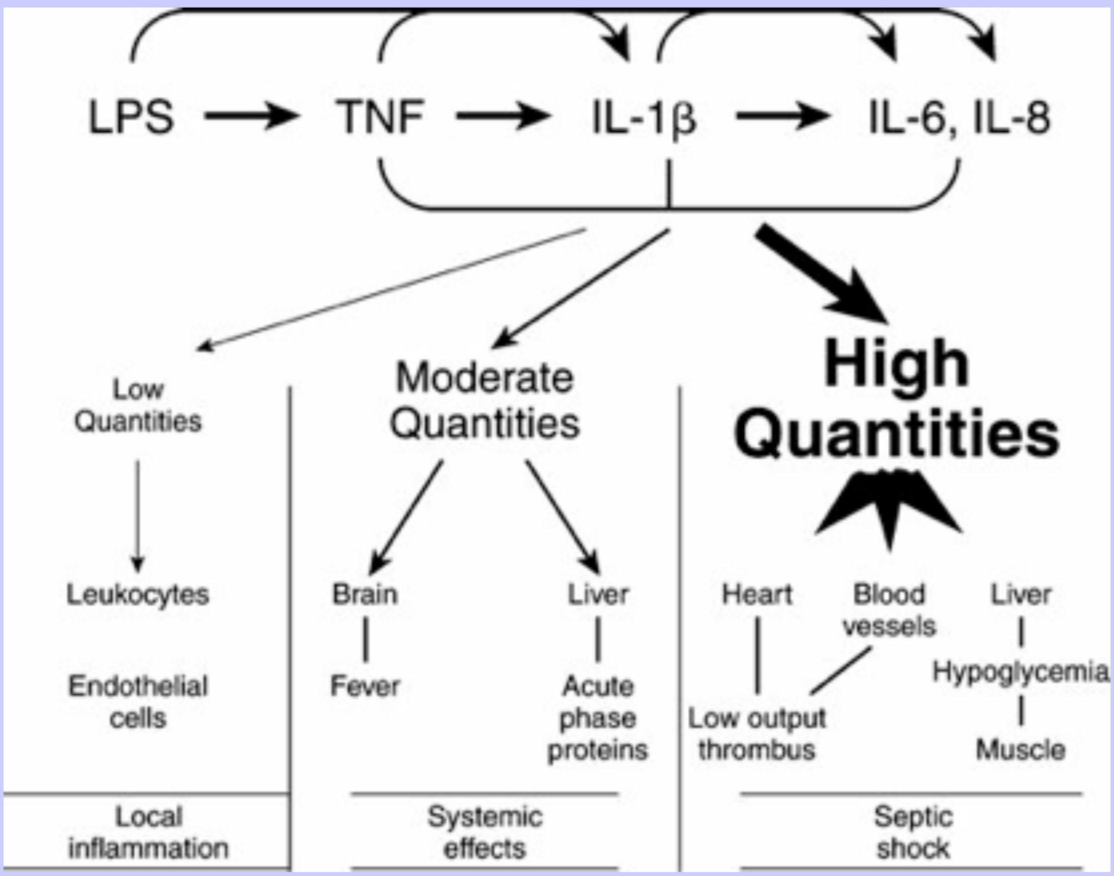
The accumulation of lactic acid therefore appears to be associated always with low pH and also signals the failure of the gram-negative lactate users. Figure 5 shows an example of the role of lactate in the accumulation of acid in the gut that demonstrates the relationship between lactic acid and pH. This figure suggests that when 1567
lactic acid is present in the hindgut at concentrations greater than 20 mmol/L, the pH normally is below 5.5. 1568
The primary lactic acid users are gram-negative bacteria, whereas the bacteria primarily involved in lactic acid production, *Streptococcus bovis* and *Lactobacillus* spp, are gram-positive.[38] Accumulation of lactic acid under these conditions is therefore likely to have a dual significance in contributing to a nonabsorbable acid to the gut contents and as an indicator of a decline in gram-negative bacteria, which is linked with bacterial endotoxin lipopolysaccharide release. Lipopolysaccharides are released during lyses of gram-negative bacteria. Lipopolysaccharide release can occur during the sudden decrease in pH associated with rapid fermentation of carbohydrates and has been demonstrated in the cecum of horses.[39] These results showed a tendency toward higher levels of endotoxin accumulation at lower pH. Considerable quantities of endotoxins can be released without the pH falling below 6.0. Studies by Hood and Stephens[40] and by Mullenax, Keeler, and Allison[41] suggest under normal conditions in the cecum, without acute lactic acidosis, little absorption of endotoxin from the gut is likely to occur.

Figure 5 Relationship between lactic acid concentration and pH. Apparent absorption of test solutions of acids from surgically sealed pouches in the rumen and cecum in the sheep. The apparent increase in lactic acid was caused by conversion from volatile fatty acids and tissue synthesis. (From Ding et al: 1997.)



Under conditions of acute lactic acidosis, gross structural changes to the cecal wall in horses[42] may allow bacterial endotoxins and lactic acid to gain access to the vascular system. Clearly lactic acid and endotoxins can be absorbed from the gut during acute lactic acidosis.[43–45] However, this situation is clearly different from acidic gut syndrome. The results from the two studies[33,43] indicate that significant absorption of lactic acid, and presumably endotoxins as well, only occurs under extreme conditions of fermentative acidosis in the gut. With lower levels of lactic acid and higher pH in the gut, little absorption of lactic acid from the gut occurred. The difference appears to be between the ratio of D- and L-lactate in the gut and in the blood. Measurable amounts of L-lactate always exist in the blood from tissue metabolism, and if lactic acid from the gut makes a major contribution to blood lactic acid, the ratio of D-lactate to L-lactate would approach that measured in the fermentation compartments in the gut.

Figure 6 Summary of the range of effects that varying levels of cytokine responses can have locally and systemically when stimulated by bacterial lipopolysaccharide *(LPS)* endotoxin. Although this model is based on systemic infection, the endotoxin *(LPS)* released with the death of gram-negative bacteria in the gut under acidic conditions likely triggers local and systemic cytokine effects. *TNF*, Tumor necrosis factor; *IL*, interleukin. (Adapted from Abbas AK, Lichtman AH, Pober JS: *Cellular and molecular immunology*, Philadelphia, 1996, WB Saunders.)



Bacterial endotoxins also stimulate tumor necrosis factor, which can initiate the cytokine cascade, releasing interleukins 1, 6, and 8.[46] The effects of these cytokines are widespread, acting locally and systemically depending on the level present.[47] Figure 6 summarizes the effects of cytokines. Pollitt[48] reported a range of histologic changes in the hooves of horses following carbohydrate overload and also the development of 1568
laminitis, both of which were consistent with cytokine activity. In the case of hoof damage at the lamellar level, 1569

Pollitt suggests metalloproteases specifically may be involved, but a sufficiently wide range of cytokine-initiated activities exists to explain damage and activation of other tissue types.

23.5.3 MANAGEMENT TO REDUCE THE RISK OF FERMENTATIVE ACIDOSIS

The factors that have the potential to contribute to lactic acid build up in the gut are numerous. They include any input or change that contributes to an increased supply of fermentable carbohydrates to any part of the digestive tract containing a dense bacterial population. Because a range of animal and feed factors affect the risk of acid accumulation in the gut, not surprisingly a significant variation exists between individual animals in the way in which they respond to similar quantities of dietary grains or other forms of fermentable carbohydrates. From this perspective, considering different management strategies for more susceptible individuals and for dietary regimens that are likely to be associated with higher risks of gut acid accumulation is appropriate. The challenge is to make this approach more practical and useful, to understand first the condition so that those individuals and diets that carry the greatest risk can be identified easily and managed appropriately. One should exercise caution concerning the potentially dangerous combination of adding probiotics to enhance lactic acid production while simultaneously increasing the amount of carbohydrates (cereal grains), causing more microbial fermentation.

The following summarizes dietary characteristics associated with an increase risk of fermentative acidosis:

Source of carbohydrates: The carbohydrate source is important because major differences exist in structure and characteristics of starch granules between cereal grains and the content of nonstarch polysaccharides. Resistance of starch to intestinal digestion increases the risk of greater hindgut fermentation and acid accumulation in the cecum and colon. The nonstarch polysaccharide fraction is highly fermentable and generates acid production in the hindgut. Nonstarch polysaccharides can also reduce starch digestion by increasing the viscosity of the digesta and in this way may act to increase hindgut fermentation.

Age of grain (storage): Aging reduces the endogenous enzyme and nonstarch polysaccharide contents of the grain and can have a significant effect in improving intestinal digestion of carbohydrates.[49] Changes from aging help explain why a sudden change in new season grain can cause production problems associated with reduced intestinal digestion and increased hindgut fermentation and fecal output.

Processing: Processing of the dietary ingredients affects particle size, solubility, gelatinization, and the rate at which food can be ingested. Any treatment that decreases particle size, reduces the resistance of starch to digestion, or increases its solubility increases the rate of carbohydrate absorption in the small intestine.

Frequency of feeding and meal size: Frequency of feeding and meal size determine the amount of fermentable substrate delivered to the stomach for acid digestion and to the hindgut for fermentation. Large amounts of carbohydrates ingested once or twice per day can overload the stomach and small intestine, leading to acid accumulation in the hindgut. Overload may result in incomplete gastric digestion and subsequent increased fermentation in the hindgut. Factors that facilitate rapid ingestion of carbohydrates are likely to result in less intestinal digestion and more hindgut fermentation.

Rate of passage: Rate of passage has an important role in determining the site of digestion and can be influenced by hormonal and other systemic factors, such as stress, cold weather, and disease. Rate of passage is also influenced by the autonomic nervous system, disease status, drug exposure, and nature of the diet. Rapid passage of ingesta through the intestine may lead to incomplete digestion of carbohydrates, which influences hindgut fermentation.

Adaptation of the bacterial population: Bacterial adaptation for starch fermentation and lactic acid use forms the basis of all practical grain mixture feeding programs. A gradual increase in the amount of grain allows a build up of bacteria able to convert lactic acid to volatile fatty acids. Bacterial buildup is not only important in terms of preventing lactic acid accumulation and low pH but also from the point of view of the stability of the gram-negative population of bacteria that use lactic acid. If this population declines sharply in response to increased acidity and if a rapid expansion of the gram-positive population of bacteria that produce lactic acid occurs, a release of endotoxins may lead to acidic gut syndrome.

Enzyme activity: Enzyme activity in the gastrointestinal tract affects the extent of carbohydrate digestion and the range of substrates degraded and absorbed. Significant differences exist between individuals in enzyme activity that can have an important effect on site of digestion and the accumulation of acid in the intestine.

Intestinal adaptation: Intestinal adaptation to the digestion and absorption of various carbohydrate fractions has an important effect on the site of carbohydrate digestion and on the potential for increased hindgut fermentation. The requirement for digestive adaptation to different carbohydrates is important in horses in which health problems are encountered often when they are changed from one type of grain to another.

Salivary secretion: Salivary secretion is an important source of enzymes and buffers. The amount of 1569
saliva secreted is related directly to how many hours per day the horse actually is chewing, and its 1570
composition varies between individuals.

23.5.4 SUMMARY

The problems of acute D-lactic acidosis are well understood in ruminants and horses, but the characteristics and adverse side effects of acid gut syndrome are not yet recognized in animal nutrition. Possibly a closer study of acidic gut syndrome and its effects on microbes and on the gut wall will increase understanding of a range of production and health problems that are well described but for which no cause is known. The variability in the types of carbohydrates and the wide range of factors that affect their pattern of intake and passage to parts of the digestive tract where fermentation occurs have made identifying and understanding the problem of fermentative acidosis as a potential disease condition difficult.

23.6 Management Tools to Help the Horse Owner

The growth and performance chart in Figure 7 provides feeding recommendations for all horses that will mature between 100 kg and more than 1000 kg in body weight. The growth curves, which indicate from birth to 3 years

of age and mature body weights with each physiologic status, are taken from the tables from the NRC.[1] Proper use of these charts assures that nutrition is not the limiting factor in growing, reproducing, and performing horses today. Feeding the correct amount of a selected balanced grain mixture or ration balancer allows all foals to reach their inherent genetic potential and reduces the nutrition-related growth and performance problems seen in horses.

23.6.1 YOUNG, GROWING HORSES

Weighing each horse and recording its body weight on a chart once a month allows the horse owner to track the growth rate of the young horse and compare it to established normal growth rates of horses with a known mature body weight. Because of differences in breeds and genetics, not all horses follow these respective growth curves. Some grow at a faster rate and some slower. Therefore one must monitor growth and then manage and feed the horse to meet its optimum growth rate. If growing horses are fed as a group, one must feed for the highest requirement in the group. If an owner is feeding for the average horse, his average horses should achieve their genetic potential. Rapidly growing horses are more susceptible to development of growth abnormalities because their mineral needs are not adequately met. Using information gained from using these charts and following an established feeding program assures adequate mineral and vitamin levels to meet their growth requirements. The number inside each rectangle reflects the amount of minerals and vitamins necessary to maintain the recommended allowance for that particular growth rate. This number is a balanced nutritional unit (BNU) and does not reflect the calories to maintain desired body condition, because the forages being consumed vary in calories and the owner/trainer/manager will feed varying amounts of a grain mixture to meet the desired body condition in the horses. What these persons need to know is what the minimum pounds are to achieve the recommended allowance (RA) and what the maximum pounds are not to exceed the safe upper limit (SUL) of the selected grain mixture they are feeding. The growth and performance chart provides this information.

The chart does not recommend trying to speed up or to slow down growth rate but states simply: “Let the young horses grow up to their genetic potential, but provide the nutrients to match their current growth rate.” On the larger, faster growing foals, the author recommends weighing and recording their weight, height, and body condition score on this chart every 2 weeks for the first 6 months of life. Their physiologic development is so great at this age, the author recommends monitoring them more closely to avoid any potential growth problems. As they become older, the growth rate slows but also may vary; therefore the author recommends weighing once a month for those more than 6 months of age to assure that their dietary needs (calculated in BNUs) are met accordingly.

23.6.2 REPRODUCING AND PERFORMANCE HORSES: MATURE/IDLE/OPEN

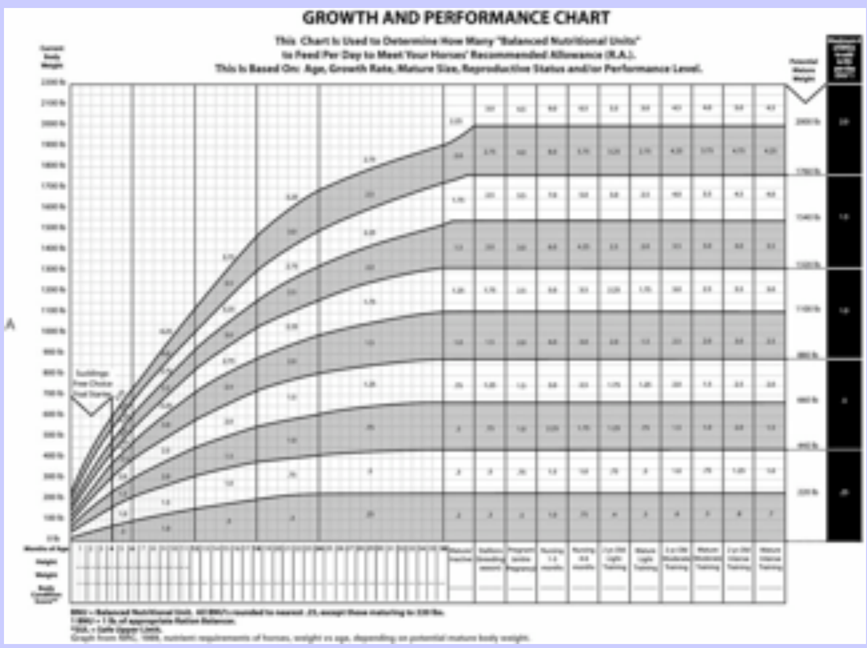
Knowing the ideal body weight of the mature, idle horse (see the section Body Condition Scoring) is essential and helpful to determine how many calories to feed per day, and use of the growth and performance chart assures that their recommended allowance is met. To this baseline maintenance, one must add the additional nutrient requirements for pregnancy, lactation, activity level, etc. This chart helps determine the recommended allowance and the SUL for each physiologic status.

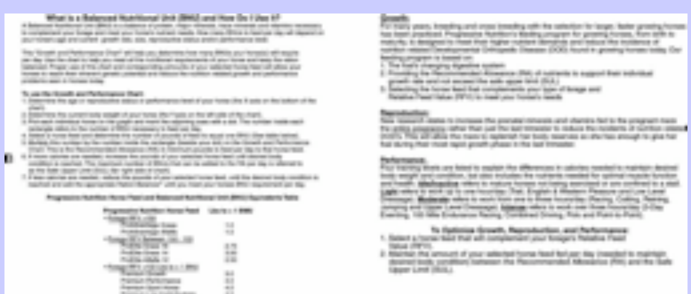
23.6.3 PREGNANCY

Implementation of research from the veterinary departments of Cornell University and University of Illinois stating that the nutrition received in the middle trimester of pregnancy is just as important as that received in the last trimester has helped many breeding farms improve the health of the mares and reduce early developmental

problems in foals. Changes in feeding practice have allowed the mare to replenish and build her body reserves to ensure she can supply the foal during their most rapid growth phase in the last trimester.[50] If the mare is not provided adequate nutrients during pregnancy, she has the ability to pull them from her body reserves to supply 1570
the fetus. Foals are not born with nutrient deficiencies until the mares' body reserves are depleted. This scenario 1573
excludes, of course, the genetic inability to manufacture quality cartilage,[51] placentitis, or older mares having reduced ability to absorb or use certain nutrients. One should note that the trace minerals copper and zinc in forages today do not meet the NRC minimum requirements for maintenance, let alone for pregnancy (see Table 3.) Management may look at the body condition score of pregnant mares on pasture and elect not to feed them any grain mixture because they are fat and shiny. Unfortunately, the major and trace minerals needed for fetal cartilage development have nothing to do with fat stores and little to do with shiny hair coats. For ease of management, improved health and reducing the incidence of nutrition-related fetal developmental problems, the author recommends providing all pregnant mares their required BNUs the entire pregnancy, rather than the age-old practice of just during the last trimester. If too much body weight is a concern, feeding the appropriate ration balancer with the forage and no cereal grain or grain mixtures is recommended.

Figure 7 **A**, Growth and performance chart. **B**, Growth and performance chart.





23.6.4
LACTATING MARE

During the first 3 months of lactation, most mares produce between 3.0% and 3.5% of their body weight in fluid milk each day.[52,53] Peak lactation usually occurs between 4 and 10 weeks post partum, with the average being 5 to 6 weeks.[52] As lactation continues, milk yield declines to 2% of body weight between the fourth and fifth months. The amount of milk a mare produces depends on her (1) genetic potential, keeping in mind that maiden mares produce less than mares with previous lactations, (2) nutrient supply (especially protein, calories, and water), and (3) individual foal intake. The nutrient composition of milk also changes during lactation. Mare's milk becomes more nutrient dilute as lactation progresses. Protein, fat, major and trace minerals, and vitamin content decrease and lactose increases.[15] Water is the major constituent of mare's milk, being approximately 90%,[52–54] and the total feed consumption of the mare of forage and grain mixture increases according to individual milk production. Table 12 shows how much total feed is consumed per day by pregnant and lactating mares. Managers must watch the nutrient input-output relationship of lactating mares. If the mare is providing more nutrients in her milk than she is taking in, she will draw from her body reserves until her nutritional reserves are depleted. If calories are in short supply, her fat stores will be used up and she will loose body condition. If protein is in short supply, her muscle mass will be sacrificed because proteins are stored in the muscle. This negative balance, major and trace minerals included, will deplete her body reserves, lower those nutrients in her milk, and may have a negative effect on her conception rate or current fetal development, in addition to her health.

TABLE 12 Total Feed Consumed Per Day by Pregnant and Nursing Mares

REPRODUCTIVE STATUS	AMOUNT OF HAY AND GRAIN MIXTURE TO FEED PER DAY AS PERCENT OF BODY WEIGHT
Pregnant	1.5–2.0
Lactating, first 3 months	2.5–3.5
Lactating, 4 to 6 months	2.0–3.0

23.6.5
PERFORMANCE

As the activities of the performance horse increase, so do the nutritional requirements: calories needed per day increase to maintain desired body condition, the amount of minerals (electrolytes) and vitamins needed for optimal muscle function and health increase (see Figure 7), and the total amount of feed consumed per day increases. Table 13 shows trainers how much total feed to expect to feed per day based on activity level, whether feeding forage and grain mixture or forage, oats, and a ration balancer.

23.6.6
SAFE UPPER LIMITS

In the last column on the right of the growth and performance chart (see Figure 7) is the maximum number of BNUs that can be added to the minimum BNUs listed in the individual rectangles, to stay within the optimal range of nutrients in the total diet. This number of BNUs ensures that the SULs are not exceeded, with no antagonisms or decreased absorption of nutrients because of major or trace mineral interrelationships or acidic gut syndrome from too much soluble carbohydrates or inadequate fermentable fiber. The chart provides the

horse owner/manager the maximum number of BNUs per day, which then can be converted to the maximum number of pounds of a grain mixture to be fed per day. The best rule of thumb to offer clients is not to feed more than 50% of the total diet, by weight, of a grain mixture per day. Therefore the maximum amount of a 1573
grain mixture to feed, to maintain normal gut function, is half of what Tables 12 and 13 show. If one feeds these 1574
amounts and the horse does not maintain body weight, one should consider using vegetable oil as a supplemental calorie source instead of more grain mixture or cereal grain.

TABLE 13 Total Feed Consumed Per Day by Horses in Training

ACTIVITY LEVEL	AMOUNT OF HAY AND GRAIN MIXTURE TO FEED PER DAY AS PERCENT OF BODY WEIGHT
Laid up	1.5–2.0
Light training	2.0–2.5
Moderate training	2.5–3.0
Intense training	3.0–3.5

The BNU is made up of protein (amino acids), fats (fatty acids), major minerals, trace minerals, and vitamins necessary to complement the analysis of different forages. A ration balancer is this concentrated source of nutrients, which means one BNU is equal to one pound of the appropriate ration balancer. How many BNUs to feed per day depend on the size, current growth rate, reproductive status, and performance level of the horse. Which ration balancer to feed depends on the type of forage fed. Ration balancer “grass” is a ration balancer formulated to be fed when the forage is over 50% grass. Ration balancer “alfalfa” is formulated to complement forage over 50% alfalfa. (In Tables 2 and 3 one may see the protein and mineral levels found in these forage types and may compare them to how each ration balancer is formulated to complement them.)

23.6.7 FEEDING EXAMPLES USING BALANCED NUTRITIONAL UNITS WITH APPROPRIATE RATION BALANCERS AND AD-LIB FORAGE

Table 14 provides analyses of two ration balancers.

TABLE 14 Two Different Ration Balancers and Their Individual Analysis to Complement Different Forage Types

NUTRIENT	FEED WITH GRASS FORAGE RATION BALANCER “GRASS”	FEED WITH LEGUME FORAGE RATION BALANCER “ALFALFA”
Dry matter (%)	90.0	90.0
Protein (%)	30.0	14.0
Fat (%)	5.5	5.5
Crude fiber (%)	5.0	15.0
Calcium (%)	3.0	1.5
Phosphorus (%)	1.5	200
Potassium (%)	1.5	3.0
Magnesium(mg/kg)	0.4	1.5
Manganese (mg/kg)	260	0.9
Copper (mg/kg)	200	240.0
Iodine (mg/kg)	3.0	0.4
Iron (mg/kg)	240.0	260
Selenium (mg/kg)	1.5	1.5
Zinc (mg/kg)	500	500
Vitamin A (IU/kg)*	48,400	48,400
Vitamin D (IU/kg)*	4840	4840
Vitamin E (IU/kg)*	770	770

* IU/kg is the same as mg/kg and ppm.

23.6.7.1 Example 1

If a grain mixture is made of 33% oats, 33% corn, and 33% ration balancer “grass” and fed with grass forage to a pregnant mare weighing 1100 lb, the manager would multiply the number inside the rectangle on the performance chart (which is 2) by 3, to see how many pounds of this grain mixture to feed per day. This grain mixture is 33% ration balancer, and so 3 pounds of this mixture make one BNU or 1 lb of ration balancer. The daily recommended allowance would be 6 lb/day. The SUL of BNUs to feed per day (see the last column on the right of the performance chart) would be one additional BNU per day, which equals 9 lb/day of the grain mixture. The minimum amount of this grain mixture to feed to this pregnant mare would be 6 lb/day, and the maximum would be 9 lb/day.

23.6.7.2 Example 2

If a grain mixture is made of 30% oats, 30% barley, and 40% ration balancer “grass” and fed to the same pregnant mare, the owner would multiply the number inside the rectangle on the performance chart by 2.5 to see how many pounds of this grain mixture to feed per day. This grain mixture is 40% ration balancer and so 2.5 pounds of grain mixture makes one BNU or 1 lb of ration balancer. For example, 2 × 2.5 = 5 lb/day. The maximum number of BNUs to feed per day would be 3, so that 3 × 2.5 = 7.5 lb/day. The minimum amount to feed per day is 5 lb, and the maximum is 7.5 lb of this grain mixture to feed this pregnant mare.

These two different grain mixtures, when correctly fed, provide similar amounts of prenatal nutrition. The body condition of the mare should determine which one to feed. The individual body condition score of the mare tells the manager how many pounds of a grain mixture to feed per day and that tells which grain mixture to select, the grain mixture that takes 3 lb to equal one BNU or the grain mixture that takes 2.5 lb. The higher the percentage of ration balancer in the grain mixture, the fewer pounds need to be fed per day, and visa versa, to meet the prenatal requirements of the mare.

23.6.7.3 Example 3

If the owner wants to feed straight oats as the calorie source with forage, the first step is to find the number of BNUs needed to feed per day and provide that many pounds of the appropriate ration balancer. If more calories are needed, one should add oats to reach the desired body condition of their horses. One BNU equals 1 lb of ration balancer.

One should use the correct ration balancer to complement their forage and, if mixed with grain, know what
percent of the grain mixture is ration balancer. One then can figure how many pounds of this grain mixture 1574
equals one BNU, or 1 lb of ration balancer, and can multiply that number by the number inside the rectangle 1575
on the growth and performance chart. In this way the manager can ensure a diet that stays between the recommended allowance and the SUL. However, one must select the appropriate ration balancer to complement the forage to meet the nutritional needs of the horse.

23.7 Body Condition Scoring

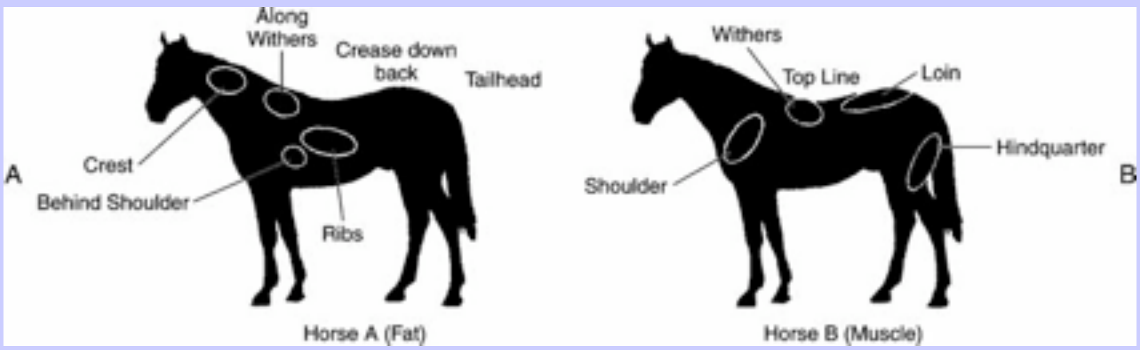
Body condition scoring is a visual and hands-on method to evaluate the amount of body fat a horse is carrying.[55] Developed at Texas A&M University by D.R. Henneke and others, this system is a good management tool to determine the optimal amount of body fat for every type of horse (Figure 8).

According to the diagram for horse A, one evaluates the amount of fat covering areas of the crest, withers, ribs, behind the shoulder, and down the back and around the tailhead. One must evaluate all of these areas because they are where the horse first deposits and stores body fat. Also, because different breeds and body types store fat in different locations, one must evaluate all of these areas.

Body condition scores range from 1 to 9, with a score of 1 being emaciated with no fat stores and 9 being extremely fat. A score of 5 indicates a moderate condition and the ideal body weight for most horses. One should be sure not to confuse body fat stores with gut fill or “hay belly.” The following provides a complete description of the body condition scores.

By regularly evaluating the condition of each horse, one can adjust the feeding and exercise program to maintain the desired condition. Each class of horse—based on age, growth rate, reproductive status, and performance level—has an optimal body condition score. When body condition scoring young, growing horses each month, one should record their weight, height, and body condition score on the growth chart. When scoring a performance horse, one should remember that they need enough body fat stores to use as an energy source to maintain performance, although too much fat can decrease performance. This system sets a standard for evaluating and communicating the condition of a horse. The BNUs on the growth and performance chart are set up for a body condition score of 5. The two most common management problems are overfeeding and underfeeding horses. To help prevent either of these problems from developing, one should evaluate the body condition score of the horse (Table 15), adjust the feeding program while assuring adequate BNUs are fed per day, and monitor the score frequently.

Figure 8 Body condition scoring. Horse **A**, Evaluating the locations of fat stored. Horse **B**, Evaluating locations of muscle stored.



In the diagram for horse B, one should not confuse body fat stores with muscle deterioration caused by a protein deficiency. Horses fed a protein-deficient diet have the ability to tear down muscle, where protein is stored, to keep the body functioning normally. The first visible loss in muscle mass is the withers, followed by the loin, the hindquarter, and then the shoulder area. In other words, the top line is the first place to look for protein deficiency and not fat stores. To round out the back area with fat, the horse will have to have a body condition score of 8 or better.

The optimal feeding program considers *all* the nutrients from the forage and the grain mixture or ration balancer. Nutrients are water, protein, fat, carbohydrates, minerals, and vitamins. A successful diet balances the recommended allowances of *all* these nutrients, including fiber, which is necessary for a healthy horse, rather than increasing any single nutrient alone. As horses age, their ability to absorb protein and phosphorus diminishes and their top line is the first area to show a deficiency, thus causing a weakened back to sag. To reduce this occurrence and meet the requirements of the older horse, Sara Ralston of Rutgers University recommends increasing the protein, phosphorus, and vitamin C quantities above the NRC minimum in the diet of the geriatric horse to meet nutritional needs.[56] 1575

TABLE 15 Description of Body Condition Scores

SCORE	NAME	DESCRIPTION
1	Poor	Animal extremely emaciated. Spinous processes, ribs, tailhead, and hooks and pins project prominently. Bone structure of withers, shoulders, and neck easily noticeable. No fatty tissues can be felt.
2	Very thin	Animal emaciated. Slight fat covering over base of spinous processes; transverse processes of lumbar vertebrae feel rounded. Spinous processes, ribs, tailhead, and hooks and pins prominent. Withers, shoulders, and neck structures faintly discernible.
3	Thin	Fat buildup about halfway on spinous processes; transverse processes cannot be felt. Slight fat cover over ribs. Spinous processes and ribs easily discernible. Tailhead prominent, but individual vertebrae cannot be identified easily. Hook bones appear rounded, but easily discernible. Withers, shoulders, and neck accentuated.
4	Moderately thin	Negative crease along back. Faint outline of ribs discernible. Tailhead prominence depends on conformation; fat can be felt around it. Pin bones not discernible. Withers, shoulders, and neck not obviously thin.
5	Moderate	Back level. Ribs cannot be distinguished visually but can be felt easily. Fat around tailhead beginning to feel spongy. Withers appear rounded over spinous processes. Shoulders and neck blend smoothly into body.
6	Moderately fleshy	May have slight crease down back. Fat over ribs feels fleshy-spongy. Fat around tailhead feels soft. Fat beginning to be deposited along the sides of the withers, behind the shoulder, and along the side of the neck.
7	Fleshy	May have crease down back. Individual ribs can be felt, but filling between ribs with fat is noticeable. Fat around tailhead is soft. Fat deposited along withers, behind shoulders, and along the neck.
8	Fat	Crease down back. Difficult to feel ribs. Fat around tailhead very soft. Area along withers filled with fat. Area behind shoulder filled with fat. Noticeable thickening of neck. Fat deposited along inner thighs.
9	Extremely fat	Obvious crease down back. Patchy fat appearing over ribs. Bulging fat around tailhead, along withers, behind shoulders, and along neck. Fat along inner thighs may rub together. Flank filled with fat.

Modified from Nutritional Research Council: *Nutrient requirements of horses,* Washington, DC, 1989, National Academy Press.

23.8 Nutritional Needs for Life Stages and Activity

Age, growth rate, reproductive status, and activity level may affect nutritional requirements significantly. Consideration of the affect of these variables on energy, protein, and mineral requirements is essential for establishing appropriate dietary recommendations for any horse.

23.8.1 NUTRITIONAL NEEDS FOR REPRODUCTION

23.8.1.1 Stallion

Nutritional management of the stallion differs little from that described for the mature horse (Table 16). During breeding season, stallions generally need more energy to compensate for the increase in activity and stress. Adjustments in feed intake should be gradual. One should increase feed to provide enough calories to maintain the stallion at the body condition score desired by the owner/manager. A calorie increase of 25% above maintenance may be needed during the breeding season. The usual digestible energy requirement for stallions in the nonbreeding season is about 15 kcal/lb body weight and during the breeding season is about 20 kcal/lb body weight.

Obesity can be a problem for all horses, especially stallions, in the off season. If the quantity of the grain mixture fed is not reduced when activity level decreases, the resulting is overfeeding of calories. The consensus of stallion managers is that stallions that are kept in good body condition through dietary control, exercise, or both, are more sound, responsive, and fertile and remain healthier than stallions that are permitted to become obese. To help maintain optimal body weight, stallions should be turned out or exercised in hand each day throughout the year.[15]

23.8.1.2 Open Mare

One should maintain mares with a body condition score of 5 to 7 and should feed them the BNUs according to their individual size (see Figure 7). One should place mares that have retired recently from athletic competition or that may be in poor condition in a weight-gaining plan before breeding to increase the likelihood of conception and improve reproductive efficiency.[15] Such management increases the chance of conception and reduces the number of covers compared with mares with a body condition score of less than 4.[50]

23.8.1.3 Pregnant Mare

For years, calcium and phosphorus (and their ratios) have been considered two of the most important
minerals in the equine diet. The reason these two major minerals received so much attention is because they 1576
are associated closely with bone development and overall health. When young horses developed distended 1577
joints, physitis, lameness, or fractures, deficiencies in calcium and phosphorus were the first suspected.

TABLE 16 Comparison of Recommended Allowances for Stallions During the Off Season and Breeding Season on a Total Ration Dry Matter Basis (Including Forage)

NUTRIENT	OFF SEASON	BREEDING SEASON
Dry matter intake (% body weight)*	1.5–2.0	2.25–2.75
Protein (%)	8.5	10.5
Calcium (%)	0.30	0.36
Phosphorus (%)	0.21	0.26
Potassium (%)	0.40	0.50
Magnesium (%)	0.10	0.12
Sodium (%)	0.14	0.30
Manganese (mg/kg)	40	50
Iron (mg/kg)	40	50
Copper (mg/kg)	15	20
Zinc (mg/kg)	40	50
Cobalt (mg/kg)	0.20	0.20
Iodine (mg/kg)	0.25	0.25
Selenium (mg/kg)	0.15	0.20
Vitamin A (IU/kg)	2000	2000
Vitamin E (IU/kg)	50	80
Thiamine (mg/kg)	3	5
Riboflavin (mg/kg)	2	2

* Feed intake is determined by body capacity, physiologic status, activity level, relative feed value of forage, and environment. Needed digestible energy (Mcal/day) is determined by body size, metabolic rate, reproductive status, dry matter consumption, and body condition score.

In the 1980s, research completed at The Ohio State University,[57] followed closely by that of the University of Guelph,[51] included the roll of trace minerals in prenatal nutrition and in suckling and weanling diets. The first trace minerals reviewed were copper and zinc in utero and after parturition, because of their involvement in cartilage formation, the transformation of cartilage into bone, and tendon elasticity.

In the early 1990s, research completed at the veterinary departments of Cornell University and University of Illinois stated that the last two trimesters of pregnancy were equally important times to provide the mare with the protein and calories to maintain normal development of the fetus and health of the mare.[50] Insufficient nutrient levels force the mare to draw from her body reserves to maintain normal fetal development and maintain her pregnancy. Once her reserves are depleted, the fetus could suffer from early embryonic death.[60]

In the late 1990s, further research published by E.C. Firth,[58a] from Massey University, New Zealand, took the concept one step further. Stating the importance of the total ration in the diet of the pregnant and lactating mare, Firth was able to show the higher incidence of developmental orthopedic disease (DOD) in their foals when the prenatal and postnatal diets of mares and their respective foals contained adequate major minerals but with trace mineral levels below recommended allowances suggested by The Ohio State University and the University of Guelph (Table 17).

The nonlactating pregnant mare should be fed the BNUs according to her individual size (see Figure 7) to meet her prenatal requirements (see Table 17). The early growth of the fetus is minimal and does little to increase nutrient demand above maintenance; however, recent research suggests that weight gain of the mare occurs during midgestation for use as an energy source later in gestation and lactation.[50] One should include in the dietary plan adequate calories to maintain the body condition score desired by the owner/manager and the protein, minerals, and vitamins to meet the recommended allowance to support the mare in pregnancy, lactation, and/or athletic activity, whichever requires the most nutrition.

The greatest increase in fetal growth and nutrient demand occurs during the last 3 to 4 months of gestation[1,18] (Table 18), necessitating increases in most nutrients to support growth and development. Supplying the extra nutrients is often confounded, however, by the reduction in digestive capacity because of the increasing size of the fetus.[15] The solution is to increase the nutrient density concentration by switching to the appropriate ration balancer with the forage and to add cereal grain *only* if necessary to maintain or increase body weight. One should monitor mares as previously described to prevent undesired increases in body condition score. Decreases in energy intake of more than 10% in obese mares are not recommended to facilitate weight loss because of the potential risk of hyperlipidemia.[1,58]

A minimum increase by 10% of the protein intake has been recommended for protein needs of the fetus.[2] The effects of higher intakes of protein on fetal health have not been evaluated; however, the fact that many mares fed alfalfa consume nearly twice the NRC requirement for crude protein and produce healthy, vigorous foals suggests that little concern is necessary[15] as long as the total diet is balanced and prenatal nutrients are supplied adequately (see Table 17).

Recent studies of fetal growth, body composition, and postnatal development have provided some estimates of mineral needs during the last 3 to 4 months of pregnancy.[59] Data suggest that to provide for fetal mineral deposition, the calcium and phosphorus intake must increase by nearly 80% above maintenance; magnesium
and potassium must increase by 25%.[2] However, mares fed diets of grass hay and unfortified cereal grain are 1577
likely to be deficient in protein, calcium, phosphorus, copper, zinc, iodine, and selenium. One should 1578
compare current intake with the recommended levels in Table 17 to determine how much extra of each nutrient is needed.

TABLE 17 Comparison of the Recommended Allowance for Mares While Open, Pregnant, and Lactating on a Total Ration Dry Matter Basis (Including Forage)

NUTRIENT	OPEN	PREGNANT	LACTATION (FIRST MONTHS)	LACTATION (4–6 MONTHS)
Dry matter intake (% body weight)*	1.5–2.0	1.5–2.0	2.5–3.5	2.0–3.0
Crude protein (%)	8.50	11.50	15.00	13.00
Calcium (%)	0.30	0.53	0.70	0.50
Phosphorus (%)	0.21	0.35	0.40	0.34
Potassium (%)	0.40	0.50	0.80	0.60
Magnesium (%)	0.10	0.12	0.15	0.12
Sodium (%)†	0.14	0.14	0.20	0.16
Manganese (mg/kg)	40	60	60	60
Iron (mg/kg)	40	80	80	80
Copper (mg/kg)	15	25	25	25
Zinc (mg/kg)	40	70	70	70
Cobalt (mg/kg)	0.20	0.20	0.30	0.25
Iodine (mg/kg)	0.25	0.25	0.50	0.35
Selenium (mg/kg) g	0.15	0.20	0.30	0.20
Vitamin A (IU/kg)	2000	3000	3000	3000
Vitamin E (IU/kg)	50	80	80	80
Thiamine (mg/kg)	3	3	3	3
Riboflavin (mg/kg)	2	2	2	2

* Feed intake is determined by body capacity, relative feed value of forage, physiologic status, activity level, and environment.

† Under average conditions 0.35% to 0.50% NaCl is recommended in the total diet. Needed digestible energy (Mcal/day) is determined by body size, metabolic rate, reproductive status, dry matter consumption, and body condition score.

A great deal of interest has arisen in work concerning trace mineral supplementation of the broodmare and its role in the DODs of foals.[51,57,58,61] Though additional studies are needed, recent research has demonstrated that supplementation of copper in the gestational diet of the mare and the diet of the foal reduced the frequency of cartilage abnormalities in the foals compared with mares and foals consuming NRC-recommended concentrations of copper.[57,58,61] An important note is that copper was not the only nutrient increased in this study. Researchers also increased manganese, zinc, and selenium concentrations between

diets to prevent antagonisms, but maintain nutrient ratios extrapolated from NRC recommendations. Therefore adding copper or any mineral alone without evaluating the other minerals is not recommended. Selenium and iodine are also of importance to the broodmare. Foals from mares fed from 35 mg to 48 mg of iodine per day were born with enlarged thyroid glands, characteristic of iodine toxicity. The levels of trace minerals listed in Table 17 currently are recommended for broodmare diets on farms where nutrition is believed to be a contributing factor to the occurrence of the DODs. In most situations, the recommended allowance fed throughout entire gestation is sufficient.

TABLE 18 Length and Weight of Equine Fetuses by Gestational Age of 450-kg (990-lb) Mares

AGE (DAYS)	CROWN-RUMP LENGTH (cm)[*]	MASS (WEIGHT)
60	6	17 g
90	16	160 g
120	25	700 g (1.5 lb)

23.8.1.4 Lactating Mare

Calorie requirements for the lactating mare are related directly to the amount of milk she is producing. Milk production volume is influenced by the number of previous lactations, the month of lactation, genetic potential, nutrient input versus output, and foal intake.[15] Mares come into milk production slowly and do not reach peak daily production until 5 to 6 weeks post partum. One should not be in a hurry to feed the 1578
maximum amount of a grain mixture to the mare that has just given birth. One can increase the amount of 1579
forage by offering hay ad lib for the first few days. On the third day, after assurance that no complications exist, one can begin increasing the grain mixture at a rate of 1 lb per day. Too much grain too soon can cause digestive upsets and colic. The key to feeding and keeping the foaling mares healthy is slowly increasing the amount of grain mixture fed per day.

During the first 3 months of lactation, most mares peak in milk production between 3.0% and 3.5% of their body weight in fluid milk per day. Pony mares give slightly more than 4.0%.[15,52–54,62] Field experiences suggest maiden mares have lower milk yields and lower immunoglobulin G (IgG) levels in their colostrum. Peak lactation occurs between 4 weeks and 10 weeks post partum,[53,54,62] with an average of 5 to 6 weeks.

[53,54] As lactation continues, milk production declines to approximately 2% of the body weight of the mare by the twelfth week of lactation.

Milk nutrient composition changes and becomes more dilute as lactation progress (Table 19). The protein, fat, caloric, mineral, and vitamin content decreases, and lactose increases with time of lactation.[53] The increase in lactose content is not high enough to offset the decreases in protein and calorie-dense fat, resulting in lower calorie content.[15] The nutrients of the mare in greatest demand are water and calories, followed by protein, major minerals, trace minerals, and vitamins. Mare's milk is approximately 90% water. A 500-kg mare producing 15 kg of milk daily would have to increase her water intake nearly twofold to replenish this loss. Early in lactation, mare's milk contains approximately 560 kcal/kg of fluid milk.[52–54,59] Assuming mares convert 60% of feed digestible energy into milk gross energy, the mare must consume an extra 792 kcal of digestible energy for every kilogram of milk produced.[2] The energy requirement increases 72% above maintenance, which is why lactating mares must consume 2.5% to 3.5% of their body weight in total feed per day[15] (see Table 12). Protein needs have been estimated to be almost double from those of maintenance (see Table 17).

Calcium and phosphorus losses from the body reserves of the mare during lactation can be significant without adequate supplementation of these essential minerals.[15] Mare's milk in early lactation contains 112 mg of calcium and 68 mg of phosphorus per kilogram of fluid milk, decreasing to 80 mg and 50 mg, respectively, during the third month (see Table 19). The recommended allowance in Figure 7 allows for these changes in mineral concentration by lowering the recommended allowance in the fourth through the sixth months of lactation.

The trace mineral and vitamin content of mare's milk is now available from several studies.[52–54,62] All trace minerals are low in mare's milk and are believed to be one of the genetic components of DOD. One now can monitor mare's milk on a monthly basis by analyzing it and comparing it with Table 19. If the foal's legs are normal at birth and acquire leg deviations with age, but all the foal is consuming is mare's milk, one logical step would be to analyze the mare's milk and compare it with the expected mineral density average. If a mare has had problems with her foals in the past with DOD, the author would consider her a suspect or at risk mare. If the mare is suspect, one should analyze her milk on day 7 after foaling and every 30 days after that and compare her milk mineral density with Table 19. Several products are on the market today formulated to complement mare's milk and to be given orally to the foal, as a drench, once a day. These products provide trace mineral and vitamin supplementation and enable the broodmare manager to keep the nutrient-deficient foal on the mare rather than wean early. However, if the foal is older than 3 months of age when these acquired tendon contractures begin to manifest, weaning the foal and putting it on a balanced weanling formula is easier and more economical to ensure adequate consumption of all nutrients. The manager must then make sure the correct number of BNUs are fed per day to complement the growth rate of the foal.

The analysis of Rejuvenaide® (per 5 ml drench or 2 ml paste) is as follows:

Ascorbic acid	100.00 mg
Copper	3.20 mg
Zinc	9.40 mg
Selenium	0.25 mg
Vitamin A	3500 IU
Vitamin D	350 IU
Vitamin E	100 IU

Reliance on adequate prenatal nutrition is important and must be emphasized greatly to prevent nutritional deficiencies from occurring in the suckling, until solid food intake begins. The point at which mare's milk and the liver stores of the foal can no longer provide the trace mineral needs of the foal can be seen in rapidly growing foals consuming only mare's milk and showing signs of DOD before the suckling begins consuming an adequate amount of dry feed. Low mineral density in mare's milk is one of the genetic components of DOD. Research completed by The Ohio State University, the University of Guelph, and most recently by Massey University clearly state that trace mineral supplementation is beneficial in the diet of the suckling when the mare has previously produced a foal with what appears to be nutrition-induced DOD. Comparing the suspect mare's milk analysis with Table 19 helps the practitioner to explain why and how much of a trace mineral supplement is necessary and recommended per day.

Body condition scoring is the best gauge for determining the caloric needs of the lactating mare.[15] Mares that 1579
lose weight during lactation should have their total ration evaluated to ensure they are being fed between the 1581
recommended allowance and the SUL of a feed formulated for the nursing mare (see Figure 7). If more calories are needed, one can add vegetable oil to the diet of the mare rather than feed over the SUL of the grain mixture. Mares that gain weight during lactation are not channeling the nutrients fed toward milk production, but are storing the extra calories as fat instead. When feeding easy-keeping mares, one should make sure the recommended allowance is provided with a lower-calorie diet and should be sure to offer a milk-based foal starter to her foal in a separate creep feeder until the foal is 3 months old.

23.8.2 NUTRITIONAL NEEDS FOR GROWTH

23.8.2.1 Sucklings

At birth, normal-sized foals should weigh between 10% and 12% of the body weight of the mare. The exception is the maiden mare: these foals usually weigh between 8% and 10% of the mare's body weight. The average foal should stand square on all four feet and nurse within 2 hours after birth. Deviations from normal may indicate something interfered with the nutritional absorption, prenatal growth, or positioning process in utero and requires evaluation by the veterinarian. Abnormalities can occur in foals born to mares that were malnourished or had chronic placental insufficiency or uterine sepsis. These foals are often born small and weak and have lower nutrient reserves. Because of the increase in nutrient demand following birth, injury, or disease, supplying ample, balanced, and complete nutrition is critical for health, development, growth, and recovery of the foal.[15] One should ensure that nutrition is not the limiting factor in raising sound, healthy equine athletes today.

The average foal drinks 7 to 10 times per hour for the first 30 days of life. The frequency is necessary because they are born with little energy reserves.[18,63] Thus a readily available food source is necessary to support thermoregulation and growth.[15,63]

Data collected from several studies have provided reasonable estimates for evaluating growth and growth rates of foals.[1,63] The greatest increase occurs in the body weight. The first 30 days is when the most rapid growth rate occurs, and the birth weight doubles in less than 60 days.[15]

Data collected from lactation and growth studies have provided some estimate of the protein, calories, and minerals needed to support the early growth of healthy foals for the first 3 months of age.[15] Between 3 and 4 months of age the enzyme activity of maltase equals that of lactase,[29] so the foal less than 3 months of age should have available a milk-based foal feed to optimize absorption and reduce the chance of diarrhea as a result of too much starch consumption before the foal can digest it. A milk-based foal starter feed should be formulated to complement the mare's milk rather than forage. The large intestine of the foal is not yet fermenting and therefore cannot digest forage. If the young foal consumes forage, it often passes undigested. The vegetable matter takes up space but provides little nutrition and may cause a distended abdomen. The only feed the foal can handle in large quantities without digestive upset is milk. The protein, calories, and minerals in the feed of the foal should complement the mare's milk analysis (see Table 19). The amount of supplementation a foal needs to consume per day is related directly to the quantity of milk the mare produces. The young foal may show an interest in eating other feed when its mare's milk is inadequate to satisfy its appetite.

When crossbreeding a smaller mare to a larger stallion, the larger, faster-growing foal may have a larger appetite. Providing every foal a milk-based foal starter feed formulated to complement the mineral density of mare's milk is critical to the health and quality of growth for the first 3 months.

As stated previously, the growth of various portions of the gastrointestinal tract parallel changes in enzyme activity. Significant increases in the length and diameter of the small intestine occur within the first month, increasing the available villous surface area and making it possible for the foal to process increasing volumes of milk to meet its needs. During the next 5 months, growth of the small intestine continues, but the greatest increases occur in the lengths of the cecum and large colon at the time when foals traditionally begin mimicking adult grazing behavior and increasing their intake of forage and grain.[30] From 6 months on, most of the growth occurs in the cecum and large intestine, allowing for the increased consumption and use of fibrous feeds.

23.8.2.2 Feeding Orphaned or Rejected Foals

Orphaned or rejected foals can be raised on a nurse mare or provided with a mare's milk replacer in a bucket in their stall. Evaluating several factors helps one make the decision:

- Pro Nurse Mare: The nurse mare may be turned out to pasture with the grafted foal with other mares and foals. This requires less time and effort to manage the orphan or rejected foal and has the added advantage of often resulting in more normal behavior in the foal.[15]
- Con Nurse Mare: The current cost for nurse mare rental is $1,500 plus transportation to and from the farm, plus returning the mare back in foal. The mare must be in the same stage of lactation as the mare

she is replacing because the natural mineral density declines in her milk. The longer the mare has been lactating, the more difficult switching foals onto her will be. The possibility exists of infectious disease transmission to the privately owned broodmare stock.[15] 1581

1582

- Pro Milk Replacer: Currently, at approximately $100/50 lb bag of powered or pelleted milk replacer with a total of five bags needed until weaning, the average cost will be $500. The nurse mare's milk mineral density question is ruled out because of the guaranteed analysis in the milk replacer. Foals can be turned out with a quiet gelding or mare until weaning or at weaning turned out with other weaned foals.

- Con Milk Replacer: Management must oversee feeding and clean the bucket every 12 hours. One must teach the foal to drink from a bucket in the stall, must teach acceptable behavior early, and must get the orphan to interact with other foals or horses as soon as possible. One must follow the feeding directions prescribed on each bag; the feeding directions for one brand do not apply to a milk replacer of another company.

Several milk replacers are currently available; however, the calf, lamb, and kid milk replacers are not nutritionally adequate or balanced for foals. Whole cow's milk and goat's milk have been advocated, but poor weight gains and metabolic acidosis were reported recently in neonatal foals consuming their required amount per day. Milk replacers containing maltodextrins, corn syrups, and glucose polymers are not recommended for foals less that 3 weeks of age because of the low level of maltase activity in the small intestine of the foal.[15,29] Also, milk replacers with a crude fiber of more than 0.15% indicate that the formula is not all milk and therefore is not recommended up to 30 days of age.

If the foal is more than 3 weeks of age when orphaned, liquid milk replacer is unnecessary and a pellet may be fed milk-based foal starter free choice. At this age the molars are in and the foal can chew the milk pellets and swallow them successfully. One should provide only milk-based pellets until the foals are 3 months old. Between 3 and 4 months of age, one should mix equal amounts of the milk-based pellets with a weanling formula that complements their forage.

Each foaling season, a number of foals end up as orphans or rejected. The following is a highly successful program for raising orphan foals that has been implemented in several universities and veterinary neonatal hospitals. Foals raised with this method grow just as well as nonorphans and attain their normal size. In fact, when orphans are raised according to the following recommendations, telling the difference between them and those raised with the mare is difficult. The program is also easy to implement and manage.

Research completed in 1999 compared the different growth rates of foals remaining on the mare and provided a milk-based pellet in a creep with foals weaned at 3 days and raised on the following feeding program. Researchers recorded weekly measurements of body weight, heart girth, body length, wither height, hip height, and cannon bone circumference of the foals. Results showed that foals developed similarly in skeletal size. Although the control group foals (remaining on the mare) were heavier, the foals in all groups received similar body condition scores and were healthy. Foals were not negatively affected by early weaning and did not develop unacceptable habits. Raising foals on an equine milk replacer is helpful to those who are managing orphaned, rejected, or early weaned foals. The program is a successful alternative to keeping the mare and foal together for 4 to 6 months if the mare is competing and can be used for aged (>20 years) brood mares to reduce the stress of raising a foal and being bred.

Colostrum, or the mare's first milk, contains high levels of antibodies to protect the foal from disease. After foaling, the mare secretes colostrum for 24 to 48 hours. Foals absorb colostrum for 12 to 24 hours after birth

or until an adequate of amount of whole protein antibodies are absorbed through the small intestine. The quicker one can get the colostrum into the foal, the faster the large openings in the small intestine will close. All foals, whether on the mare or orphaned, need colostrum. After birth, preferably within the first hour, the foal should begin to receive colostrum. A 100-lb foal should receive 250 ml (approximately 1 cup) of colostrum each hour for the first 6 hours after birth for a total of 1500 ml, or about 3 pints of colostrum per 100 lb of body weight. All breeding farms should have a minimum of 3 pints of frozen colostrum in storage. When needed, one should remove the colostrum from the freezer and thaw it at room temperature or in warm water, pour it into a bottle that has a nipple opening of at least ½ inch, and let the foal suckle. One should *never* warm colostrum in a microwave because the radiation destroys the whole protein antibodies.

Septicemia continues to be the leading cause of death in neonatal foals. Permeability of the bowel during the first 12 to 24 hours of life is increased, which allows the foal to absorb immunoglobulins such as IgG, IgM, IgE, and IgA from the colostrum but may also allow the absorption of harmful pathogens from the environment. Bacterial exposure to the "open gut" is considered a likely route for exposure to bacteria in neonatal foals. Early (rapid) gut closure may be equivalent to or more important than simple absorption of serum IgG in preventing neonatal bacterial infection.[64] If colostrum is unavailable, a suitable substitute must be provided. These substitutes and recommendations for their use are discussed in Chapter 19.

Foals with only 200 mg/dl IgG at 24 hours of age do not get sick on some farms, suggesting that low IgG alone is not sufficient to result in septicemia in all foals.[64] Lack of illness may result from good management as well as conditions that favor the ingestion of colostrum by the foal rather than a specific IgG level in the foal. 1582

1583

After colostrum or a colostral substitute has been provided, one should introduce the orphaned or rejected foal to an ad lib mare's milk replacer. One may start the orphan drinking from a plastic bowl or with a lamb nipple, depending on how aggressive they are. (If one uses a nipple, one should make sure the *opening* is a least ½ inch wide.) However, a nipple is not necessary, and the foal will learn to drink from a shallow bowl or bucket at any age. The foal does not have an esophageal groove like the calf, so nipple feeding offers no bypass benefit. The foal learns to drink readily if one places a finger in its mouth and then, while it is sucking, raises the small bowl containing the liquid milk replacer up to its muzzle. One slowly removes the finger from the mouth of the foal while it is drinking. If the foal stops, one should repeat the previous steps until the foal is drinking by itself. One always should bring the milk up to the foal and *should never force the head of the foal into a bucket*. The first day one can warm the mare's milk replacer to encourage consumption. When the foal drinks without assistance, one can hang a bucket from the stable wall at shoulder height that will allow the foal to drink whenever it wants. The bucket should be a contrasting color to the wall to make it easy for the foal to find.

Select an ad lib mare's milk replacer formulated to be mixed in water and fed at room temperature free choice. Two frequently used milk replacers for foals are Foals First® from progressive nutrition and Mare's Milk Plus® from Buckeye Nutrition. The ingredients in the milk powder help maintain the natural pH in the digestive system of the foal. Table 20 gives proportions for mixing Foals First® powder and water to ensure the correct amount of milk solids (10%) and a pH of 5.3.

When mixed with cool water, the milk replacer has a tart taste that discourages a foal from drinking too much at one time, even when offered free choice. One should make sure the mixing directions are carefully followed. Foals less than 30 days old drink from their dams an average of 7 to 10 times per hour. Feeding Foals First® insolution free choice allows the foal to follow this natural inclination to drink.

The average mare produces 3.0% to 3.5% of her body weight in milk per day, so a 1000-lb (454-kg) mare can produce 30 pounds (14 kg), or 4 gallons (18 L) of milk per day.

TABLE 20 How to Mix Foals First® Milk Replacer Powder With Water

	FOALS FIRST(R) POWDER	
WATER (GALLONS)	**ENCLOSED RECEPTACLE**	**POUNDS**
1.0	2.00	1.0
2.5	5.0	2.5
5.0	10.00	5.0

One should start feeding the foal just like the mare would—slowly. One begins by providing half of the recommended amount on the first day according to the size of the dam and then gradually increases the amount over the next 2 to 3 weeks, but no faster than 1 qt or 1 L per day, until the suckling is consuming the recommended amount. If the stools of the foal become loose, one should slow down; the rate of increase may be too fast. One should remember, however, that even orphaned foals may go through "foal heat" scours. One should mix the amount a foal should consume in 12 hours (one half of the daily amount) and make it available free choice. Giving a foal access to milk at all times is feeding the natural way, or on demand. Allowing a foal to drink a little at a time, as often as it wants, results in fewer digestive upsets, improved milk digestibility, dramatic weight gains, and improved overall foal health. Each time one mixes new formula, one should discard any milk not yet consumed and thoroughly clean the bucket before adding fresh milk replacer.

From birth to weaning, at 4 months of age, a foal that weighs 100 lbs at birth will need 3/50 lb bags of Foals First® milk replacer powder, 4/50 lb bags of Foals First® milk replacer pellets, and 7/50 lb bags of Foals First® starter and creep feed.

After the foal is drinking the recommended amount of equine liquid milk replacer, one should provide clean water in another bucket free choice along side the milk replacer bucket.

When the foal consumes the recommended amount of equine liquid milk replacer before the next feeding, one should add a handful of the milk replacer pellets into the bucket. Foals are creatures of habit, so one must teach them that eating dry feed is okay. At the time of the next feeding of liquid milk replacer, one should empty any milk replacer pellets left in the bucket and give the liquid milk replacer as usual. Once foals begin to eat the pellets from the bucket, one should provide them in a separate feed tub free choice. Because of the milk formula, one can offer them free choice. A cereal grain–based weanling ration is not recommended at this time because of the low maltase activity and it could cause acidosis and loose stools. This digestive upset decreases absorption of nutrients, predisposing the foal to nutritional deficiencies that could lead to DOD.

At 4 weeks of age one can begin weaning the foal by reducing the liquid Foals First® milk replacer, one gallon (4.5 L) at a time. As the liquid milk is reduced, the foal will increase the amount of milk pellets consumed per day. For every gallon reduced, the foal should consume 1 pound more of milk pellets per day.
This weaning off of liquid milk replacer should take 7 to 10 days. The pelleted milk replacer should be 1583
formulated for the young foal with a monogastric digestive system. One should let the foal eat as much of 1584

them as it wants until it is 2 months old. At that age the digestive enzymes of the foal are changing from lactase to maltase and amylase and the cecum begins to function (ferment), allowing the foal to start digesting forage (hay or pasture).

At 2 months of age, change to the Foals First® starter and creep feed. This is a transition feed and the ingredients include extruded soybean and steam rolled oats. This complements the foals changing digestive system and should be provided free choice up to 4 months of age. Between 3 to 4 months of age, one should select a high-quality weanling ration formulated to complement forages and should mix it 50/50 with the foal starter and creep feed for the next 2 to 4 weeks. After 4 months of age, feeding milk is not necessary. This management follows the normal changes in the digestive system of every foal and promotes optimal growth and maximum nutrient absorption while reducing the chance of digestive upsets.

23.8.2.3 Weanlings

Because no one in the United States continues to breed mares for milk production, some of the genetic lines of good milk producers have been lost. Thus earlier weaning times are more common. The following two management tools help determine the time to wean:

1. The amount of milk-based foal starter and creep feed consumed per day before 4 months of age or the amount of a growing ration consumed per day after 4 months. When the foal is consuming more than 3 lb per day of either, the mare is not producing enough milk to satisfy its appetite. At this time, foals are easy to wean no matter how old they are.

2. When the foal is not eating anything but the mare's milk and starting to show signs of nutritionally related growth abnormalities such as DOD, physitis or acquired contracted tendons.

If weaning time is before 4 months of age, one must remember that offering milk-based foal starter and creep feed ad lib is critical. Just because the foal is weaned does not change the enzymatic activity in its digestive system. One should follow the same feeding program for the early weaned foal as recommended for the orphaned foal, depending on their age at weaning.

TABLE 21 Estimated Body Weights for Growing Horses Maturing at 400, 500, and 700 kg While Growing at a Moderate Rate

	MATURE BODY WEIGHT 400 kg		500 kg		700 kg	
AGE	WEIGHT (kg)	PERCENT OF MATURE WEIGHT	WEIGHT (kg)	PERCENT OF MATURE WEIGHT	WEIGHT (kg)	PERCENT OF MATURE WEIGHT

36 months	400	100	490	98	650	93

From Nutritional Research Council: *Nutrient requirements of horses,* Washington, DC, 1989, National Academy Press.

After 4 months of age, no reason exists to feed quantities of milk to the growing foal. One should provide a growing ration according to desired body condition and recommended allowance (see Figure 7). Because the body capacity of the foal is small, the percentages of all nutrients must be high to ensure the foal consumes adequate amounts per day. As the body capacity increases, one can lower the percentages fed because the foal is consuming more pounds or kilograms per day (Table 21).

After 6 months of age the digestive system of the foal is changing more into that of a continuous grazer, and the author recommends managing the weanling to complement its digestive system. The larger the body capacity, the larger the fermentation vat and therefore the more forage that can be consumed. However, the increased body capacity for forage does not usually keep up with the increased mineral requirements for
skeletal development. The larger, faster-growing foals are more prone to skeletal problems because of their 1584
higher mineral needs to support their larger structure. Therefore using the growth chart (see Figure 7) to 1585
determine their individual recommended allowances is the managers' best tool to reduce the incidence of nutrition-related growth problems.

Because foals do not grow at the same rate or mature to the same size, their nutritional needs differ. Table 21 is the accumulation of different breeds and the average rates at which they mature. The small horses mature earlier, and the larger horses mature later. Even within breeds maturing rates differ. The only way to meet the nutrient needs of the growing horse is to monitor its growth and feed according to its own growth rate. This feeding program does not recommend trying to speed up growth or to slow down growth but to provide all the nutrients foals need to grow optimally up to their genetic potential.

To meet the weanling caloric requirements to maintain desired body condition, the diet is approximately 70% growing ration and 30% forage.[1] As the body capacity changes, the proportion of the growing ration to forage shifts to more forage. The owner/manager must make sure to meet the recommended allowance with the pounds of growing ration they are feeding per day.

23.8.2.4 Yearlings

One should balance the total ration for yearlings according to their size, growth rate, and age. Their size and growth rate determines the necessary recommended allowance of protein, minerals, and vitamins needed per day (see Figure 7). As the body capacity increases and/or the forage RFV improves, less growing ration is needed per day to maintain desired body condition. One should increase the forage portion of their diet and decrease the growing ration, but make sure their recommended allowance (RA) of nutrients is met.

TABLE 22 Comparison of the Recommended Allowance for Growing Horses on a Total Ration Dry Matter Basis (Including Forage)

NUTRIENT	WEANLING (4–6 MONTHS)	WEANLING (6–12 MONTHS)	YEARLING (12–18 MONTHS)	LONG YEARLING (18–24 MONTHS)	2-YEAR-OLD TO (MATURE)
Dry matter intake (% body weight)*	2.25–2.75	2.75–3.125	2.25–2.75	2.0–2.5	1.75–2.25
Crude protein (%)	18.00	16.00	14.00	12.00	11.00
Calcium (%)	0.90	0.80	0.70	0.60	0.53
Phosphorus (%)	0.65	0.55	0.45	0.40	0.35
Potassium (%)	0.90	0.80	0.70	0.60	0.53
Magnesium (%)	0.20	0.19	0.18	0.15	0.12
Sodium (%)	0.10	0.12	0.14	0.14	0.14
Manganese (mg/kg)	65	60	55	50	45
Iron (mg/kg)	100	90	80	70	60
Copper (mg/kg)	35	30	25	22	20
Zinc (mg/kg)	100	90	80	70	60
Cobalt (mg/kg)	0.20	0.20	0.20	0.20	0.20
Iodine (mg/kg)	0.25	0.25	0.25	0.25	0.25
Selenium (mg/kg)	0.30	0.30	0.25	0.25	0.20
Vitamin A (IU/kg)	3000	3000	2500	2500	2000
Vitamin E (IU/kg)	95	95	90	85	80
Thiamine (mg/kg)	4	4	3.5	3.5	3
Riboflavin (mg/kg)	3	3	2.5	2.5	2

* Feed intake is determined by body capacity, physiologic status, activity level, relative feed value of forage, and environment. Needed digestible energy (Mcal/day) is determined by body size, metabolic rate, growth rate, dry matter consumption, and body condition score.

By 12 months of age their diet should be approximately 50% growing ration and 50% forage by weight[1,15] (see Table 11). The differences in amounts fed per day are related to the RFV of the forage (see Table 1), size

of the foal, metabolic rate, activity level, and environmental temperature. The sum of these determines how much of the growing ration the foal requires to maintain desired body condition, or calories needed per day.

One key management tool in developing easy-keeping yearlings is to provide the recommended allowance by feeding only the appropriate ration balancer and forage. On the opposite end of the spectrum, to manage the hard-keeping or the sales prep yearlings successfully, one should not feed over the SUL (see Figure 7) of the growing ration per day. This practice ensures optimal pH in the digestive system and maximum absorption of the nutrients fed per day.

Yearlings have attained nearly 90% of their adult height by 12 months and 95% by 18 months.[15] Table 22 lists, by percentage or nutrient per kilogram consumed per day, what the total ration nutrients should be from 4 months to 24 months of age. As the total ration dry matter consumed increases, one can lower the percentages or milligrams per kilogram of the nutrients and still meet the nutrient needs of the foal. 1585

1586

The 2-year-olds have slowed in their growth rate per day but are still growing, and one must meet the individual recommend allowance to ensure optimal growth, health, and performance.

23.8.3 NUTRITIONAL NEEDS OF THE PERFORMANCE HORSE

The largest increase in nutrient needs for horses in training is calories per day to maintain desired body condition. Body condition scoring is the best way to determine if one is meeting the individual caloric needs of the horse. The recommended allowances of protein, major and trace minerals, and vitamins do not increase at the same rate as the caloric requirements. Therefore to prevent possible digestive upset and acidosis from too much cereal grain (starch), one must know the SUL for every feed given to performance horses (see Figure 7). Table 23 allows for the increase in feed consumed per day, depending on the individual workload, and lists how the protein, major and trace minerals, and vitamins change with work intensity.

To help one understand the different levels of work, the NRC has put together four different, broad terms to evaluate them[1]:

- *Laid up/Idle/Inactive:* Refers to horses not being exercised or confined to a stall (limiting activity level while giving them time to heal or recuperate).
- *Light:* Refers to work up to 1 hour per day, 6 days per week (trail, English and Western pleasure, and low-level dressage).
- *Moderate:* Refers to work from 1 to 3 hours per day, 5 days per week (racing, cutting, reining, jumping, and upper-level dressage).
- *Intense:* Refers to work more than 3 hours per day, 3 days per week (100-mile endurance racing, Three-Day Eventing, combined driving, polo, and point-to-point).

TABLE 23 Comparison of the Recommended Allowances for Performance Horses While Layed Up or in Light, Moderate, or Intense Training on a Total Ration Dry Matter Basis (Including Forage)

	LAID UP OR IDLE		LIGHT		MODERATE		INTENSE	
NUTRIENT	2-YEAR-OLD	MATURE	2-YEAR-OLD	MATURE	2-YEAR-OLD	MATURE	2-YEAR-OLD	MATURE
Dry matter intake (% body weight)*	1.5–2.0	1.5–2.0	1.75–2.25	2.0–2.5	2.0–2.5	2.5–3.0	2.5–3.0	3.0–3.5
Crude protein (%)	11.00	8.50	12.00	10.50	12.50	11.00	13.00	12.00
Calcium (%)	0.53	0.30	0.55	0.40	0.56	0.42	0.57	0.48
Phosphorus (%)	0.35	0.21	0.36	0.27	0.37	0.28	0.38	0.30
Potassium (%)	0.53	0.40	0.70	0.70	0.80	0.80	0.90	0.90

Thiamine (mg/kg)	3	3	3	3	3	3	3	3
Riboflavin (mg/kg)	2	2	2	2	2	2	2	2

* Feed intake is determined by body capacity, physiologic status, activity level, relative feed value of forage, and environment. Needed digestible energy (Mcal/day) is determined by body size, metabolic rate, growth rate, dry matter consumption, and body condition score.

The author realizes that one needs to consider time and intensity of work, as well as ambient temperature and environmental conditions, when evaluating these workloads. The author also realizes that all trainers train intensely; however, the duration at that level of training determines the term. These names were given to help define caloric needs to maintain desired body condition and the recommended allowance needed to maximize muscle function, animal health, and performance.

Calories may be provided by carbohydrates, fats, digestible fiber, and protein. Carbohydrates and fats (vegetable oil) are the most concentrated sources of energy. Carbohydrates are abundant in cereal grains and in forages with a RFV greater than 115. Cereal grains average 3.0% to 4.0% fat, whereas forages contain between
1.5% and 5.0% fat, depending on their maturity when harvested or eaten. Horses easily digest and use vegetable 1586
oils, even though they have no gall bladder. The continuous flow of bile from the liver to the small intestine 1587
allows this, but for that reason also the author recommends not exceeding 8% fat in the total diet. If overfed fat, the horse either stops eating or develops diarrhea from not being able to emulsify the level of fat being consumed. Interference with calcium absorption and fiber fermentation may occur also with overfeeding. Forages provide fiber, but how fermentable the fiber source is relates directly to the RFV of the plant. The higher the RFV, the easier fermentation is for the bacteria and protozoa in the hindgut, to break down the plant cells and produce usable energy sources (volatile fatty acids). Protein can be used as an energy source if other calorie sources are deficient or protein is in excess in the diet, but protein is not an efficiently converted energy source.

Water and the necessary electrolytes are critical in moderate and intensely trained horses (see the section Practical Approach to Management of Fluid and Electrolyte Balance later in this chapter).

Body condition and the performance of the individual horse is still the best way to evaluate a feeding program. But one must remember to evaluate the total diet, forage and grain mixture.

23.9 Developmental Orthopedic Disease From a Nutritional Standpoint

23.9.1 MULTIFACTORIAL PROBLEM

Research continues to try to find the answers to perplexing problems dealing with the growth and development of foals today. Researchers realize a *genetic* component exists; for example, the inability of the mare to produce quality cartilage in utero. This inability can be passed on to the foal and could affect its ability to form healthy cartilage and strong bone as it grows.[51,57] Researchers also realize that *management* is involved. How do veterinarians handle the old, debilitated mares with chronic illness or injuries and mares with placentitis? When a foal is born compromised, for whatever reason, or it acquires the problems, attention to early foal nutrition is indicated. If the foal responds to nutrition therapy, one can use the flow chart on DOD (Figure 9)[18,65] to correlate the age of onset with its possible nutritional cause. This is the *nutrition* component of DOD.

This section discusses only the nutritional aspects of DOD and what recommendations have shown the most promise with nutritional intervention.

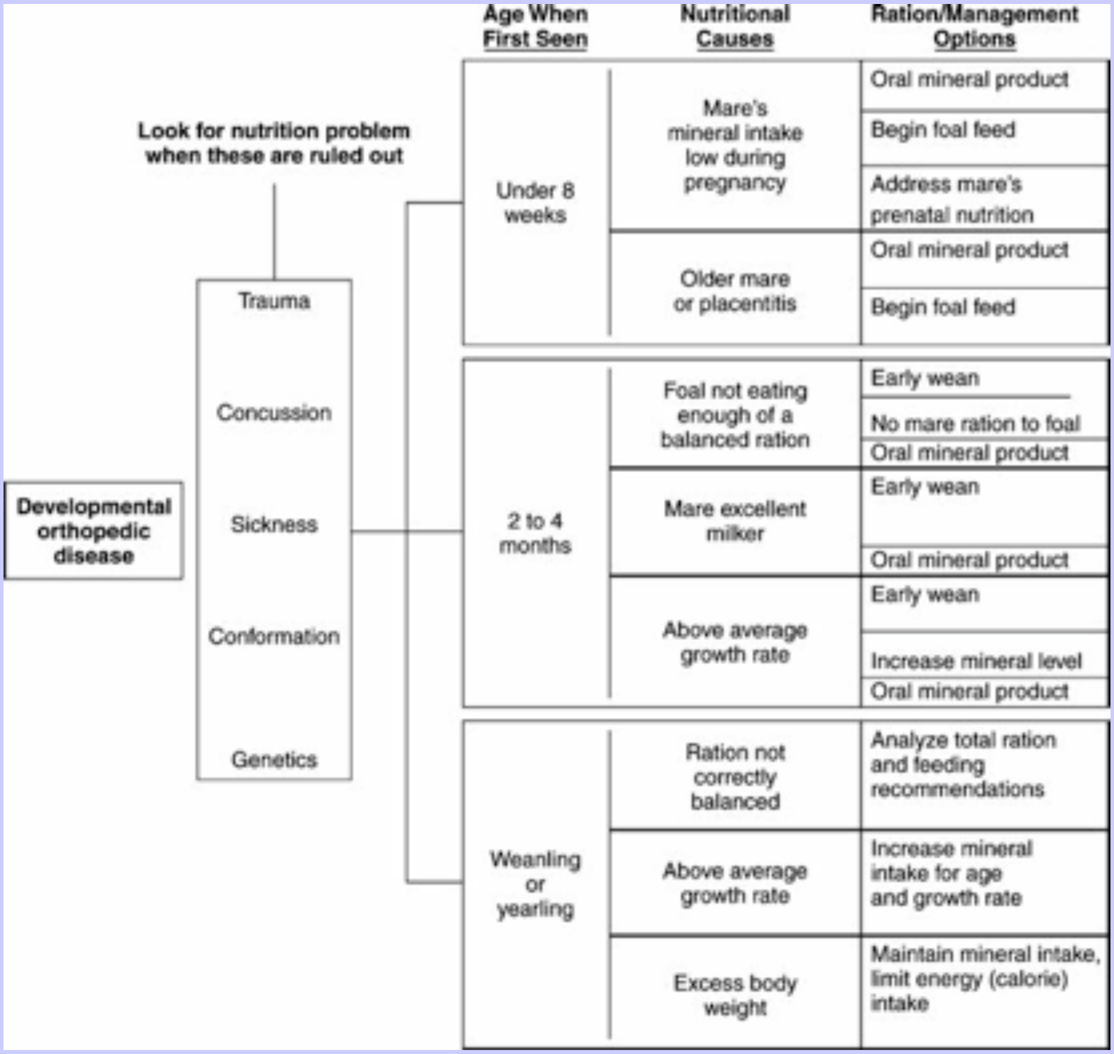
Several research projects have been completed to prove that adequate or higher amounts of protein do *not* cause DOD. However, Ott and Asguith[66] have proved that feeding protein levels below NRC recommendations decreases bone density and has a negative affect on tendon and ligament strength. When they increased the mineral density in the diet, the increase had no affect on the growing horse as long as the protein was inadequate. The only link between the more than adequate protein and DOD is when one or more of the minerals calcium, phosphorus, copper, or zinc was inadequate. Unfortunately, protein continues to be blamed, and horsemen remain afraid to feed an adequate amount.

In the field, two types of growing horses with increased incidence of DOD are common. They are the rapidly growing and the very small foals.

Very large, growing foals have an increased requirement for all nutrients and minerals to support their larger, faster-developing skeletal structures.[1] Often accompanying this type of foal is a lower metabolic rate, causing it to be an easy keeper. Fewer pounds of a grain mixture fed per day may be recommended to reduce calories; however, along with the decrease in calories comes a decrease in all the nutrients needed to support the developing cartilage and bone. If a deficient amount of protein accompanies this decrease, the horsemen effectively can create many of the forms of DOD known today. The other end of the spectrum is also true. When the horseman overloads the digestive system with too much of a grain mixture (starch) trying to fill out this large frame, the result is acidic gut syndrome, which deceases the absorption of nutrients fed and causes mineral deficiencies and digestive upset.[45,67,68]

The small foal weighing at birth less than 7% of the body weight of the mare but normal in all other aspects also is predisposed to skeletal problems if the small size is caused by the mare being fed a deficient diet. Such deficiencies usually occur because the owners did not want to overdo nutrition. Figure 10 is from a breeding farm where workers measured growth and development from birth and recorded the growth rates of all foals. These 3 years of observations showed the mares were fed little to no grain mixture because they were too fat while turned out for 24 hours per day in their pasture. Therefore the owners selected a 12% protein grain mix (which was formulated for mature, idle horses) because they thought protein was causing more than 60% of their foals to have osteochondritis dissecans, requiring surgery. After year 1, the owners made a concerted effort to ensure that the recommended allowances were met on prenatal nutrition during the entire pregnancy and lactation. The graph shows the first year before the plane of nutrition increased, which resulted in the smallest foals having the highest percentage of DOD. The second year reduced the incidence, and the third year had the largest foals in body size, with the fewest, 16%, requiring surgery for osteochondritis dissecans. The mares remained the same and the management remained the same, except for feeding a ration balancer for the entire pregnancy and ensuring the recommended allowance was met during lactation. 1587

Figure 9 Developmental orthopedic disease problem-solving flow chart.



23.9.2 INVESTIGATING GROWTH-RELATED PROBLEMS ON A FARM

The following procedures allow one to investigate growth-related problems (DOD) on a farm. Numbers 1 to 7 consider nutrition and management, whereas 8 and 9 address genetics.

1. Record the ages, heights, weights, and body condition scores of all horses on the growth and performance chart (see Figure 7).

2. Complete the Ration Balancing Client Information Worksheet (Figure 11). Record the feed and supplement tag analysis in detail. If the mares are on pasture, then record the number of hours they are outside eating fresh grass.

a. For the mares, record the pounds of hay, grain mixture, and pounds/ounces of any supplement fed to the mares while pregnant and nursing: first 3 months and the second 3 months.

b. For growing horses, record the pounds of hay, grain mixture, and pounds/ounces of any supplement fed to the sucklings, weanlings, yearlings, and long yearlings while on the farm.

3. Record or make copies of the analysis of all supplements provided free choice and note on the Ration Balancing Client Information Worksheet which horses had access to them. How much has been consumed of each supplement and over what time frame?

4. On the Ration Balancing Client Information Worksheet, record how long the pregnant mares and growing horses were on the current feeding program.

5. Get accurate samples for analysis of their appropriate (a) hay, (b) pasture, (c) grain mixture, (d) supplements, and (e) water (Table 24).

6. Because veterinarians look into every nutrient and certain mineral combinations when they evaluate the 1588
total ration, send all samples to a laboratory that can analyze the following: dry matter, total protein, 1589
available protein (heat-damaged protein), fat (ether extract or acid hydrolysis if cooked/extruded/milk based), equine digestible energy in Mcal/kg (not ruminant), acid detergent fiber, neutral detergent fiber, relative feed value, calcium, phosphorus, potassium, magnesium, sulfur, sodium, chloride, dietary cation:anion difference, manganese, iron, molybdenum, copper, and zinc. These are the first nutrients to evaluate, but if further investigation is necessary, then one also should evaluate selenium, iodine, vitamin A, vitamin D, and vitamin E. The selenium and iodine in the forage and grains is related directly to the soil type and location (state or country) where they were grown. The amounts of the oxidizable vitamins A and E found in forages are related to time in storage, whereas the levels in cereal grains, grain mixtures, and supplements are related to nutrients that antagonize them, such as iodine and choline chloride or any processing (cracking, crimping, rolling) that breaks their protective hulls.

7. Enter the amounts of everything fed, and the analysis of each feed, into an equine ration balancing program and check for deficiencies, interferences, or toxicities of each nutrient.

8. Review the pedigrees of all sires and dams, looking for similar names in affected foals.

9. Review and record, on the Ration Balancing Client Information Worksheet, leg conformation of all growing foals. Look for deviations from normal: base wide, base narrow, toe-in, toe-out, bench kneed, too upright in their pasterns and shoulders, post-legged, sickle hocked, etc. All of these conformation faults increase the trauma on the growth plates and joint surfaces because of the uneven weight distribution placed on them.

Figure 10 A breeding farm that measured growth and development from birth and recorded growth rates of all foals.

23.9.3 RATION BALANCING CLIENT INFORMATION WORKSHEET

23.9.3.1 Forage Samples

When one sends a forage sample (hay or pasture) to a laboratory to be analyzed (e.g., Holmes Laboratory), several tests are available. Selection of tests for analysis are dependent on the clinical problems being recognized on the farm or training center.

The minimum amount of information needed of forages, grain mixtures, and supplements: percents dry mutter, protein, acid detergent fiber, MCAL DE (horse), calcium, phosphorus, magnesium, potassium, sodium; and parts per million of copper, manganese, zinc, and iron. Add sulfur if you suspect a selenium deficiency. Add neutral detergent fiber (NDF) if you need relative feed value (RFV) and non-structured carbohydrates (NSC). Include (DCAD) dietary cation:anion difference if you suspect electrolyte problems or skeletal problems. Have heat damaged protein in the hay analyzed if you smell the carmalization which occurs during the browning reaction. This occurs during the first 30 days in storage only and is associated with too much moisture when baled.

23.9.4 MANAGEMENT AND FEEDING RECOMMENDATIONS

Once all of the information is available and potential nutritional problems have been identified, one then can make management and feeding recommendations. If deficiency or mineral interference is the culprit, the most

successful nutritional approach, based on field experience, has been to meet the requirements for protein, adjust the major and trace mineral and vitamin levels above their requirements for a short period of time until one sees a positive response, and then adjust down to meet the requirements. This process needs to be completed on the lowest-calorie diet possible, which can be accomplished by providing grass forage ad lib, *without* feeding any cereal grain (straight oats, barley, rice, etc.) but providing only the grass ration balancer for the horses to eat other than hay. Using the growth and performance chart (see Figure 7), one can find how many BNUs are needed per day to meet the needs of the horses according to their ages and sizes. If mineral deficiency or unbalanced diets are found, one should provide one half BNU more than the chart recommends per day for the first 30 to 60 days. When one can see and record improvements, one should reduce the BNUs to the required amount for each horse per day. One should remember that the growth and performance chart is for all horses with a body condition score between 5 and 6. One must adjust accordingly. If mineral or vitamin toxicities are identified as the cause, one should feed only the required BNUs per day. 1589

1592
The younger the horse, the faster the response, if nutrition is the limiting factor, because of the rate of tissue turnover in younger horses. If the inflamed physis or acquired contracted tendons results from a nutritionally deficient diet, foals under 30 days of age show a positive response within 10 to 14 days; weanlings up to 6 months of age, within 30 to 45 days; and yearlings, within 60 to 90 days. Horses more than 2 years of age with tendon contractures respond minimally to a change in nutritional status.

TABLE 24 Analysis of Water Supplies

ITEM	EXPECTED RANGE[1]	POSSIBLE PROBLEMS[2]
Total dissolved solids	500 or less	Over 3,000
Total hardness	0–180	0–60 Relatively Soft
		61–120 Moderately Hard
		121–180 Hard Water
		Over 181 Very Hard
Calcium	0–43	Over 500
Magnesium	0–29	Over 125 ppm, is laxative and diuretic
Alkalinity (phenothalein	0-trace	High is unusual
Alkalinity (total)	0–400	Over 5,000
Carbon dioxide	0–50	Over 300 ppm
Chlorides	0–250	Over 250 ppm
Iron	0–0.3	Over 0.3 off-odor, taste, staining
Manganese	0–0.05	Over 0.05 (taste)
		Over .2 may stain
Sulfate	0–250	Over 250 may be laxative
		Over 2000 in some mine drainage wastes
Fluorides	0–1.2	Over 1.5 may stain
		Over 2.4 mottling of teeth
Silica	0–10	
Copper	0–0.6	Over 1.0 gives bitter taste
Phosphate	0–1.0	High when contaminated from sewage, agricultural wastes and some industrial waters
pH	6.8–7.5	Under 5.1 or Over 9.0. Wide values may indicate contamination with industrial or mine wastes
		Over 8.0 may give drying effect on skin and soda taste
Stability index	6.0–7.5	Below 6.0 is scale-forming
		Above 7.5 is corrosive
Sodium	0–3	Response to lower salt intake might result at about 40 ppm
Potassium	0–20	

Arsenic	0.05	Over 0.20
Cadmium	0–0.01	Over 0.05
Chromium	0–0.05	
Mercury	0–0.005	Over 0.01
Lead	0–0.05	Over 0.10
Hydrogen sulfide	0–2	Over 0.1 (taste)
Barium	0–1	Over 0.1 (health)
Zinc	0–5	Over 25
Molybdenum	0–0.068	
Nitrites as NO_2	0–0.33	Over 4.0 ppm may be toxic
Nitrates as NO_3	0–44	High values may indicate pollution with organic matter
		Over 45 may cause methemoglobinuria in infants

EXPECTED EFFECTS OF NITRATES IN WATER

CONTAMINANT	RECOMMENDATION	EFFECTS
NITRATE CONCENTRATION (ppm)		
0–45	Approved	None
46–135	Doubtful	May cause methemoglobinuria
136–225	Risky	Reproductive problems and subclinical rickets are possible
226–450	Do not use	Definite interference syndrome, vitamin deficiencies, arthritis
451–675	Do not use	Serious health problems
676–900	Do not use	Reduced resistance to disease
More than 900	Do not use	Possible heavy acute toxicity and death losses
BACTERIAL COUNTS/POLLUTANTS		
Total bacteria/100 ml	Less than 200	More than 1 million
Total coliform/100 ml	Less than 1	More than 1 for young; more than 15–50 for mature
Fecal coliform/100 ml*	Less than 1	More than 1 for young; more than 10 for mature
Fecal streptococcus/100 ml	Less than 1	More than 3 for young; more than 30 for mature

Content developed by Dr. Richard Adams, Penn State University Department of Dairy Science.

* If pollution is from human wastes, fecal coliform should exceed fecal streptococcus by several times. If pollution is from an animal source, streptococcus should exceed coliform in refrigerated samples tested soon after taking.

23.9.5 CONDITIONS THAT RESULT FROM A NUTRITIONALLY DEFICIENT DIET

Physitis and acquired contracted tendons are the only DODs in the early stages that are visible to the client. The following identification and management recommendations can assist the horse owner/manager.

23.9.5.1 Physitis

If inflammation is caused by a nutritional deficiency, mineral interference, or toxicity, it will be evident on all four legs, medial and lateral. Unequal weight distribution, caused from a deviation in leg conformation and trauma, causes only medial or lateral inflammation on the affected legs. If only one leg is inflamed, inflammation probably came from an injury and is trauma induced. The author recommends handling all of these physis problems by limiting calories while providing adequate protein, minerals, and vitamins to support healing and skeletal development. The previous feeding program provides such a diet. The owner/manager must understand the only physis one can see is in the ankle and knee/hock areas. If the inflammation is nutrition induced, other physes also will be inflamed but not visibly so.

To assist the horse owner/manager in understanding where they are starting and to see improvements, the veterinarian should have them measure the circumference of the inflamed area with a cloth measuring tape and record. Measurements should be completed once a week to reinforce that healing is taking place. If the inflamed area stays the same or becomes smaller, the problem is under control. If the inflamed area becomes larger, one then must limit trauma by limiting activity or changing the hardness of the surface area where the horse exercises.

23.9.5.2 Acquired Contracted Tendons

When presented with the deep digital or the superficial digital flexor contractures, one must try to eliminate the pain and provide adequate nutrition at the same time.

If the contractures worsen with exercise, one should limit activity to hand walking and completely bandage the area.

Support from the foot to the knee or hock is warranted, and if the heels are not touching the ground, one should tape on a wedge pad for 7 days, which will raise the heel and eliminate the pain caused from stretching. Once the pain is alleviated, relaxation occurs, and proper nutrition can assist the healing and growing process. One can apply the wedge pad in 7-day intervals but should not leave it on for more than 7 days (thus on 7 days and then off for 7 days). One can reapply the wedge pad if necessary. Once the pain is gone, the farrier can begin lowering the heels of the foot, but no more than 2 degrees per month. A toe extension may cause increased pressure and pain will return. Toe extensions are not recommended when pain is involved.

If the contractures improve with exercise, one can recommend a tip shoe or a toe extension. One achieves success by not being in a hurry to fix this problem. Too much stress on the flexors may cause a set back and extend the healing time by months.

The foregoing management and nutrition programs are recommended for tendon contractures also. The age of the affected horse has a great deal to do with the amount of success with this management and nutritional intervention.

23.9.5.3 Wobblers

If the inflamed physis in the vertebra is causing a narrowing of the spinal canal, the foregoing feeding program is recommended. Reducing caloric intake while increasing the plane of nutrition is critical for skeletal growth and healing. This nutrition program is recommended for all postoperative cases to ensure optimal results.

23.9.5.4 Osteochondritis Dissecans and Bone Cysts

To ensure adequate nutrition after surgery and provide every opportunity to heal, the foregoing nutrition program is recommended. Reducing caloric intake while providing the nutrients for skeletal growth and healing is critical.

23.10 Practical Approach to Management of Fluid and Electrolyte Balance

Gayle Ecker

The goal of electrolyte and fluid supplementation should be to “maintain optimal performance through optimal health.” One should view fluid and electrolyte supplementation as a means to maintain health and performance by *preventing* the problems associated with losses. One should use electrolytes *and* water to support rheostasis of water and ions in the fluid compartments. Physiologically, one *must* use water with electrolytes to replace the losses that occur with sweating. One must consider those electrolytes that are effective for maintaining or restoring extracellular fluid volume—sodium and chloride—and to those that help maintain or restore intracellular fluid volume—potassium and chloride. 1592

1593

The maintenance of fluid and electrolyte balance within the intracellular and extracellular fluid compartments plays a critical role in muscle function and in virtually all processes within the body. Under normal resting conditions, the body strives to maintain the fluid and electrolytes in balance inside and outside the cells. Disturbances in this balance can predispose the horse to a myriad of health and performance problems such as fatigue, dehydration, heat injury, muscle cramping, and reduced gut function. With vigilance, hydration, and health monitoring and a deeper understanding, experienced riders can avoid and have avoided these disturbances, thus maintaining the optimal health and performance of the horse before, during, and after the event.

The veterinarian's role at an equine event is to be the advocate for the horse. Helping clients, owners, and riders of horses understand good management practices of water and electrolyte supplementation can help prevent many problems and needless suffering of the animal.

Fifteen years ago, only a few sectors of the horse industry were using electrolytes and with highly variable effects: misinformation on their use was prevalent. Today, thanks to the efforts of many researchers worldwide, veterinarians have a great deal more information. However, this information has not permeated the equine industry to the point of providing consistent, beneficial effects for the horse. Fluid and electrolyte research has made significant inroads most notably to the endurance sector and to a lesser extent to other disciplines such as

eventing. The veterinarian's role is important for helping to educate the client on effective use of electrolytes and dispelling misinformation or old horsemen's tales that have been proved incorrect.

23.10.1 HOW DEHYDRATION AFFECTS THE BODY

With exercise comes an increase in heat production. Some heat storage is desirable for enhancing certain metabolic reactions; however, beyond that, the heat must be dissipated. The main route for heat dissipation is through sweating, resulting in losses of water and electrolytes in the sweat. Depending on the intensity and duration, the losses of water and electrolytes can range from minimal, with a minimal effect on health and performance, to the profound, resulting in serious performance decrements and life-threatening health problems for the horse.

Dehydration, a deficit of body water, negatively affects virtually every process in the body. Dehydration is a disturbance of fluid and electrolyte balance that can result in premature fatigue and increased risk of heat illness. Dehydration compromises the production of energy in the muscles, increases stress on the heart, impairs the blood flow and perfusion to the tissues, and compromises dissipation of body heat. Proper hydration is critical, for even small losses can negatively affect performance. Losses as little as 3% have been shown to affect performance in horses, and losses of as little as 1% negatively affect performance in human beings.[69] In horses, losses of 1% to 5% are common because of exercise, transport, and even spending a day at a horse show in hot weather. Losses easily exceed this for more active or prolonged equine events such as endurance, Three-Day Eventing, polo, and racing. One must realize that sweat losses can be moderate to high even in horses that undergo slower but extended exercise in the heat, such as the pleasure trail horse and possibly the equine that is competing in a horse show that includes reining, games, and equitation style classes over the day. The horse is usually somewhat dehydrated from the trailer ride, followed by less than normal feed and water intake and combined with prolonged sweating because of standing in the sun for most of the day. So, although the losses are not nearly as profound as the endurance-type events, the losses can be at levels that potentially affect health and performance, which is particularly true when these losses are not corrected before the start of endurance-type activities.

23.10.2 WHY THE HORSE NEEDS FLUID AND ELECTROLYTE REPLACEMENT

In human beings, production and excretion of dilute sweat results in an increase in sodium concentration, and the associated increase in plasma osmolality triggers the thirst drive as the body tries to regain euhydration, through drinking, reduced urine excretion, and renal retention of sodium. The dilemma for horses is that sweat is not dilute, rather it contains high concentrations of Na^+, K^+, and Cl^-. Because of this, sweating does not produce an increase in plasma Na^+ and osmolality and thus no osmotic thirst response occurs. The thirst response is delayed and may be a function of reduced circulating volume and blood pressure. Thus many horses may not voluntarily drink until a 5% dehydration or greater has occurred, that is, clinical dehydration. Chronic dehydration and electrolyte depletion will increase the risk of heat illness and can lead to death. Typically, dehydrated horses only replace about two thirds of the sweat loss[70,71] when left to their own devices, that is, no electrolyte supplementation.

When a horse sweats, a loss of water, sodium, and other electrolytes occurs, and there is little change in sodium concentrations despite significant losses.[71] Water alone delays proper rehydration because the water intake dilutes the plasma sodium concentration and decreases plasma osmolality and the thirst drive before fluids are

replaced and may actually increase urine output. Also the increased urine output causes additional loss of Na^+, K^+, and Cl^-, further exacerbating the electrolyte deficits.

1593

Without a rise in sodium concentration and plasma osmolality, the thirst response is not triggered until a large volume deficit has occurred, resulting in baroreceptor response to decreases in central blood pressure. Electrolyte supplementation with the water helps prevent dilution of the sodium concentration and results in greater fluid consumption. Research has shown that fluid losses of more than 18 L can occur in as little as 20 miles[71,72]; therefore fluid and electrolyte intake should start before the event. When used effectively, this method has prevented dehydration and performance decrements in endurance horses by providing a reservoir in the gastrointestinal tract during performance; effective supplementation strategies during endurance events enhance recovery after the event. Waiting until the horse is thirsty results in a horse that is substantially dehydrated. Trying to catch up while exercise continues becomes more difficult, especially in the face of continued sweat losses. Little can be gained by prolonging dehydration; therefore the author holds that the health and performance of the horse are served best by prevention of losses as much as possible and rapid restoration of fluid and electrolytes during recovery. The longer the state of dehydration and electrolyte deficits linger, the greater the chances of health problems. 1594

23.10.3 FACTORS THAT INCREASE SWEAT LOSS AND INCREASE THE RISK OF HEAT STRESS/DEHYDRATION

23.10.3.1 Environment

High temperatures impede heat dissipation in the equine athlete. Heat and humidity compromise heat dissipation even further. Heat and especially humidity increase the sweat rate during exercise and increase water and electrolytes losses. Sweat losses during hot/humid conditions (temperature, 32° to 34° C; relative humidity, 80% to 85%) increased by 5% over the sweat rate during hot/dry conditions (temperature, 32° to 34° C; relative humidity, 45% to 55%) and were 32% higher compared with exercise in cool/dry conditions. Additionally, the composition of sweat changed with changing environmental conditions. McCutcheon, Geor, Hare, et al. found that osmolality and Na^+ concentration was high in the hot/dry conditions but lowest in the cool/dry conditions.[73] Also of practical importance, McCutcheon and Geor found that horses training in hot/humid conditions lost approximately twice the total sweat water and electrolytes compared with training during cool/dry conditions.[74] The authors concluded that the losses, particularly during training in hot/humid conditions, exceeded the dietary intake and that therefore electrolyte supplementation is warranted.

23.10.3.2 Intensity

The harder the horse works, the more body heat the horse generates and therefore the more sweating is needed to dissipate the heat. Intensity can increase because of speed, hilly terrain, and “giving” footing such as mud or sand. Electrolyte losses increased when mean ride speed or increased muddy terrain were encountered. For example, Cl^- losses (from the extracellular fluid compartment) increased from about 2% to 3% at an average ride speed of 6 mph to a loss of about 30% at an average ride speed of 12 mph in endurance rides. The losses could increase by about 5% to 10% roughly when the terrain included muddy conditions.[71]

23.10.3.3 Acclimatization

A horse that has been acclimatized to training in the heat actually loses more water and electrolytes because the response to acclimatization is increased sweating. Horses that have been trained in the heat (and humidity) undergo thermoregulatory adaptations that allow improved performance and heat tolerance; however, adaptation did not decrease the electrolyte losses during exercise.[75,76] The practical significance of this then is that one should not decrease electrolyte supplementation during and after acclimatization as many horse owners have believed in the past.

23.10.3.4 Surface Area

Covering the limited surface area of the horse minimizes the area available for sweating. The optimal method is to free up as much surface area as possible by minimizing coverage by saddle pads, loosening girths slightly and clipping areas on the neck, shoulders and upper legs for better evaporation of sweat. One should remove the saddle and pads when possible and keep the horse walking in a breeze to help the cooling process. Applying water frequently with a sponge or soaked towel increases heat loss and should continue until vasodilation of the skin decreases.

23.10.3.5 Preexisting Dehydration

Dehydration leads to decreases in blood volume, thereby decreasing perfusion to the muscles. Dehydration can affect heat dissipation negatively and therefore necessitates higher sweating rates to cool the horse. Wet feedstuffs, such as well-soaked beet pulp, soaked hay, soaked extruded/pelleted feeds, and fresh, wet grass are high in moisture content. One can use these types of feeds to help prevent dehydration and restore hydration. Adding water (and electrolytes as necessary) to this feed and giving it to the horse the night before and the morning of the competition can be useful in providing a reservoir of water and electrolytes in the gut for use during exercise.

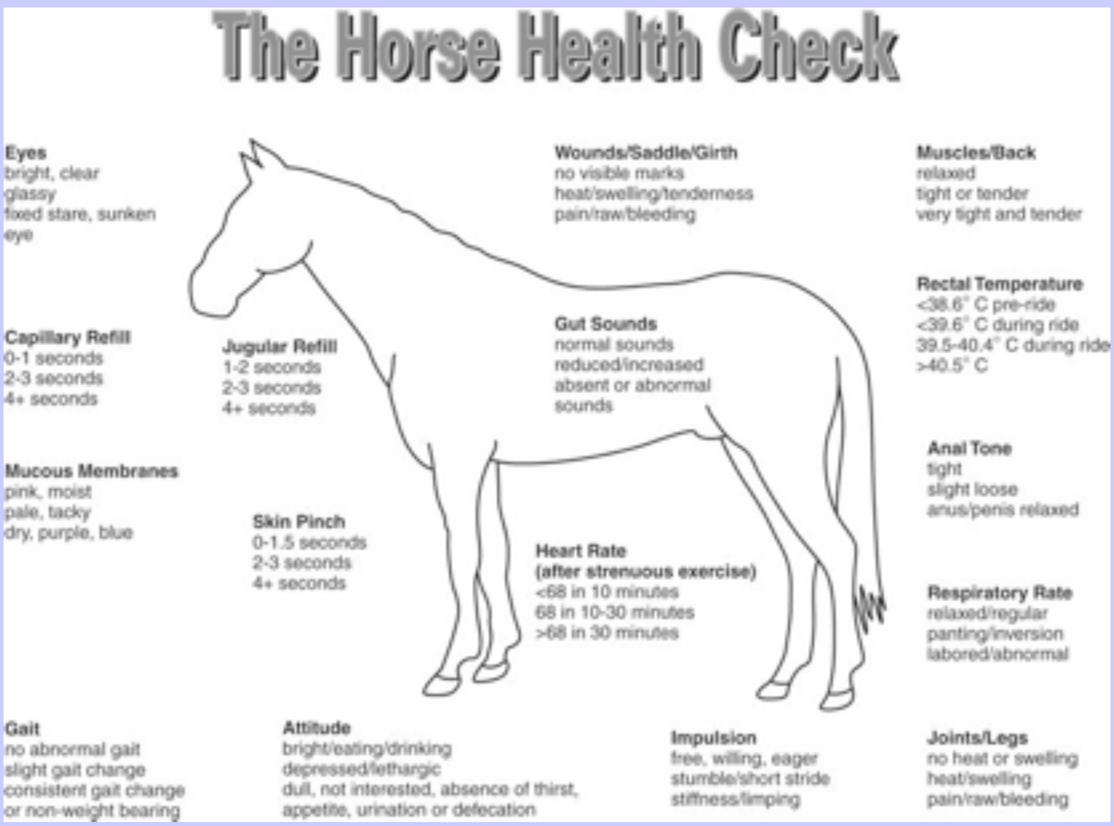
23.10.4 DETECTION OF FLUID AND ELECTROLYTE DEFICITS IN THE FIELD

A common scenario is that a veterinarian is called in to an equine event to treat a horse for a metabolic or 1594
lameness-related disorder. Whenever pharmaceutical treatment is required, such treatment is well known to be 1595
potentially life-threatening for the dehydrated horse because of the potential damage on the kidney. So rehydration and correction of the fluid and electrolyte balance are critical when pharmaceutical treatment has been deemed necessary. If possible, at least beginning the process of restoring hydration before administering the pharmaceutical is important. The diuretic lasix and bute are the two most life-threatening under these conditions.

So how does one detect dehydration and its extent, before the administration of pharmaceuticals? The standard methods of detecting dehydration have been the skin pinch test and capillary refill time. For the skin pinch test, one grasps the skin on the shoulder between the thumb and first finger, pulls the skin away with a slight twist, and then releases it. Skin that snaps back quickly is believed to represent a condition of little or no dehydration. Skin that “tents” or stays in the pinched state for longer than 1 second before returning to a flat position indicates dehydration. Textbooks often suggest that a slight tenting represents 3% to 5% dehydration, and definite tenting represents 5% or greater dehydration. However, the experience of the author and many others is that this method is not dependable for many horses. Some horses with a definite skin pinch response (greater

than 3 seconds to return flat) had only minimal dehydration as measured by body weight change (less than 2%) at the end of an endurance ride (G.L. Ecker and M.I. Lindinger, unpublished observations) and plasma protein measured by refractometer (less than 6.7 g/dl). Yet others horses showed little change in skin tenting but had a 5% to 6% body mass loss because of dehydration (with elevated plasma proteins). Noting the breed, body condition, age, normal skin elasticity, and other factors that can affect the skin pinch test is important. The skin pinch test is not a reliable test for dehydration without looking at other factors such as plasma proteins, along with body mass losses if possible and the other parameters (Figure 12). One must consider the parameters assessed in Figure 12 altogether to present the whole picture on the state of the horse.

Figure 12 Parameters for checking the status of the endurance horse.



1595

1596

Figure 12 represents the health check commonly performed on endurance horses. The parameters are outlined and color coded. Green indicates normal for a healthy horse. Yellow indicates that caution is necessary, particularly as the number of parameters that fall into the yellow category increase. Red indicates that a serious problem exists and all exercise should cease. Water and electrolyte deficits affect virtually all parameters because of loss of blood volume and therefore decreased perfusion and changes to the muscle membrane potential.

As water leaves the plasma compartment, plasma protein concentrations and hematocrit increase. Can one then use hematocrit alone to determine dehydration? Although this certainly is done, acknowledging the changes in hematocrit and how they come about is important. The spleen of the horse is capable of storing and then releasing up to one half of the red blood cells. Nervousness or stress can induce splenic contraction, but the response is not all or none. If the horse is stressed (and this is difficult to determine in many horses simply by

observing that many horses can be stressed for a variety of reasons without showing much outward sign), then the hematocrit may be raised. Therefore to assess dehydration of the extracellular fluid compartment more accurately, including measurement of plasma proteins is beneficial. Lindinger and Ecker found that during moderate-intensity exercise, 50% of the increase in hematocrit was caused by plasma water loss and 50% was caused by splenic release of red blood cells, thus emphasizing the importance of using the changes in plasma proteins.[72]

A quick calculation can give one a good indication of the plasma fluid compartment change in water content as follows:

$$\text{Percent change in plasma volume} = \frac{\text{Plasma protein at rest} - \text{plasma protein at finish}}{\text{Plasma protein at finish}} \times 100\%$$

This equation assumes no net change in plasma proteins.[71,72]

Knowing the average range of normal, rested, and fully hydrated horses is important before one begins so that one can determine if the horse is dehydrated at the first sampling. If the plasma protein is above normal, then the horse has preexisting dehydration and subsequent calculations will underestimate fluid losses. Waiting at least 15 minutes following the cessation of exercise before taking blood samples to assess plasma volume changes is important, so that the exercise-induced fluid shifts do not influence the calculations.[75] No direct method of detecting intracellular fluid volume loss exists, but one can estimate this from the difference between changes in total body water and the changes in extracellular fluid volume (ECFV) calculated from the change in plasma proteins.

One then can use the change in fluid content to calculate the change in electrolyte content. The calculations are as follows and use the typical values from an endurance horse.[71]

The following values are used:

- ECFV is assumed to be 0.222 L/kg.[70]
- Preride mass of the horse is 430 kg, and postride mass is 420 kg.
- Preride sodium concentration is 144 mmol/L, and postride it is 142 mmol/L.
- Preride plasma protein concentration is 6.2 g/dl, and postride it is 7.1 g/dl.
- Step one: The horse weighs 430 kg before the start of the ride. Extracellular fluid volume at rest would be 0.222 L/kg[70] × 430 kg = 95.5 L.
- ECFV ion loss = {plasma $[\text{ion}]_{rest} \times \text{ECFV}_{rest}$} − {plasma $[\text{ion}]_{finish}$}, where $\text{ECFV}_{finish} = \text{ECFV}_{rest}$ − (ECFV_{rest} × % change in plasma volume)

  $\text{ECFV}_{finish} = 95.5 - (95.5\ \text{L} \times 8.8\%)$

  $\text{ECFV}_{finish} = 87.1\ \text{L}$

Then,

$$\text{ECFV Na}^{+}\text{ loss} = \{144\text{ mmol/L} \times 95.5\text{ L}\} - \{142\text{ mmol/L} \times 87.1\text{ L}\} = 1383.8\text{ mmol}$$

Therefore the loss of Na^+ for this horse would be 1384 mmol or approximately 60 g Na^+ from the ECFV.

23.10.5 PREVENTION OF FLUID AND ELECTROLYTE DEFICITS DURING PROLONGED EXERCISE

Prevention of health and performance problems related to fluid and electrolyte imbalances is the goal to maintaining optimal performance.

The ideal would be to replace water and electrolytes at the same rate as they are lost; however, replacement is not always possible, given the circumstances of the competition. Therefore other management techniques are needed to prevent the dehydration and to restore the losses as soon as possible. Such techniques include using well-soaked feed (hay, extruded beet pulp, etc.) to put a large volume of water into the gastrointestinal tract, preloading with electrolytes before the event to help provide a reservoir and encourage drinking, the provision of small amounts frequently of electrolytes *and* water throughout the event if possible and immediately after events with prolonged sweating (i.e., longer than 2 hours).

23.10.6 SUMMARY

The veterinarian can give guidelines to help clients determine the best course of action for their horses, but 1596
unfortunately, trial and error still must play a role for the majority of horseowners to adjust the supplementation 1597
for the conditions of the day. A more detailed, individualized method has been used for individual consulting, and this includes blood samples and body weight measurements before, during, and after the event (or mock event), along with sweat electrolyte analysis. This allows designer electrolytes and individualized electrolyte supplementation for the horse owner based on objective data collection. One then can adjust supplementation for the conditions and develop guidelines that will help for future ride conditions.

23.10.7 PRACTICAL HINTS AND APPLICATIONS

The following section gives, in short form, some of the important points that clients need to understand. This collection is based on the questions most asked of the author.

- During transport, the horse loses water and electrolytes because of the stress. Because recovery can take several days, prevention is important. Introducing soaked beet pulp to the diet of the horse during the week before transport helps. Two to 4 hours before loading, one can add soaked beet pulp to the feed and then provide wet hay and access to fresh water. One to 2 hours before transport, one can administer electrolytes orally. If possible, one should add the electrolytes to the water during transport; the addition of more sodium keeps up the thirst drive.

- Any horse that is off feed also will drink less and therefore is likely to have varying degrees of dehydration. If the horse is eating less, adding electrolytes, well-soaked beet pulp, and wet hay to the feed may be beneficial. The beet pulp delivers large amounts of water to the intestinal tract, and the electrolytes help increase the thirst response.

- Water intake alone dilutes the Na^+ concentration and diminishes the thirst drive, which usually happens long before the water deficit has been replaced. Adding electrolytes, or in particular sodium, to the water helps prevent the sodium concentration from being diluted, and the horse will continue to drink more during the trip.

- A horse that will not drink despite clinical signs of dehydration needs assistance to replace the water and electrolytes. Although the belief is prevalent that one should not give electrolytes to a dehydrated horse, one should give the horse small amounts of water frequently and electrolytes orally, along with soaked beet pulp and soaked hay. The small amounts of electrolytes with a glucose source frequently help increase the sodium concentration without causing massive fluid shifts into the gut and away from the other tissues. This method often is enough to stimulate a thirst response and get the horse to eat and drink. If the condition is serious, then nasogastric administration of oral fluids with a balanced isoosmotic solution of electrolytes containing Na^+, Cl^-, K^+, Ca^+, Mg^{2+}, and glucose is required for rapid restoration. The oral approach has the advantage of providing badly needed fluids into the gastrointestinal tract in an effort to maintain or restore intestinal motility (improve gut sounds).

- Glucose is needed for the intestinal cells for absorption of Na^+, K^+, and water to occur. Therefore the ideal electrolyte solution contains the appropriate amounts of glucose, along with the electrolytes lost in sweat (Na^+, K^+, Cl^-, Ca^{2+}, and Mg^{2+}). The forms of electrolytes should be highly soluble, the pH should be balanced (7.4), and the taste should be palatable. One gains little by using an unpalatable electrolyte because the horse will find ways to refuse to swallow it and some may refuse to eat and drink following forced administration of the unpalatable supplement. Another important note is that some electrolyte supplements have been associated with burns in the mouth, particularly with copper bits, and one should avoid these electrolyte mixes.

- A conditioned horse often is believed to need fewer electrolytes. In fact, the research shows the opposite. Horses that have undergone an acclimation protocol had higher sweat losses and therefore a greater need for electrolyte supplementation to maintain fluid and electrolyte balance.

- Regaining water and electrolyte balance quickly is desirable. Nothing is gained by allowing dehydration to linger except a delayed recovery, inadequate hydration *and* energy status, and higher risk of health and performance problems. Simply allowing a horse to recover from prolonged exercise results in delays in restoring normal fluid, electrolyte, and energy balance.

- About 15 years ago, many competitors and veterinarians told this author that dehydration during endurance events was inevitable. With improved fluid and electrolyte supplementation regimens, such statements have been shown incorrect. Proper administration of water and electrolytes before, during, and after an event has been shown to maintain body weight throughout the ride, despite the challenges of demanding, international-level, 100-mile endurance rides.

- Anecdotal evidence suggests that some electrolytes cause a horse to develop a sour stomach and hence go off feed and refuse to drink. Continuing to use such an electrolyte is ill-advised because the electrolyte exacerbates the very state one hopes to correct.

- Ideally, to achieve optimal hydration state and performance, one needs to adjust the electrolyte supplement for each horse and for the specific conditions under which the horse is being transported or is performing. Factors such as heat, humidity, lack of feed intake, higher-intensity work, and hilly terrain

increase the need for higher supplementation. Each horse is an individual, and one must adjust the supplementation regimen accordingly. 1598

- The veterinarian can help the client improve the fluid/electrolyte balance of the horse by passing along helpful hints and guidelines. The following section includes a variety of helpful hints that the veterinarian can use to help increase the effectiveness of clients' electrolyte supplementation regimens.

- The veterinarian should encourage the client to use a quality electrolyte supplement that has been developed and supported with proper scientific procedures and can help the client select a quality electrolyte supplement by studying the label. The product should consist of about 60% electrolytes and 40% glucose (or glucose/fructose mixture). If the product lists glucose or other sugars as the top ingredient, then the product is unlikely to be an effective a supplement for replacing the salts lost in sweat. Conversely, if the product lists no glucose, then absorption likely will be less and the product will not be palatable to the horse.

- An important note is that potassium plays a critical role in maintaining muscle function. The considerable amount of K^+ lost in sweat is derived from cells, not from the plasma or extracellular fluid, because these compartments maintain the K^+ concentration. Many studies clearly indicate that potassium plays an important role for maintaining skeletal muscle function, but what is less clear is the effect of potassium loss on smooth muscle. However, one can reasonably assume that potassium loss from the entire body is a risk for skeletal and smooth muscle. Therefore when gut function is diminished, one must consider potassium replacement a priority. For optimal absorption of the potassium, one should administer sodium, glucose, and water orally at the same time.

- Following oral administration of electrolytes and water, one should monitor for changes in 30 to 60 minutes. If the supplementation has been effective, the horse should improve noticeably during this time. For example, the absorption and uptake of an effective electrolyte supplement should reach maximal levels in about 45 minutes, and visual examination of the horse should show changes in any or all of the following: gut sounds, capillary refill, jugular refill, and sometimes skin pinch, anal tone, muscle.

- Many horses will not drink despite obvious dehydration. The loss of sodium in the sweat contributes to this lack of drinking despite water volume losses. Administering small amounts of electrolytes frequently may encourage the horse to drink or, if the horse is interested, one may feed wet hay, for often the horse will begin to drink once it starts to eat hay. Then one can follow water ingestion with appropriate amounts of electrolytes.

- One should not depend solely on the skin pinch to indicate the level of dehydration. The skin pinch test works well for some horses but can be erroneous for others. For example, in the research conducted by Lindinger and Ecker, horses with less than 3% body mass loss from sweating have had distinct skin tenting, and yet more than one horse with greater than 5% body mass loss from sweating has shown no skin tenting.[72]

- Horses do not store electrolytes. Electrolytes that are ingested in excess of what the horse needs for restoring and maintaining ECFV, intracellular fluid volume, and cellular function are cleared *rapidly* from the bloodstream by the kidneys. Therefore one should give electrolyte supplementation according the sweat losses once the basic diet has been balanced. Moreover, the kidneys cannot be trained by depriving them of electrolytes during the week, in the hopes of better retention of electrolytes during the competition. One should make sure the horse is on a balanced diet that provides all the nutrients,

including adequate minerals, and then add electrolytes according to the sweat losses during training and competition.

- Horses cannot be toughened to withstand dehydration and electrolyte deficits. Such practice is likely to cause chronic deficits that will have an affect on performance and eventually on health. Using electrolytes during training/heat acclimation is necessary to restore the losses quickly for enhanced recovery and to get the horse used to the procedures on a routine basis.

- Provision of a salt block may not be adequate for sodium intake. Loose sodium chloride should be available along with fresh water at all times. Horses that lick salt blocks for prolonged times or chew or scrape salt blocks are likely candidates for sodium (and therefore water) deficits.

- One should meet the basic (nonexercise) requirements for all the electrolytes through a properly balanced diet that has been analyzed and balanced for the hay ration and geared toward the age, activity, and breed of the horse. Then for performance horses that are engaged in sports where activity is prolonged, or in other words where the horse is sweating because of exercise for longer than 2 hours, replacing the electrolytes lost in the sweat for rapid recovery and optimal health and performance is beneficial. The use of electrolytes does not make up for inadequate diet and preparation of the equine athlete. This holds true for horses in prolonged transport.

- More than 10 years ago, when this author began studying fluid and electrolyte balance in endurance
horses, many competitors and veterinarians generally believed that weight loss and dehydration were 1598
unavoidable. Some participants in the sport even felt that such weight loss and dehydration problems 1599
were not that serious and could be tolerated during the event and then corrected over several days by leaving the horse alone. Further research in human beings and in horses has demonstrated that maintaining fluid and electrolyte balance is a highly desirable goal in athletes, with positive outcomes on health and performance. Maintenance applies to before, during, and after the event.

- Although many previously doubted this, a horse can compete in a tough, 100-mile ride with little to no weight loss. Weights collected at the PanAm Championships in Vermont in 2001 and at other rides demonstrated that when effectively managed with feed, fluid, and electrolytes, horses can be competitive and experience little weight loss (M. Foss and G.L. Ecker, M.I. Lindinger and G.L. Ecker, unpublished observations).

- One should realize that horses pulled for lameness may have underlying and potentially serious metabolic/dehydration problems. Monitoring the electrolyte/hydration balance on horses pulled for lameness is important to ensure that they recover metabolically afterward. Lameness could result from fatigued muscles, leading to compensation or stumbling and less coordinated movement.

- Sweat concentrations have received more study during the last 7 years, and veterinarians now have a better understanding of the individual differences in sweat concentrations (M.I. Lindinger and G.L. Ecker, unpublished observations). Some horses have higher than average concentrations of sodium or potassium, and these horses have benefited from specially tailored electrolyte mixes to ensure rapid restoration of electrolyte balance.

- In some cases, gut sounds are present, yet other parameters such as capillary refill, jugular refill, and mucous membranes indicate dehydration. Possibly, strong concentrations of electrolytes or insoluble salts in the intestinal tract without adequate ingestion of water creates an osmotic draw that pulls water from the extracellular fluid and ultimately from the intracellular environment. This may not be an issue

for a resting, hydrated horse; however, for a dehydrated horse, this possibly could tip the horse into a serious state of dehydration.

- Potassium plays a key role in the functioning of smooth muscle in a manner similar to that in skeletal muscle. Therefore in the presence of reduced gut sounds, one must consider potassium a priority for replacement with water, other electrolytes, and volume in the gastrointestinal tract. Well-soaked beet pulp or wet hay along with water consumption and electrolytes may help restore gut function quickly, thus significantly reducing the risk of colic and other health concerns.
- One must emphasize that a fluid and electrolyte supplementation program during athletic events will not compensate for a poor daily diet, inadequate conditioning, or poor selection of genetic material for the type of event. However, when the horse is well-suited for the event, the daily nutritional intake is balanced, and the horse has been properly conditioned, then an effective fluid and electrolyte management program goes a long way to develop optimal performance and health.
- Laboratory research around the world has provided new insights into electrolytes, but from the practitioner's point of view, the results must be applied in the real world, and often the transition is difficult. With the new portable blood analyzers, real-world application is easier; however, this information rarely is available.
- The future may hold a different picture for monitoring of hydration and electrolyte state through the use of bioelectric impedance analysis, but for now field-based systems are limited.[77] Portable weigh scales are useful for monitoring body water losses if one obtains weights before and after the event.
- If one has access to a portable blood analyzer, then the veterinarian possibly can help clients determine optimal supplementation regimens. One should be sure to take the blood sample at least 15 minutes after the horse has stopped exercising to allow time for exercise-induced fluid and electrolyte shifts to revert. Disturbances persisting after 15 to 30 minutes are attributable to dehydration. When one assesses blood analysis for electrolyte and hydration, interpreting the results of concentrations relative to the fluid shifts is critical. Sodium and other plasma electrolyte concentrations commonly remain within normal values despite large losses of water and electrolytes because the sodium and water are lost are roughly the same rate; therefore the concentration may change little. One should interpret concentrations relative to plasma protein changes (see the foregoing equations).

If one is able to collect blood in the field for later electrolyte analysis, then proper handling of the blood sample is critical. One should centrifuge the blood as soon as possible and then pipette the plasma and store it on ice until analysis of electrolytes and plasma proteins is possible.

23.11 Glucose Intolerance and Hyperinsulinemia

Sarah Ralston

Abnormalities in glucose/insulin metabolism are not uncommon in horses. Fasting glucose and insulin concentrations, however, rarely are affected. The abnormalities are detected most easily when the system is 1599
challenged with a load of dextrose or glucose, absorbed from the small intestine or administered intravenously. 1600

23.11.1 ABNORMALITIES OF GLUCOSE/INSULIN METABOLISM

Glucose intolerance is determined by observing abnormally high responses in glucose and/or insulin to a standardized glucose challenge. In human beings such response most commonly are associated with insulin-dependent diabetes (type 1 diabetes), with high blood glucose, and low to normal insulin release following deficient β-cell function in the pancreas. Insulin deficiency/type 1 diabetes rarely, if ever, has been diagnosed in horses.

However, *hyperinsulinemia* (typical of type 2 diabetes and obesity in human beings) is not uncommon in equines. The higher than normal plasma insulin concentrations associated with this syndrome may precede actual glucose intolerance with the concommitant elevations in blood glucose and reflect a relative resistance to the action of insulin on cellular uptake of glucose.[78] Other actions of insulin (such as inhibition of lipolysis and stimulation of lipogenesis and growth hormone) may or may not be affected.

Most studies of glucose/insulin metabolism in horses have reported at least one hyperinsulinemic individual.[79–87] In studies using adult horses or ponies, pituitary adenomata and obesity were associated most commonly with the reported hyperinsulinemia.[80,83,86] In other studies the hyperinsulinemia was a serendipitous finding and appeared to be caused by genetic predisposition[81,82,84,85] or was unexplained by the authors.[79,88]

The potential causes of glucose intolerance/hyperinsulinemia in horses are many, with obesity and pituitary dysfunction being the most common. Daily injections of equine recombinant growth hormone in aged horses resulted in significant hyperinsulinemia in all of the treated animals that persisted for at least 4 weeks after cessation of the treatment.[89] A strong correlation exists between postprandial hyperinsulinemia and the radiographic presence of osteochondrosis lesions in Standardbred horses less than 9 to 12 months of age.[84,85] Horses between 3 and 12 months of age also were documented as having higher insulin responses to meals than those greater than 18 months of age.[84,90] These studies led to the hypothesis that abnormally high insulin, whether caused by an inherited insensitivity, age-related alterations, or response to large amounts of carbohydrates being fed, would alter bone metabolism, which contributes to the appearance of osteochondrosis lesions or other growth abnormalities in young, rapidly growing horses.

Postprandial hypoglycemia has been reported in horses with polysaccharide storage disease.[91–93] In these animals insulin secretion was within normal limits but they suffered profound hypoglycemia following a meal of starch, supposedly because of an enhanced sensitivity to the action of insulin.[91] As in human beings, dietary control of the disease consists of a high-protein, high-fat diet with limited starch intake.[94]

23.11.2 FACTORS AFFECTING BLOOD GLUCOSE AND INSULIN IN HORSES

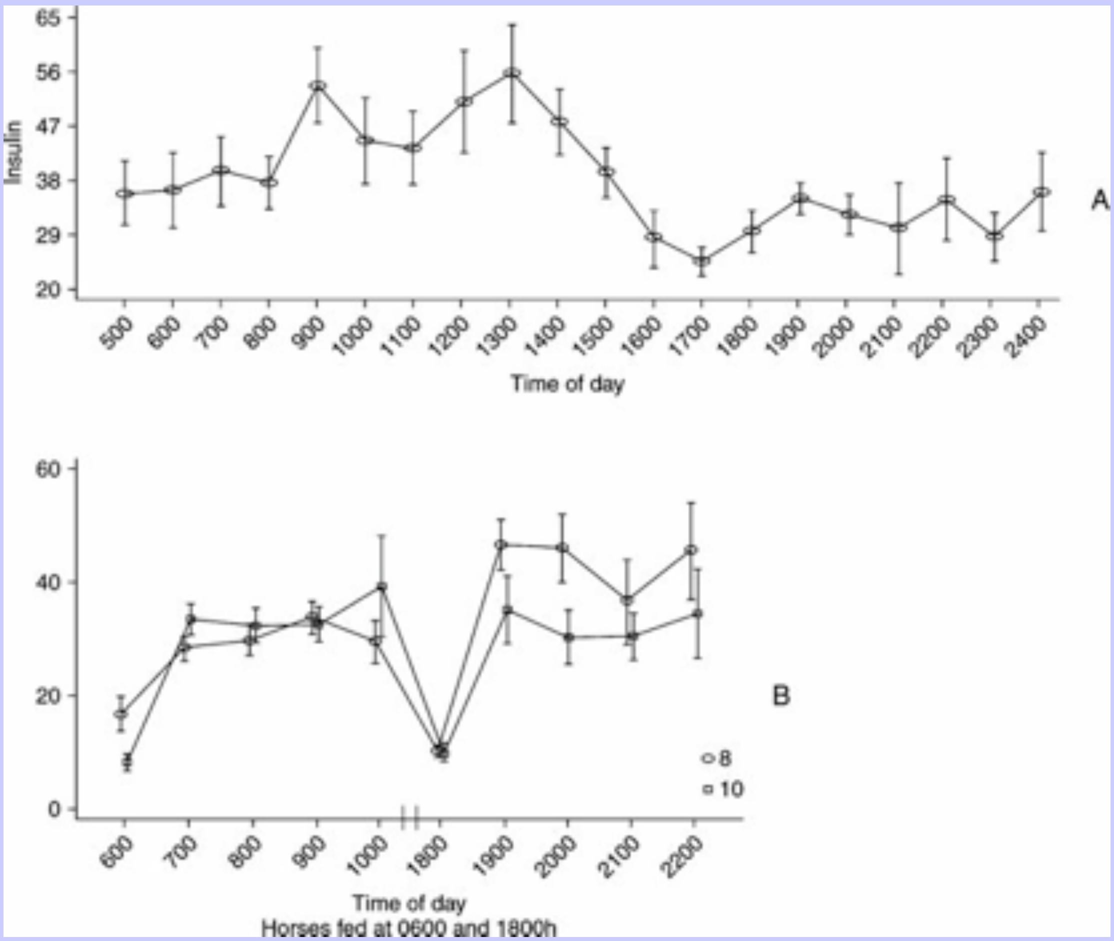
The regulation of insulin secretion in horses appears to be similar to that in human beings. Horses respond to insulin secretagogues such as arginine and lysine similarly to the way human beings do.[78] Glucose uptake differs with the type of ration the animals are fed, with lower insulin responses reported in animals adapted to only forage versus those fed higher-carbohydrate grains.[83,88,95,96]

In most studies of postprandial glucose/insulin responses in horses, however, the animals were fed their test meals in the morning.[83–85] In a 24-hour study of eight horses, researchers noted a striking difference in the

response to a meal of grain fed at 8 A.M. relative to the same amount fed at 4 P.M. The horses had significantly lower insulin responses to a meal of grain in the afternoon than in the morning (S.L. Ralston, H.F. Hintz, and T.J. Divers, 1998, unpublished data). The horses were fed 4 to 5 kg of hay and 1 kg of grain concentrate at 8 A.M. and 4 P.M. daily. They had been confined to their stalls for 4 days before the study and were well adapted to the routine. An important note is that while all the horses ate the grain concentrate meals within 30 minutes of feeding, they took 5 to 6 hours to consume the hay completely. This resulted in their having no feed available for more than 8 hours overnight but fasting only 1 to 2 hours before the afternoon feeding. Researchers hypothesized that the length of fast was more of a factor in their glucose/insulin responses than was the actual time of day.

In follow-up studies, horses were fasted for 0 (continuous access, fed at 4-hour intervals), 8, or 10 hours between feedings. This group of horses was not adapted to being confined to stalls for 24 hours and also were fasted for the allotted amount of time during the day before the initiation of sampling, starting at 10 A.M. (8-hour fast) or noon (6-hour fast) before the first feeding at 6 P.M. The continuously fed horses exhibited the same diurnal variation in insulin response observed previously (Figure 13, *A*), with higher insulin and cortisol release in the morning than in the late afternoon. When fasted for 8 hours or more before feeding in the afternoon, however, the horses did not exhibit diurnal variation in insulin response (Figure 13, *B*). Indeed, after the 8-hour 1600
fast, the horses had higher (P <0.05) insulin responses in the afternoon than they had the next morning, a 1601
reversal of the usual pattern. Researchers hypothesized that the animals were stressed by the daytime fast, which caused the higher than normal plasma cortisol at the first afternoon feeding. When the horses were kept in for a second afternoon feeding, the cortisol concentrations were lower, as were insulin responses to the concentrate feed. These results are comparable to the effects of stress and time of day on insulin sensitivity in human beings and emphasize the need to consider possible effects of diurnal variation in cortisol release higher in the morning than the afternoon in unstressed horses) and stress on glucose/insulin when testing for abnormalities.[97,98]

Figure 13 **A**, Diurnal variation in postprandial insulin (IU/ml) in horses offered feed every 4 hours for 24 hours. Values are means ± standard error. **B**, Morning versus late afternoon plasma insulin (IU/ml) response to feeding after 8 or 10 hours of fasting. Values are means ± standard error for eight horses.



23.11.3 TEST OF GLUCOSE/INSULIN METABOLISM

The use and interpretation of the traditional intravenous and oral dextrose challenges have been reviewed previously.[99] The focus of this section is novel or modified tests and interpretations.

23.11.3.1 Grain Test

In a study of the effects of chromium supplementation in aged mares, researchers found that a test meal of grain was a more sensitive test for abnormal glucose/insulin responses in aged horses than the traditional

intravenous glucose test.[87] One should feed 1 to 2 kg (depending on previous feeding history) of a grain concentrate to the subject horse and a control animal(s). The controls should be the same age and size and should have similar feeding histories and activity levels, because these factors influence the responses. The test should be done between 7 A.M. and 9 A.M. One then takes blood samples for glucose and insulin analysis before feeding and at 60, 90, and 120 minutes after feeding. These are the times at which one sees the peak glucose and insulin responses. Normal glucose responses are usually between 100 to 130 mg/dl, and insulin should not peak at more than 60 IU/ml in adults and 25 IU/ml in horses less than 9 months of age. 1601

Insulin responses 1 or 2 times higher than normal are associated with obesity and early pituitary dysfunction 1602
in adult horses and developmental orthopedic disease, specifically osteochondrosis, in horses less than 9 months of age. Insulin responses greater than 2 times normal usually indicate severe pituitary dysfunction. These results suggest only a potential problem, and one should perform definitive tests before making a diagnosis. In nonobese adults, one should consider a modified dexamethasone suppression test to confirm pituitary dysfunction. In horses less than 9 months of age, taking radiographs of the hocks and fetlocks to determine the presence or absence of osteochondrosis lesions is prudent. In all cases, one should limit and formulate concentrates to provide most of the calories in the form of fat, fiber, and protein rather than a highly soluble carbohydrate (i.e., sweet feeds with a high molasses content).

If neither glucose nor insulin concentrations increase following ingestion of the meal within 30 minutes of feeding, the horse may have delayed gastric emptying or a malabsorption syndrome. Again, one should perform more definitive tests before making a definitive diagnosis.

If blood glucose and insulin increase initially but then rapidly decline in a horse suspected of polysaccharide myopathy caused by chronic rhabdomyolysis, one should obtain muscle biopsies for a definitive diagnosis.[91] Placing such animals on a low-carbohydrate, high-fat, and high-fiber ration will not hurt them while one waits for results and may help the horses.[81,100]

Drawbacks of the grain challenge are variations in the rate at which horses consume the feed, differences in glycemic indices of feeds, and concerns in some horses regarding feeding large meals of grain as a risk factor for founder or colic.[100,101]

23.11.3.2 Low-Dose Oral Dextrose Challenge

The traditional oral dextrose challenge, which tests glucose absorption and metabolism, dictates that 1.0 g dextrose per kilogram body mass be delivered as a 50% solution by nasogastric tube after a 12-hour fast. One should take blood samples at 30-minute intervals for more than 3 hours. This test is not practical for standard use in practice and causes nonphysiologic elevations in blood glucose and insulin that may obscure more subtle alterations in glucose/insulin metabolism.[78]

Administering 0.25 gm dextrose per kilogram body mass as an oral paste even to nonfasted nursing foals and weanlings gives glucose and insulin responses that are indistinguishable from those observed after a standard meal of grain and allows a fairly nontraumatic, rapid assessment of glucose/insulin metabolism in a more controlled manner than the grain test. One should conduct the test between 7 A.M. and noon at the time that maximal responses are expected. One should be aware that horses adapted only to hay may have higher responses than those accustomed to more than 2 kg of grain per day. One should draw blood samples before dosing and at 60 and 90 minutes after dosing, the time at which peak responses are expected. In adult horses being screened for pituitary function, abnormally high responses also may be caused by obesity. In young

horses the responses even in abnormal animals are blunted after 10 to 12 months of age and may not reflect genetically induced abnormalities in glucose/insulin metabolism. One can intrepret and act on abnormal responses as for the grain test. Again, one should not consider this test definitive but rather a rapid screening for gross abnormalities.

23.12 Feeding and Management Today and in the Future: Environmental Concerns

Today phosphorus and nitrogen are recognized as potential environmental pollutants that can affect water quality negatively. The current Clean Water Act addresses the surface water runoff and groundwater contaminates as well as air pollutants. The federal government enforces the act under the Environmental Protection Agency and currently is evaluating dairy, swine, poultry, and horse farm operations. The Nutrient Management Plan affects horse farms with more than 8 horses or that have a gross farm income of more than $2,500 per year. Horses fed diets with excess amounts of nitrogen or phosphorus or fed any feed above the SUL produce manure with higher concentrations of phosphorus and possibly of nitrogen. Many states have enacted (or plan to enact) regulations concerning phosphorus and nitrogen to limit the amount of these nutrients that can be applied to cropland or pastures from the manure. These regulations provide a strong incentive in the horse industry to keep the phosphorus and nitrogen excretion under control. Each farm must write and submit an input and output balance plan for all ingredients brought onto the farm and how to handle the amounts excreted by the horse. These manure handling procedures will be written out for each farm and recorded in the county or regional office.

Feeding horses in the future will be more precise. The nutrient overages fed per day will be reduced because of the environmental concerns and regulations, and the nutrient deficiencies will be reduced because of new research and improved feed formulations and feeding directions. In the noble and appropriate attention to environmental concerns, not letting the proverbial pendulum swing too far in the direction that compromises animal health is important.

Proper diet formulation is now more important than ever. Diets should be formulated precisely to meet all the 1602
nutrient needs of the horse, and the feeding directions should be listed plainly on the bag. Each manufactured feed 1603
must have a tag or bag that lists a purpose statement and includes feeding directions to help the horse owner select the correct grain mixture to meet the needs of the horses. Such directions currently include the following:

- What horses should be fed this feed based on their physiologic status
- How much should be fed per day to meet the minimum nutritional requirements of the horse based on size and physiologic status; for example, idle, growing, reproducing, or performing

The NRC publication *Nutrient Requirements of Horses* remains an excellent starting point for developing diets and feeding programs involving specific levels of all nutrients for various physiologic stages. Ultimately, decisions about these nutrients are made on each farm. Those decisions will be based on the metabolic rate (genetics) of different breeds, the feed ingredients fed (forage and grain mixtures) with their daily consumption of each, the nutrient profiles of those ingredients, and other farm-specific factors including stress. No single publication presently addresses all of these issues. Management tools are now available within this textbook that include the following:

- Nutrient analysis of forages, hay, and pasture, including RFV
- Growth monitoring charts to determine individual growth rates and the amount of nutrients recommended to support that rate of growth

- Performance charts to determine individual nutrient recommendations based on size and reproductive status, such as open, pregnant, or nursing, and the nutrient recommendations based on performance level; for example, idle/laid up and light, moderate, and intense training

One management tool for everyone to use is the growth and performance chart. This management tool provides the minimum (recommended allowance) and maximum (SUL) amount to feed per day to meet the nutritional needs of the horse, without having a negative effect on the horse or the environment (see Figure 7).

24 APPENDIX B DOSAGES OF HORMONAL PREPARATIONS*

HORMONE		DOSAGE	INDICATIONS
PGF2a analogues			Luteolysis
	Lutalyse	10 mg IM	Induced abortion (ineffective after 120 d)
			Sustained myometrial contraction
	Estrumate	250–500 mg IM	Uterine involution
			Induction of parturition
Progestins			
	Progesterone (oil)	150–300 mg IM	Estrous synchronization
			Delay ovulation
			Delay estrus
	CIDR		Maintenance of pregnancy
	Regumate	0.044 mg/kg PO	Behavioral changes
			Hasten cyclicity in transitional mares
		0.088 mg/kg PO	
GnRH agonist			
	Ovuplant	2.2 mg SQ	Induction of ovulation
hCG			
	Many	1500–5000 iu IM, IV	Induction of ovulation
Oxytocin		10–20 iu IM, IV, SQ	Uterine evacuation
			Induction of parturition
			Retained placenta
			Uterine involution
Estrogens			
	ECP		Estrous behavior
	Estradiol-17B		Synchronization of ovulation (with P)
PGE1	Misoprostol	100–200 μg	Cervical relaxation

* Many compounding companies provided hormonal preparations. Some preparations are not licensed for use in horses. Furthermore, they may not be available commercially.
